Applications in Metabolism Studies: To study the application of this system, ^{13}C and ^{15}N -labeled phenytoin and its metabolites in urine were examined by GC-RIMS using $[2-^{13}\text{C}-, 1,3-^{15}\text{N}]$ -phenobarbital and thiopental as internal standards. To follow phenytoin metabolism, oxygen was first used as a reactant gas. Chromatograms showing nonselective ^{12}C and enriched ^{13}C and ^{15}N are shown in Figure 3. Selective detection of sulfur containing compounds in this urine was then followed using HCl as a reaction gas. The result is shown in Figure 4. Several of these peaks occur in urine samples from untreated animals. There are no known endogenous sulfur-containing compounds which would elute in this portion of a chromatogram. Further studies will be undertaken to obtain mass spectra of these unknown peaks to aid in their identification.

Figure 4. Selective detection of sulfur containing compounds in urine, using HCl as a reactant gas.

CONCLUSION

Reaction Interface mass spectrometry is a powerful technique which can be used both as an selective element and stable isotope detector. Its low detection limits, wide dynamic range, minimum instrumental modification and simplicity makes it an attractive tool in metabolism investigations. We have shown here that one can switch from study of stable isotopes such as ^{13}C and ^{15}N to selective element detection of sulfur and carbon by simply changing from one reactant gas (e.g. O_2) to another (e.g. HCl).

DETERMINATION OF ^{14}C -LABELED DRUGS AND THEIR METABOLITES BY CAPILLARY GAS CHROMATOGRAPHY - REACTION INTERFACE / MASS SPECTROMETRY (GC-RIMS)

Donald H. Chace and Fred P. Abramson

The George Washington University Medical Center, Washington, D.C., 20037

The coupling of a high resolution capillary gas chromatograph column to a proportional flow counter either degrades chromatographic resolution due to the volume of the radiodetector or has low sensitivity due to limited residence time required by narrow GC peaks. To circumvent these problems we have used a mass spectrometer as a selective ^{14}C detector.

A capillary gas chromatograph - reaction interface/ mass spectrometer (RIMS) technique has been shown to selectively detect ^{13}C -, ^{15}N -, and ^2H -labeled phenytoin and its metabolites in a sensitive, reproducible, and structure independent manner. Its design and operation has been described¹. A reaction interface is a microwave-powered device which decomposes a complex molecule in the presence of helium. The addition of a reactant gas forms stable products which reflect the elemental composition of the original analyte and which are detected by a conventional mass spectrometer.

A Varian Model 3300 gas chromatograph which was equipped with a Varian Model 1075 split/splitless injector, was used with a 30 meter DB-5, 0.25 mm i.d., 0.25 μm film thickness, capillary column. Ultra pure carrier grade helium was fitted with high purity stainless steel regulators and was operated with a helium flow of 1 or 2 mL per minute. The injector temperature was 265°C and the initial column temperature was 80°C. Following injection of 2 μL of sample, the chromatograph was programmed at various rates to 250°C. This work used a Dupont 21-492 mass spectrometer which was equipped with Trek Model 667 power supply. The Trek power supply was controlled by a Teknivent data acquisition interface, software, and an IBM XT Model 286 computer.

A male beagle dog used in the stable isotope experiments was placed in a metabolic cage 24 hours prior to administration of ^{14}C -labeled phenytoin during which time urine was collected, filtered, and frozen until analysis. Ninety μCi of 4- ^{14}C -labeled phenytoin (S.A. 55.8 mCi/mmol) or 0.41 mg, present in 1 mL of ethanol, was administered through a Y-tube into a saline solution which was flowing at a rate of 1 mL/min. The phenytoin solution was injected intravenously over a period of 1 minute. Urine was collected for 48 hours following the injection of labeled phenytoin, filtered, and frozen until analysis. Three hundred eighteen nCi of 2- ^{14}C -phenobarbital (Amersham, S.A. 55.8 mCi/mmol), was added as an internal standard to a 1% aliquot of the total volume of urine collected (10 mL). The samples were hydrolyzed, extracted using XAD-2 resin, and derivatized by extractive ethylation followed by trifluoroacetylation. One hundred microliters of toluene was added to the dry derivatized residue.

Detection of ^{14}C was achieved using hydrogen as the reactant gas and monitoring $^{14}\text{CH}_4$ at m/z 18.034 with a resolution of 1800 so that $^{14}\text{CH}_4$ was resolved from both H_2O , at m/z 18.011, and $^{15}\text{NH}_3$ at m/z 18.024. A non-selective chromatogram of carbon-containing compounds can be generated by monitoring CH_4 at m/z 16.031 at this resolution of 1800 which separates this mass from NH_2 at m/z 16.019, and O at m/z 15.995. Similarly, a chromatogram which detects nitrogen can be generated by monitoring NH_3 at m/z 17.027 or its isotopic variant, $^{15}\text{NH}_3$ at m/z 18.024.

Radioactivity in each standard was measured with a liquid scintillation counter. This calibrates the amount of ^{14}C labeled internal standard present in each chromatogram. These data were then manipulated to represent on-line flow ^{14}C monitoring. To preserve chromatographic integrity from GC peaks having 6 second half widths, a flow counter could retain a sample for no more than 1 second. Therefore, the total disintegrations per second in a peak should be divided by its half-width to express the peak height which would have been observed in a 100% efficient detector. For example, the ^{14}C -labeled peak in a chromatogram was equivalent to 4754 dpm or 4754 / 60 = 79 dps as measured by liquid scintillation counting. This value is then divided by the peak width at half height resulting in the calculation 79 dps / 6s = 13 dps per second. The right hand y-axis of the $^{14}\text{CH}_4$ chromatograms is labeled with this value. The quantity of radiolabel detected represents 30-50% of the amount of radiolabel added. This was a result of losses which occurred during the extraction, hydrolysis, and derivatization of each sample.

In separate experiments, between 4.8 nCi and 195 nCi of ^{14}C -labeled phenytoin was added to 10 mL of control urine. Each urine sample was hydrolyzed, extracted, and derivatized as described above. In a separate experiment, between 4.8 nCi and 48 nCi of ^{14}C -labeled phenytoin was derivatized directly. In each of these experiments, 159 nCi of ^{14}C -phenobarbital was added to each preparation as an internal standard. These samples were used to test the linearity for detection of ^{14}C . The ratio of areas under the peak for phenytoin and the internal standard in the chromatograms generated by monitoring m/z 18.034 was determined and plotted against the calculated ratio of nCi of phenytoin to nCi of internal standard. The data from each experiment was regressed and performed using a weighting of $1/y^2$. To evaluate the detection limit of ^{14}C -labeled phenytoin metabolites using RIMS, the smallest peak present in a ^{14}C - chromatogram was determined from the ratio of the area of this peak to the area of the internal standard which contains a known quantity of radiolabel.

Carbon-containing molecules are converted to $^{12}\text{CH}_4$ and detected at m/z 16.031. Figure 1 shows this non-selective chromatogram of urine from a dog administered ^{14}C -labeled phenytoin. This is similar to what would be obtained by a flame ionization gas chromatographic detector. A selected portion of a chromatogram of $^{14}\text{CH}_4$ at m/z 18.034 with a resolution of 1800 is shown in Figure 2 (bottom). Note that the majority of peaks present in the non-selective carbon chromatogram are not detected in the ^{14}C - chromatogram. However, the selectivity is not perfect. The peak at 18.4 min. in the ^{14}C chromatogram (Figure 2 bottom) is a result of NH_4^+ formed by ion molecule reactions from the NH_3 produced by large amounts of nitrogen-containing compounds. NH_4^+ cannot be easily resolved from $^{14}\text{CH}_4$. It was found that only nitrogen containing compounds in amounts greater than 250 ng on column are detected at m/z 18.034. Although phenytoin is a nitrogenous compound, the amount analyzed in each experiment was less than 10 ng on column. Therefore the nitrogen content of phenytoin did not contribute to the detection of ^{14}C -labeled phenytoin.

Nitrogen-containing peaks were detected in a chromatogram of NH_3 at m/z 17.027 as shown in Figure 2 (top). By comparison of the two chromatograms, peaks present in the $^{14}\text{CH}_4$ chromatogram which were likely produced from nitrogen can be determined; the remaining peaks are presumed enriched with ^{14}C . The peak shoulder at r.t. 24.4 minutes represents 34 pCi or 187 pg of a ^{14}C -labeled metabolite. The peaks at 22.7, 24.4, and 24.6 contain ^{14}C and are ^{14}C -labeled metabolites of phenytoin. These retention times coincide with phenytoin metabolites detected in previous studies using the stable isotopes, ^{13}C , ^{15}N , and ^2H .

The linearity of ^{14}C detection was determined by an analysis of ^{14}C -labeled phenytoin added to urine or when it was derivatized directly. The ratio of the ^{14}C signal for phenytoin to the internal standard, ^{14}C -labeled phenobarbital against the calculated ratio of nCi added was found to be linear and the two data sets were superimposable. The correlation coefficient of the pooled data set was 0.97 with a slope of 1.26. As little as 40 pCi (200 pg) on column of ^{14}C -labeled phenytoin was detected for phenytoin added to urine or derivatized directly.

Three metabolites of phenytoin were detected in a ^{14}C chromatogram compared to 9 using ^{13}C and ^2H and 20 for ^{15}N (Chace and Abramson, ASMS 1988). This relates to the dose of ^{14}C -labeled phenytoin which was 0.41 mg versus 50 mg for the stable isotope studies. RIMS provides detection of radiolabeled material at lower concentrations and higher resolution than other on-line radiocarbon detection schemes. Further improvement of selectivity will make the use of this method even better. However, the hazard of using radiolabels will always limit their application. We have demonstrated that detection of stable labels in a structure-independent manner is more selective.

The analysis of ^{14}C was not completely selective due to the presence of NH_4^+ from large quantities of nitrogen-containing compounds. If a ^{14}C -labeled compound coelutes with a nitrogenous compound present in large amounts on column, it will not be selectively detected. Although other radio-gas chromatographic methods are totally selective, resolution is inadequate. The use of an in-line cold trap for ammonia prior to detection by the mass spectrometer should improve selectivity substantially.

Figure 1: Nonselective RIMS capillary gas chromatogram of a derivatized extract of urine from a dog receiving 90 μCi of $[4-^{14}\text{C}]$ -phenytoin obtained by monitoring $^{12}\text{CH}_4$ at m/z 16.031. The left side of the y-axis represents ion intensity. The x-axis represents time.

Figure 2: RIMS capillary gas chromatograms of a derivatized extract of urine from a dog receiving 90 μCi of $[4-^{14}\text{C}]$ -phenytoin representing detection of nitrogen as NH_3 at m/z 17.027 (top) and $^{14}\text{CH}_4$ at m/z 18.034 (bottom). The left side of the y-axis represents ion intensity and the right side represents dps calculated from the measured dpm (4754 dpm) of the internal standard. The x-axis represents time. The peak shoulder at r.t. 24.4 min. represents on column detection of 34 pCi which is equivalent to 187 pg of a ^{14}C -labeled phenytoin metabolite.

**MASS SPECTROMETRIC STUDIES ON AZIDOTHYMININE (AZT) USING FAB, THERMOSPRAY,
PLASMASPRAY AND MS-MS.**

J. Roboz, G. Lappin * and E. Nieves. Mount Sinai School of Medicine, New York, NY 10029, U.S.A. and
VG MassLab Ltd., Altrincham, Cheshire WA14 5RZ, U.K.

Azidothymidine (Zidovudine, 3'-azido-3'-deoxythymidine) has been shown to be efficacious in the treatment of AIDS. We studied the mass spectra using these ionization techniques to investigate which may be best for the development of a mass spectrometric analysis of AZT in serum.

EXPERIMENTAL. FAB: glycerol matrix, gun operated at 8 kV and 2 mA discharge current using xenon. Thermospray and plasmaspray: mobile phase 0.1 M ammonium acetate in methanol-water (1:1, v/v), flow rate 1.2 mL/min. No HPLC column used, samples directly injected via 20 μ L loop. MS-MS: collisional activation using argon at 2 uBar (5 eV energy). Mass range of 20-350 amu scanned in 1 s.

MASS SPECTRA. The FAB spectra (Fig. 1) consisted of the (M+1) ion, $m/z=268$ (60% intensity) and the base peak (after glycerol subtraction) at $m/z=128$, the sugar residue with loss of N from the azide group. The peak at $m/z=242$ (15% intensity) could not be interpreted as part of AZT. It also appeared in thermospray and plasmaspray using three batches of AZT. In the thermospray spectra (Fig. 2) the (M+1) ion was the base peak. Two fragments were found, $m/z=128$ and $m/z=115$, the latter representing further decomposition of the sugar residue (sugar residue-2N+H). Plasmaspray yielded the same fragment ions but, in general, at higher intensities which were strongly affected by the discharge current. At 300 μ A the (M+1) ion was the base peak with other fragments at 40-50% intensity (compare to thermospray). At 750 μ A the $m/z=128$ peak became the base peak and the (M+1) peak reduced to 40%; the ratio of $m/z=128$ to 115 increased 5-fold.

$m/z=242$. MS-MS was used to ascertain the relationship between the "unknown" at $m/z=242$ and AZT. The daughters of the (M+1) peak of AZT (Fig. 3) included one at $m/z=128$, which was also detected by the other ionization modes and another at $m/z=143$, designated as the (sugar residue+H) ion, detected only in MS-MS. The $m/z=242$ peak was not detected as a daughter of AZT. No parent of $m/z=242$ was found, except for the glycerol adduct peak. This suggests that the $m/z=242$ peak is the (M+1) or parent ion of the unknown. The only daughter ion of $m/z=242$ was at $m/z=117$ (Fig. 4). These data suggest that the structure of the unknown may be similar to that of AZT except the azide group is replaced by an amino group, 3'-amino-3'-deoxythymidine. Efforts to separate the compound from AZT by HPLC will establish whether it is an impurity, possibly related to the synthesis of AZT, or it originates during the ionization process; the latter would prompt further mass spectrometric studies.

AZT IN SERUM BY THERMOSPRAY. We demonstrated the feasibility of a novel approach in pilot experiments: serum ultrafiltrate (Centricon-30, Amicon Co.) was directly injected (50 μ L), without an HPLC column, and selected ion monitoring of the (M+1) ions to quantify AZT (Fig. 5). Injection of mobile phase did not effect the baseline of $m/z=268$. Blank serum (no AZT added) gave only small ripples. The int. std. commonly used in HPLC (3'-beta-azido stereoisomer of AZT) yields the same ions as AZT and could not be separated from AZT since no HPLC column was used. Detection of 30 ng/mL, which represent the low end of the AZT concentrations in patients on current experimental protocols, was readily achieved. Potentially available detection limit (5-10 ng/mL) appears adequate for anticipated pediatric applications. Advantages include simple and rapid sample preparation, high specificity, low detection limit and fast analysis (2-3 min/run). Work in progress include optimization of experimental conditions to eliminate annoying cloggings of the capillaries and a search for a suitable int. std. for improved quantification and reproducibility.

USE OF PYROLYSIS CI/MS OVER THREE DIFFERENT TEMPERATURE RANGES TO IDENTIFY BACTERIA

D.C. Conway and Humberto Lopez, Department of Chemistry, and
J.M. Quarles, Jr., Department of Medical Microbiology and Immunology,
Texas A&M University, College Station, TX., 77843

The object of this research is to develop a rapid method for the identification of bacteria by MS using CI to reduce fragmentation. Time consuming steps such as solvent extraction or derivatization are to be avoided. The bacteria were pyrolyzed at lower temperatures than is the case with the well-known Curie-point method. The experimental procedure was the same as described previously [1] except that the discharge pulse rate was 2.5 kHz and three pyrolysis temperature ranges were used, 250-330, 330-390 and 390-440 C. Three temperature ranges were used for each sample to determine if the accuracy of the analysis could be improved by the additional data.

Five types of bacteria were studied, (1) Escherichia coli, (2) Staphylococcus aureus, (3) Staph epidermidis, (4) Listeria monocytogenes ATCC 9113 and (5) List monocytogenes ATCC 9115. Bacteria can vary from batch to batch, so different batches were used for the standard and "unknown" samples for each bacteria. The spectra were normalized at mass 18, and masses of 10-20% reproducible intensity were selected from the standard spectra for each bacteria. Then masses were selected at each temperature such that the reproducibility is good, but the intensity ratio between bacteria types is as large as possible. This produced the following sets of analysis masses:

Pyrolysis Temperature Range	Analysis Masses
Low	66,77,136
Medium	60,77,90,107
High	42,83,99,181

The unknowns and standards were represented by vectors using the intensities of the analysis masses. The $(\cos \phi)^2 \equiv T$ was calculated for each standard, where ϕ is the angle between the unknown vector and the standard vector. The results are shown in the three figures below, where the bacteria numbers have been defined above. One method for analysis is the 'T'-maximum method where the identification of a bacteria is considered to be correct if only the correct unknown has the highest 'T'-value when compared to the five standards. By this method E. coli and L. mono 9115 can be identified by low temperature pyrolysis and L. mono 9113 can be identified by high temperature pyrolysis. At the medium range S. aureus and S. epid would both be identified as the former.

Another way to identify the bacteria is from the five line patterns. It is seen from the figures below that the patterns can be used to identify all but S aureus and S epid, which can not be distinguished from each other. It is interesting that the patterns for L mono 9113 and L mono 9115 are so different, whereas those for S aureus and S epid are so similar. This could be a result of the fact that the selection of the analysis masses is somewhat arbitrary, so the selection may not have been optimized for the two Staph types.

The use of three temperature ranges for the identification of the bacteria is an improvement over one temperature range. However, the method of selecting the analysis masses must be improved because the present sets do not distinguish S aureus from S epid.

HIGH TEMPERATURE PYROLYSIS MATCH

MOLECULAR WEIGHT DETERMINATION OF UNDERIVATIZED
GALACTURONIC ACID OLIGOMERS BY LIQUID SIMS

P.W. GENO, DEPARTMENT OF CHEMISTRY; N.O. MANESS AND A.J. MORT DEPARTMENT OF
BIOCHEMISTRY, OKLAHOMA STATE UNIVERSITY, STILLWATER, OK 74078

Galacturonic acid oligomers (Gala) are derived from pectin, which are major components of plant cell walls. The generalized structure of a Gala oligomer is shown in Fig. 1. Galacturonic acid oligomers are believed to be involved in fruit maturation (1) auxin-induced stem elongation (4) and as potential elicitors for resistance to pathogens (3). In order to facilitate the study of these compounds, liquid SIMS was investigated as a possible tool for the rapid determination of molecular weight distribution of mixtures of Gala oligomers. Negative ion LSIMS spectra have been reported for underivatized Gala oligomers up to ten residues in length (4). These spectra are characterized by intense matrix peaks due to solvent suppression effects and a rapid decrease in peak intensity as a function of mass. We have developed a procedure for the molecular weight determination of mixtures of underivatized Gala oligomers up to 15 sugar residues in length using positive LSIMS.

Mixtures of Gala oligomers were produced by autoclave hydrolysis and characterized by anion exchange HPLC (5). A chromatogram showing the relative concentrations of Gala oligomers used for this work is shown in Fig. 2. Liquid SIMS was performed on a VG Analytical ZAB2-SE mass spectrometer equipped with a Cs⁺ primary ion gun operated at +30 kV. Samples were first dissolved in water, 10% trifluoroacetic acid (TFA) or 10% acetic acid (HAc) (10 ug/ul). Approximately one microliter of the oligosaccharide solution was then mixed with an equal amount of thioglycerol or NaCl/thioglycerol on the probe tip immediately prior to data acquisition.

First investigations involved the acquisition of positive and negative ion LSIMS spectra using a variety of matrices. Figure 3. shows a positive ion LSIMS spectrum of the Gala mixture in water and thioglycerol. Molecular ions of oligomers up to 13 sugar residues in length are detected. For most oligomers, the (M+H)⁺, (M+Na)⁺ and (M+K)⁺ forms of the molecular ions are detected (see Fig. 3B). The samples, solvents and matrix used in the acquisition of this spectrum were all deionized using ion exchange resin prior to use. It is apparent that for Gala oligomers the ionization efficiency for sodiated molecular ions is significantly higher than for their protonated counterparts. It is also important to note that the relative intensities of the molecular ion peaks do not correspond to the relative concentrations of the oligomers in the mixture (see Fig. 2). The appearance of various molecular ions can be attributed to the fact that the pH of the sample solution is well above the pKa of the carboxylic acid functionality of the Gala oligomers resulting in the partial deprotonation of the molecule. Studies on the effect of pH of the positive-ion LSIMS spectrum of these oligomers shows that at low pH, the (M+Na)⁺ and (M+K)⁺ ions disappear. Dell (4) has reported similar results for negative ion LSIMS spectra of underivatized Gala oligomers. In positive ion mode, however, little increase in the intensity of the (M+H)⁺ peaks is observed. We have found that the best results are obtained when the sample is dissolved in a low pH medium—i.e. 10% TFA— followed by incorporation into a thioglycerol matrix containing NaCl. When no NaCl is added to the matrix, the (M+H)⁺ ion predominates but has little intensity. At higher pH (i.e. 5% NaAc) no molecular ion peaks are observed. As NaCl is added to the thioglycerol, the (M+Na)⁺ increases in intensity and at high NaCl concentrations the (M+2Na-H)⁺ ion begins to appear. Figure 4 shows the molecular ion region of the positive LSIMS spectrum of pentadeca-galacturonide (15mer) in 5% HAc incorporated into thioglycerol containing 0.02M NaCl. We believe that with the high efficiency of ionization of sodiated Gala oligomers, further optimization of pH and NaCl concentration will result in molecular ion detection well beyond 3000 m/z.

CF-FABMS OF PROTEOLYTIC DIGESTS OVER TIME
FOR PRODUCING SEQUENCE ORDERED TRYPTIC MAPS

Brenda S. Whaley and Richard M. Caprioli

The Analytical Chemistry Center and
Department of Biochemistry and Molecular Biology
The University of Texas Medical School at Houston
Houston, Texas 77225

CF-FABMS has been shown to be an effective tool for the analysis of the peptide fragments generated by proteolytic digestion (1). The use of CF-FAB for sample introduction into the mass spectrometer allows the facile monitoring of a proteolytic hydrolysis over time, enabling the analyst to correlate the release of many of the protease fragments from the original peptide structure (2). For a tryptic digest the mass spectra of reaction products from early time points in the hydrolyses reveal masses which are combinations of two or more tryptic fragments. These masses disappear from the spectra as the hydrolysis proceeds to completion but their presence early in the reaction allows the identification of adjacent tryptic fragments. For example, data taken from several time points in the tryptic hydrolysis of calcitonin allowed all four tryptic peptides of calcitonin to be located in the original structure relative to one another.

Carboxy-terminal sequence information can also be obtained by monitoring the reaction products of carboxypeptidase hydrolysis of whole peptides or tryptic fragments over time. The exopeptidase gives rise to fragments whose masses differ from one another by the exact mass of an amino acid residue. This mass difference allows identification of the amino acid present in the C-terminal position. Thus, the C-terminal fragment of calcitonin can be identified by determining the tryptic fragment whose C-terminal sequence matches that of the whole peptide. This information, combined with information from the tryptic digest of calcitonin, allows accurate mapping of all the tryptic fragments into their correct positions in the original peptide structure.

Tryptic digests of calcitonin were performed with trypsin-TPCK from Worthington at an enzyme to substrate molar ratio of 1:40. Carboxypeptidase Y from Sigma was used for C-terminal hydrolysis of calcitonin at an enzyme to substrated ratio of 1:27. Carboxypeptidase Y hydrolysis of calcitonin tryptic fragments was performed at an enzyme to substrated ratio starting at 1:250 and increasing up to 1:2. All proteolytic reactions were performed in 50 mM pyridine acetate (pH = 6.2). Aliquots of 5 μ L were removed at specified time intervals and were either quick frozen with dry ice or treated with 2N HCl to stop the enzymatic reaction.

All samples were analyzed by CF-FABMS performed on a Finnigan MAT 90 using the Finnigan MAT Bioprobe. A flow probe solvent of 5% glycerol/3% acetonitrile in water was employed at a flow rate of 7 μ L/min. Samples were injected via a Rheodyne valve Model 7410 fitted with a 1 μ L sample loop. The mass spectrometer was generally run with a resolving power of 1400 and an accelerating voltage of 4.8 kV.

Figure 1 shows the mass spectrum of the reaction products of the tryptic digest of 200 pmoles of calcitonin after 3 minutes. Spectra for aliquots taken 5 to 15 minutes into the reaction are identical to that seen in Figure 1, indicating that the masses 1122, 854, 777 and 716 represent the final products of the tryptic digest. These four masses, when combined, would yield a peptide of a molecular weight equal to that of calcitonin. In a 1 minute aliquot of the tryptic digest, several peaks were identified which each represent combinations of two tryptic fragments of calcitonin. The mass at 1613 is a combination of 854 and 777, while the mass at 1474 is a combination of 777 and 716. A peak was also found at m/z 1960 which is a combination of 1122 and 854. In addition, two peaks were identified which each represent a combination of three of the tryptic peptides of calcitonin. A peak at 2717 represents a combination of 1122, 854 and 777, while a peak at 2311 represents a combination of 854, 777 and 716. The

presence of these combinations indicates these tryptic fragments must be adjacent in the original calcitonin structure. This information allows the analyst to determine the order of the tryptic fragments in calcitonin as: (1122)(854)(777)(716) or (716)(777)(854)(1122). The identification of either 1122 or 716 as the C-terminal fragment enables one of these to be differentiated as the correct sequence.

The results of the digest of whole calcitonin by carboxypeptidase Y are shown in Figure 2. After 60 minutes a peak at m/z 3318.4 appears in place of the molecular species at m/z 3415. The difference between these masses is 97, and is equal to the mass of a proline residue. A digest of the tryptic fragments of calcitonin indicates the fragment with a mass of 716 also contains proline as its C-terminal amino acid, identifying it as the carboxy terminal tryptic fragment. This allows the correct tryptic map of calcitonin, (1122)(854)(777)(716), to be deduced.

The work presented here demonstrates the utility of incorporating the dimension of time into the analysis of protease digests. The mass specificity of mass spectrometry is critical in following the various fragments in multiple sample analyses. The dimension of time permits the analyst to observe combinations of tryptic fragments which allow them to be linked together in the original sequence. This results in the deduction of an ordered tryptic map which is useful for the quick and accurate characterization or verification of protein structure.

TANDEM MASS SPECTROMETRY OF LIPOSIDOMYCIN ANTIBIOTICS

Chad C. Nelson, James A. McCloskey, and Kiyoshi Isono*
Department of Medicinal Chemistry, University of Utah, Salt Lake City,
Utah 84112 and *Antibiotics Laboratory, RIKEN, Wako-shi, Saitama 351, Japan

The liposidomycins are a family of novel nucleoside antibiotics which strongly inhibit bacterial cell wall synthesis¹. These lipid-containing nucleosides have several unusual structural components such as a seven membered heterocycle and a sulfate moiety. As part of the complete structure determination of the liposidomycins², MS/MS proved useful in establishing the interconnectivity of structural subunits by determining detailed decomposition pathways from a series of collision-induced dissociation (CID) reactions. Mass spectrometry (including high resolution and GC/MS of hydrolysis products) was used in concert with 2-D NMR to establish intermediate structural models and to confirm specific structural features. The present study also demonstrates the utility of tandem mass spectrometry as an efficient method for screening samples (or fractions collected by HPLC) to identify molecular ions, common structural features, and modifications of these antibiotics. Low-energy CID spectra were acquired with a VG 70-SEQ instrument (EBQQ geometry) using argon or krypton as collision gas with incident ion translational energies of 15 to 50 eV, and FAB ionization with glycerol matrix.

Liposidomycins A, B, G, and H were analyzed by MS/MS and CID spectra were obtained from molecular ions and several fragment ions appearing in primary mass spectra of these compounds. Decomposition pathways established from these CID reactions showed losses corresponding to structural components of sulfate, an amino sugar, uracil, ribose a seven membered heterocycle, and a complex fatty acid (Fig. 1). The four liposidomycin structures were found to differ only in the fatty acid side chain, R. For instance, a net structural difference of C₂ in liposidomycin A, compared with liposidomycin B, was determined to be located in the fatty acid based on shifts of 24 mass units in the CID spectra and on high resolution data.

Reaction pathways were also instrumental in determining how all of the components are interconnected in the antibiotics. For example, the ribose component in liposidomycin B was determined to be bound between uracil and the seven membered heterocycle as indicated by ions at m/z 555 (fatty acid and seven membered heterocycle) and m/z 315 (seven membered heterocycle and ribose) in the CID spectrum of m/z 687. Ions at m/z 315 and m/z 183 (seven membered heterocycle) in the CID spectrum of m/z 427 support uracil as being bound directly to ribose. MS/MS analysis in the negative ion mode was essential for the placement of the sulfate moiety on the amino sugar and attachment of the amino sugar to the seven membered heterocycle.

The liposidomycins readily lose SO₃ from the sulfate moiety to form an intense MH⁺-80 ion. This unusual mass loss was utilized to screen several HPLC fractions collected from *Streptomyces* cell extracts by scanning for a neutral loss of 80 mass units. Molecular ions were identified for liposidomycins A, B, G, and H (e.g. Fig. 2) as well as several new modified liposidomycins which were otherwise difficult to

determine from their primary mass spectra. For screening biological samples, neutral loss experiments such as this can be used as a relatively efficient method for testing specific differences in structurally similar antibiotics or other natural products which are potentially biologically active.

STRUCTURE DETERMINATION OF A NOVEL ANTIFUNGAL NUCLEOTIDE ANTIBIOTIC

D.R. Phillips, J.A. McCloskey, M. Uramoto*, and K. Isono*. Department of Medicinal Chemistry, University of Utah, Salt Lake City, Utah 84112 and *Antibiotics Laboratory, RIKEN, Wako-shi, Saitama 351, Japan.

RK-16 is an antifungal nucleotide antibiotic which occurs in *Streptomyces durhamensis*. RK-16 cannot be easily isolated, making structure determination difficult. FAB of the isolate shows only one molecular ion, RK-16 (MH^+ 474). No other molecular ions were observed contrary to expectations from HPLC data, indicating possible ion suppression by RK-16. It is believed that RK-16 readily isomerizes to form what has been designated "RK-16 Isomer". Microscale isopropylidene derivatization of RK-16 followed by FAB shows m/z 474 shifts to m/z 514 indicating the presence on one cis-diol. RK-16-14 and RK-16+14, not detected previously, are easily seen in the FAB spectrum due to enhanced surface activity conferred by the hydrophobic isopropylidene group. MS/MS of the isopropylidene products indicate the cis-diol is contained in the sugar. Deuterium exchange experiments using [3H]NBA (V.V. Mykytyn, A.M. Reddy and K.H. Schram, 36th ASMS Conference, 171 (1988)) indicate the number of active hydrogens in RK-16 is seven. MS/MS of MD⁺ demonstrated that two of the active hydrogens reside in the side-chain, two in the sugar, and three in the base.

Acid hydrolysis of the RK-16 isolate followed by isolation of the products and NMR studies show that RK-16 contains L-proline. Tandem mass spectrometry and NMR show RK-16 contains 8-oxoadenine. Base hydrolysis of RK-16 produces a product designated RK-16B2. Treatment of RK-16B2 with additional base at elevated temperature, produces a product which was compared to authentic 8-oxoadenosine by LC/MS. When hydrolyzed RK-16B2 is co-chromatographed with authentic 8-oxoadenosine, no peak broadening is observed thus confirming RK-16 contains 9-B-ribofuranosyl-8-oxoadenine.

MS/MS and LC/MS were used to overcome isolation problems by direct analysis of the nucleotide isolate. Detailed parent-daughter ion relationships were established by experiments involving mass selection and collision induced dissociation (CID) of MH^+ and its fragment ions, Figures 1 and 2. The ions m/z 115 and 129 in the CID spectrum of m/z 209 (figure 2) were the best indicators of the existence of an RK-16 isomer. Positive assignment of m/z 115 and 129 ions were accomplished only with the use of LC/MS which shows the ions come from the side-chains of RK-16, and RK-16 Isomer, respectively.

LC/MS of the isolate showed the presence of four major compounds: RK-16, RK-16 Isomer, RK-16-14 and RK-16+14. Traces of the side-chain ions m/z 115 (belonging to RK-16-14 and RK-16) and 129 (belonging to RK-16+14 and RK-16 isomer) show the difference between RK-16 and the RK-16 isomer to reside in the side-chain. Selected ion monitoring of the proline group m/z 70 and m/z 84 (methylated proline) demonstrated the RK-16 isomer and RK-16+14 contain a methylated proline whereas RK-16 and RK-16-14 do not.

Instrumentation:

Primary FAB spectra were acquired on a MAT 731 mass spectrometer using Xe gas. MS/MS data were acquired with a VG 70-SEQ (EBQQ geometry) instrument using FAB with Xe. Kr was the collision gas and the ion translational energy (lab frame) was 13-40 eV.

A Vestec 201 instrument with thermospray ionization was used for all of the LC/MS work, with a Supelcosil LC-18-S column. The LC system is that of Buck et al., Anal. Biochem. 129, 1 (1983) with a flow rate of 1.5 ml/min.

Derivatization:

1-5 ug of the nucleotide were placed in a capillary tube with 30 ul of 2,2-dimethoxypropane, to which 1 ul of concentrated HCl was added. The reactants were stirred for 5 min. and then dried using a Savant Speed Vac concentrator.

STUDIES OF OLIGONUCLEOTIDE IONIZATION BY CONTINUOUS-FLOW FAST ATOM BOMBARDMENT

Margaret M. Sheil, Jeffrey A. Kowalak and James A. McCloskey

Departments of Medicinal Chemistry and Biochemistry, University of Utah, Salt Lake City, UT 84112

Continuous-flow fast atom bombardment (CF-FAB) enables the quantitative study of ion yields of oligonucleotides since the samples can be introduced directly into the source in a highly reproducible manner. In addition, the effects of hydrophobicity/hydrophilicity are reduced [1], thus reducing effects of relative surface activities.

It has been recognized for some time that the efficiency of ionization of oligonucleotides, by any ionization method, is lower than for peptides. This places greater limitations on nucleotide measurements by desorption mass spectrometry, both from the standpoint of sensitivity, and in terms of the maximum molecular size that can be studied. In order to gain a better understanding of the factors contributing to low ion yields with FAB ionization of oligonucleotides, a homologous series of oligonucleotides $[d(pA)_n, n = 1 \text{ to } 8]$ has been examined by CF-FAB and the ion yields compared to those of peptides of similar mass.

Ion yields of peptides depend strongly on both the molecular weight and the particular amino acid composition of the peptide considered. Naylor *et al.* found that peptides containing more hydrophobic residues generally are ionized more efficiently by FAB [2]. Table I shows that a typical dinucleotide ApC has a lower ion yield than both a very hydrophobic peptide, leu-enkephalin and a hydrophilic peptide, tuftsin. There is some improvement when negative ions are considered but there is still a 50-fold difference in ionization efficiency between leu-enkephalin and ApC.

TABLE I: PEPTIDES VS NUCLEOTIDES

	leucine enkephalin	tuftsin	ApC
Mr	555.3	500.3	571.2
Amt.	1 nmol	1 nmol	1 nmol
Hydrophobicity ^a	-596	+310	n.a.
RELATIVE PEAK AREAS ^b			
$[M+H]^+$	100	6	1
$[M-H]^-$	100	c	2

leucine enkephalin: Tyr-Gly-Gly-Phe-Leu

tuftsin: Thr-Lys-Pro-Arg

a. Calculated according to the indices for amino acids given in [3]. The more negative the index the more hydrophobic the peptide.

b. Normalized to leu-enkephalin, the ratio of responses $[M+H]^+ / [M-H]^-$ is not addressed.

c. Not measured.

FIGURE 1. Ion yields of both $[M+H]^+$ and $[M-H]^-$ ions of the oligonucleotides $d(pA)_n$, $n = 1$ to 8 (5 nmol). In each case the peak heights have been scaled to that of the mononucleotide pA. The yields of pA $[M+H]^+$ and $[M-H]^-$ ions are of the same order of magnitude.

We have found much less variation in ion yields of nucleotides of similar mass compared with peptides. This is an expected result in as much as the structural features of nucleotides are not as diverse as those of amino acids. There is some correlation of hydrophobicity for mononucleotides, with the greatest ion yields measured for the most hydrophobic of the common nucleotides, pA. Fig. 1 shows the dramatic decrease in ion yields as the number of nucleotide residues considered is raised. This clearly demonstrates the increasing difficulty with FAB ionization of large oligonucleotides.

The differences in ion yields of oligopeptides and oligonucleotides may be attributed to the substantial structural differences between the two classes of biopolymers. For oligonucleotides there are more solvating matrix molecules (up to 14 per residue for peptides compared with 20 per nucleotide unit), with protic solvents or glycerol matrix bound by unusually strong hydrogen bonds to the phosphate groups. Normal hydrogen bonds are of the order of 3-6 kcal/mol whereas bonds between water molecules and ionized phosphate groups have been estimated to have energies up to 10 kcal/mol [4]. Thus it is reasonable to assume that the energy required for desolvation during ionization of oligonucleotides will be substantially greater than for oligopeptides of similar size. The greater hydrophilicity of oligonucleotides also may reduce the concentration of molecules at the surface of the matrix, leading to reduced ion yields. In addition, the polyanionic phosphate backbone of oligonucleotides may be difficult to protonate during vaporization (solution $pK \sim 1$), although the thermochemical gas phase acidity of organic phosphodiester is presently unknown. Finally, steric constraints may limit the ability of oligonucleotides to self-solvate in the gas phase compared with peptides, thus contributing to lower ion yields for oligonucleotides.

INTRODUCTION

O-alkylation of nucleic acids and their precursors currently generates much attention in view of its possible role in mutagenesis and carcinogenesis. It is known, for example, that the mutagenic and carcinogenic potential of alkylating agents correlates with their tendency to attack oxygen (1) and with the size of the alkyl group (2). To obtain information about the effects of alkylation on nucleic acid components in solution and in a solvent-free environment, we have analyzed a series of O4-alkylated di- and trinucleotides by fast atom bombardment (FAB) as well as by time-of-flight (TOF) secondary ion mass spectrometry (SIMS) (3,4).

These compounds include two pairs of isomeric dinucleotides, $d(r^4TpT)$ and $d(Tpr^4T)$, where $r = Et$ or $i-Pr$, as well as three trinucleotides, $d(Tpr^4TpT)$, with $r = Me, Et$ or $i-Pr$ (Fig. 1). We here outline some similarities and differences observed between negative ion mass spectra of these modified nucleotides, obtained by TOF-SIMS and FAB-MS.

Figure 1: O4-alkyl di- and trinucleotides

EXPERIMENTAL

1. Sample preparation:

For FAB-MS analysis, the titled compounds were dissolved in glycerol at a concentration of *ca* 10 mg/ml. A few μ L of each solution were then deposited on a stainless steel sample probe-tip. For TOF-SIMS analysis, the compounds were dissolved in a mixture of methanol and water (80:20) to give a final concentration of *ca* 1 mg/ml, and a few μ L of the solutions were deposited on aluminum foil treated to give a boehmite, $AlO(OH)$, surface (5).

2. Mass spectrometry:

Negative FAB mass spectra were recorded with a VG 7070E-HF double focussing mass spectrometer. Samples were bombarded by 8 keV xenon atoms generated in a Saddle-field neutral beam gun, and the negative ions produced were accelerated to 6 keV. Negative TOF-SIMS mass spectra were recorded on the Manitoba TOF II mass spectrometer, which incorporates an ion mirror (3). Sample targets were bombarded by a pulsed beam of 28 keV Cs^+ primary ions and the negative secondary ions produced were accelerated to 10 keV.

RESULTS AND DISCUSSION

1. Dimers:

For the two pairs of positional isomers, several features that allow unequivocal indications of isomeric form were found to be common to both FAB and TOF-SIMS mass spectra. First, all compounds show intense quasimolecular ion signals; the relative intensity of these peaks is always greater when the alkyl group is on the 3'-end nucleobase. Moreover, the loss of a nucleobase (TH or ¹TH) from the [M-H]⁻ ion is always more prevalent from the 3'-end than from the 5'-end of the molecule. Additionally, the ratio 4-alkylthymine/thymine anions is always greater when the alkyl group is on the 3'-end thymine, an indication that dealkylation occurs more slowly and/or that deglycosylation (scheme 1) is taking place more rapidly for these compounds. On the other hand, notable differences between TOF-SIMS and FAB mass spectra include a greater of 5'-phosphate/3'-phosphate ratio of sequence ions (i.e. Y⁻/X⁻, see Fig. 1) in TOF-SIMS spectra, and greater loss of a nucleobase from sequence ions in FAB mass spectra.

2. Trimers:

We have noticed more differences than similarities between TOF-SIMS and FAB mass spectra of the trimers with the central nucleobase alkylated at the O4- position. Some similarities include (i) a $(X_1 + Y_1)/(X_2 + Y_2)$ ratio of sequence ions that is greater than one in all instances, meaning that the sugar-phosphate bonds on the central nucleoside are more readily cleaved than those on terminal nucleosides, and (ii), the ratio $^1\text{T}^-/\text{T}^-$, understandably smaller for trimers than for dimers, becomes even smaller with bulkier alkyl groups such as ethyl and i-propyl.

As to differences observed between TOF-SIMS and FAB spectra of these modified nucleotides, we have found that fragmentation of quasimolecular ions takes places to a much lesser extent under FAB conditions. A second major difference is the presence of sodiated quasimolecular and sequence ions under SIMS conditions. Interestingly, only those ions that contain the central alkylated nucleoside were found to be sodiated, leading to e.g. $[\text{M}-2\text{H}+\text{Na}]^-$, $[\text{X}_2 \text{ (or } \text{Y}_2)\text{-H}+\text{Na}]^-$, and not X_1^- or Y_1^- . These observations support our earlier findings that suggest an increased stability for thymidines alkylated at the O4-position (6).

This negative ion studies of O-alkyl di- and trinucleotides has provided many examples of the complementary nature of FAB-MS and TOF-SIMS. Each of these "soft" ionization techniques has not only allowed full characterization of these modified nucleotides, but has revealed clear indications of the site of alkylation in addition to its effect on fragmentation patterns.

THE IDENTIFICATION OF 5,6-DIHYDROURIDINE IN NORMAL HUMAN URINE
BY COMBINED GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Mark L.J. Reimer and Karl H. Schram, Department of Pharmaceutical Sciences,
College of Pharmacy, University of Arizona, Tucson, Arizona 85721 and
Katsuyuki Nakano and Toshio Yasaka, PL Comprehensive Research Institute,
1 Kamiyamacho, Tondabayashi, Osaka, 584, Japan.

Partial purification and isolation of 5,6-dihydrouridine (D; Figure 1) from normal human urine by boronate gel affinity chromatography and reversed-phase HPLC preceded its characterization by combined GC/MS techniques. Structure proof is based upon a comparison of mass spectral and chromatographic features of the urinary component to those of an authentic reference sample. Additional data derived from high resolution mass measurements and deuterium isotope-labeling experiments provide confirmation of fragment ion structures.

Figure 1.

A pooled normal urine (PNU) sample obtained from more than 300 normal male and female subjects at the PL Osaka Health Control Center was used in the analysis. The boronate gel affinity chromatography methods used to isolate the urinary nucleosides were a modification of a published procedure (1). A Shimadzu HPLC system equipped with uv detection (260 nm) was used in the isolation of the individual nucleoside fractions. Analytical and preparatory HPLC procedures used a 5 μ m Develosil ODS-5 reversed phase column and the following solvent gradient (v/v; time in parentheses): water (0 min); 13:87 methanol-water (25 min); 45:55 methanol-water (35 min); water (40 min). Each HPLC fraction was lyophilized and TMS derivatives prepared by heating in a 50 μ l solution of BSTFA/TMCS and pyridine (80:20 (v/v)) for one hour at 100 $^{\circ}$ C (2). GC/MS analyses were performed using a Varian Model 3400 gas chromatograph coupled to a Finnigan MAT90 double-focusing (BE) instrument. Sample introduction was via splitless injection onto a 30 m fused silica DB-5 capillary column heated from 150 $^{\circ}$ C to 300 $^{\circ}$ C at 6 $^{\circ}$ C min $^{-1}$. Standard low resolution, EI mass spectrometer conditions were used for detection.

For several of the HPLC-separated fractions, preliminary identification of the major constituent(s) was made by comparing the HPLC retention times and uv absorption spectra of the urinary components to reference samples. For example, the fraction eluting at 6.63 min (denoted PNU/1) exhibited an absorbance maximum at 257 nm, which corresponded to that of the modified nucleoside m 1 A (HPLC retention time 6.13 min). However, a GC/MS examination of the TMS derivative of PNU/1 revealed the presence of several possible nucleosides in addition to m 1 A. One apparent nucleoside, having a GC retention time of 21.73 minutes, was given the designation PNU/1/A for identification purposes.

The 70 eV EI mass spectrum of PNU/1/A is shown in Figure 2. Structural assignments and mechanistic origins for most of the molecular- (M), sugar- (S) and base-related (B) ions have been described (3). Molecular weight information was obtained by examining the [M] $^{+}$ and [M-15] $^{+}$ regions, the latter ion formed via the loss of a methyl radical. Although a molecular ion was not observed, the molecular weight of the sample was assigned as 534 Da on the basis of a [M-CH $_3$] $^{+}$ ion at m/z 519 (2.7% RI). Other molecular weight-related ions detected were: [M-CH $_2$ OTMS] $^{+}$ (m/z 431, 0.6%), [M-CH $_3$ -TMSOH] $^{+}$ (m/z 429, 0.2%) and [M-(TMSOH) $_2$] $^{+}$ (m/z 354, 0.7%). Ions normally associated with a ribose-(TMS) $_3$ sugar were observed, namely [S-H] $^{+}$ (m/z 348, 0.6%), [S-TMSOH] $^{+}$ (m/z 259, 1.6%), [S-H-CH $_2$ OTMS] $^{+}$ (m/z 245, 2.5%), [S-O-TMSOH] $^{+}$ (m/z 243, 2.9%), [C $_4$ H $_4$ O $_2$ (TMS) $_2$] $^{+}$ (m/z 230, 4.7%) and [C $_3$ H $_5$ O $_2$ (TMS) $_2$] $^{+}$ (m/z 217, 100%). Subtraction of the mass of the ribose

Figure 2

Figure 3

(349 Da) from the suspected molecular weight of the unknown (534 Da) gave an aglycone mass of 185 Da, suggesting a maximum incorporation of one TMS group in the base. Analysis of the TMS-²H₉ derivative of PNU/1/A confirmed the presence of three TMS groups in the sugar and one in the base. The assignment of 185 Da for the weight of the aglycone was substantiated by other ions commonly associated with a pyrimidine base: [B+C₂H₂O(TMS)₂]⁺ (m/z 373, 0.8%), [B+C₂H₃O₂TMS]⁺ (m/z 317, 0.4%), [B+C₂H₃OTMS]⁺ (m/z 301, 1.9%), [B+CHOTMS]⁺ (m/z 287, 0.9%), [B+C₂H₂OTMS-CH₃]⁺ (m/z 285, 0.9%), [B+H+TMS]⁺ (m/z 259, 1.6%), [B+TMS-CH₃]⁺ (m/z 243, 2.9%), [B+H+CHO]⁺ (m/z 215, 4.6%), [B+CH]⁺ (m/z 198, 1.1%) and [B+H-CH₃]⁺ (m/z 171, 4.1%). Subtraction of 72 Da, the weight of one TMS group less a hydrogen, from 185 Da gave 113 Da as the weight of the free base, which was indicative of 5,6-dihydrouracil. Comparison of the mass spectrum of PNU/1/A with a library spectrum of 5,6-dihydrouridine-(TMS)₄ resulted in a close match. Final confirmation of identity was obtained by comparing the GC and mass spectral behavior of PNU/1/A with that of an authentic reference sample of 5,6-dihydrouridine-(TMS)₄. The GC retention time for the urinary component was 21.73 minutes while the reference compound had a retention time of 21.32 minutes (1.9% error). The low resolution EI mass spectrum of D-(TMS)₄ (Figure 3) exhibited fragmentation and ion intensities essentially identical to its urinary counterpart. Therefore, on the basis of strong similarities in GC retention times and mass spectra between the reference compound and PNU/1/A, the identity of the unknown urinary component was established as 5,6-dihydrouridine.

GC/MS ANALYSIS OF SPE ISOLATED URINARY NUCLEOSIDES. Victoria V. Mykytyn and Karl H. Schram. University of Arizona, College of Pharmacy, Tucson, AZ, 85721.

Modified nucleosides released during the process of tRNA turnover are not reutilized, but rather excreted intact in urine. Although normal subjects excrete low and constant levels of modified nucleosides, there appears to be an increase in excretion levels of certain modified nucleosides in a wide variety of cancer patients.¹ Previous methods used for the isolation of urinary nucleosides have been time-consuming and, in general, identification and quantitation of these compounds has been based on the use of non-specific detectors.² In addition, isolation procedures that expose base sensitive nucleosides to an alkaline environment may lead to structural modification. For example, Wilson and McCloskey have reported that 1-methyladenosine converts to N⁶-methyladenosine at pH 11.³ Likewise, 3-methyluridine has been shown to be unstable in the presence of Dowex-1 (borate) at pH 9.0.⁴ In order to avoid conditions which may result in the alteration of structure in base sensitive nucleosides, a solid phase extraction (SPE) procedure⁵ has been developed for the simple and rapid isolation of 1-methyladenosine (m¹A), 1-methylinosine (m¹I) and 1-methylguanosine (m¹G) from human urine under neutral conditions.

Human urine (pH 7.0) was centrifuged at 12,000 X g for 10 minutes at 4°C. A 3.0 ml aliquot containing 10 ug of 1,N⁶-ethenoadenosine as the internal standard was then transferred to a 6 ml, 500 mg C-18 SPE column. Under vacuum, the nucleosides retained in the column were washed with 500 ul of distilled water. GC/MS analysis showed that none of the compounds of interest were eluted in the water wash. The nucleosides were then eluted with 3 X 500 ul of methanol. m¹A, m¹I and 1,N⁶-ethenoadenosine had a recovery of 60% while m¹G showed a 100% recovery (n=3). The methanol was then evaporated under a stream of dry nitrogen. The sample residues were derivatized with 10 ul of pyridine + 40 ul of BSTFA containing 1% TCMS at 100°C for 1 hour.

Samples were analyzed by GC/MS using a Finnigan MAT 90 mass spectrometer coupled to a Varian 3400 GC. For capillary GC, a 30m DB-5 column was used. Injections were made in the splitless mode using helium as the carrier at a head pressure of 10 psi. The injection port temperature was 300°C. The column temperature was programmed from 150 to 300°C at a rate of 6°C/min. The transfer line to the mass spectrometer was maintained at 300°C. Electron ionization was employed at a source temperature of 250°C. The scan range was 450-600 daltons at a scan speed of 1 sec/dec. The ion chromatograms of the most intense ion from each compound were plotted. These were m/z 498 for m¹I, m/z 507 for 1,N⁶-ethenoadenosine, m/z 585 for m¹G and both m/z 554 and 482 for m¹A which represent the TMS₄ and the TMS₃ derivatives, respectively.

Quantitation was achieved using the peak area ratios of each compound to the internal standard followed by linear regression analysis. Calibration curves were very reproducible with correlation coefficients of 0.999 for m¹I, 0.992 for m¹G and 0.980 for m¹A (n=9). (See Fig. 1) The lower limit of detection is approximately 6 ng injected.

Table 1 lists the mean concentration of each nucleoside isolated from the urine of 6 normal subjects. The concentrations of these same compounds in a pooled urine sample of 300 normal subjects are also shown. The values from the pooled urine sample represent the average values from 7 replicate aliquots. Table 1 compares the values from the current study to those published by Chheda, et al.. (Units converted for direct numerical comparison.)

The C-18 SPE procedure described is simple, rapid and avoids conditions which may alter the structure of pH sensitive nucleosides. Specifically, m¹A, m¹I, m¹G and 1, N⁶-ethenoadenosine can be isolated from human urine with good recovery and reproducibility. Precise quantitation of m¹A, m¹I and m¹G by GC/MS is easily performed.

Structural Characterization of Alkyl and Hydroxyalkyl DNA Bases
as Pentafluorobenzyl Derivatives

Roland S. Annan and Paul Vouros, Department of Chemistry
Roger W. Giese, Department of Medicinal Chemistry
Northeastern University, Boston, Ma., 02115

The use of electrophore labeling to increase the sensitivity of analytes to electron capture MS is well established. In the field of nucleic acid chemistry detection limits as low as 1 femtogram have been reported for perfluoroalkyl and perfluoroacyl derivatives of nucleobases under ECNI-MS conditions. Pentafluorobenzyl derivatives (PFBz) of DNA bases are easily prepared under mild conditions and thus are suitable as a general electrophoric derivative. In this study, a number of alkyl and hydroxyalkyl modified DNA bases have been prepared as PFBz derivatives and their EI spectra investigated for structural utility. Fragmentation pathways were investigated using deuterium labeling, high resolution accurate mass measurements, and metastable analysis. The chromatographic properties and sensitivity of these derivatives under GC-ECNI-MS conditions was also investigated.

While in general the electron impact fragmentation patterns of the PFBz derivatives follow the modes described by previous researchers for the common nucleobases, the PFBz group exerts some influence on the fragmentation, especially in the case of bis PFBz derivatives. Furthermore, modification of the bases via substitution at various heteroatoms induces some alternative cleavages. Common to all of the derivatives is the loss of the PFBz group with the charge being shared by either fragment. The PFBz ion at m/z 181, which is always one of the most intense peaks in the spectrum, subsequently undergoes loss of HF to produce a low abundance ion at m/z 161. Low abundance ions arising from the loss of F or HF from the molecular ion are also common. Molecular ion peaks for the PFBz derivatives are typically well defined. Fragment ions yield information about both the final derivative and the starting nucleobase. In general the positive charge tends to remain with the base fragments, and rearrangement ions are of low intensity. In fact even for those ions formed by a rearrangement process, the resulting charged species still contains the nucleobase. This contrasts with the behavior of the commonly employed TMS derivatives which are highly prone to rearrangements. In the latter, the charge is frequently localized on the TMS function, so that the spectra are generally rich in TMS fragment ions.

The complete mass spectra of the isomeric compounds O^2 - and O^4 -ethylthymine as PFBz derivatives are shown in Figures 1 and 2. While the spectra of the underivatized compounds differ by only one ion, several distinct differences in the spectra of the derivatives permit the complete characterization of these compounds. Both derivatives lose $CH_2=CH_2$ from the molecular ion to yield an ion a, as shown in Scheme 1. A retro Diels Alder cleavage proceeding through the preferred N3-C6 and C2-N1 bonds (path A) results in two distinctly different ions. Subsequent ejection of two hydrogens yields the highly conjugated and stable ions b. In the O^4 isomer this ion contains the PFBz group and thus appears at high mass (m/z 262), while its counterpart, O^2 does not have the PFBz and consequently appears at a low mass (m/z 82). That some loss of HNC O also occurs in the O^4 compound is evidenced by low intensity peaks at m/z 262 (ion e) and 264 which presumably result from the alternative pathway B (cleavage through the N3-C $_4$ and N1-C2 bonds). Pathway A, which produces ion b in the spectrum of O^2 also results in formation of a complementary ion $C_6F_5CH_2NCO$, which upon further loss of a hydrogen yields ion f at m/z 222.

These derivatives exhibit good chromatographic properties and can be detected at the low femtogram level using ECNI-GC-MS and single ion monitoring conditions.

FAB MASS SPECTRA OF SOME NATURALLY OCCURRING MODIFIED NUCLEOTIDES AND THEIR ANALOGS. S.P. Dutta, J. Wesolowski and G.B. Chheda, Department of Biophysics, Roswell Park Memorial Institute, Buffalo, New York 14263

Fast Atom Bombardment (FAB) mass spectrometry has been proven to be of major importance in the analysis of polar and thermally labile biological molecules such as nucleotides, peptides and oligosaccharides. The ease of sample preparation coupled with the production of normally intense quasimolecular ion $(M+H)^+$ or $(M-H)^-$ and other structurally significant fragment ions make FAB a method of general utility in the analysis of biomolecules. In our laboratory we have been interested in the characterization and quantitation of the naturally occurring modified and chemically altered nucleotides of nucleic acids. With a view to developing a mass spectrometric detection and assay method for the modified nucleotides present in nucleic acid hydrolysates, we have examined the FAB mass spectra of some of the modified nucleotides present in tRNA.

The modified nucleotides were prepared synthetically in our laboratories or obtained from commercial sources. Approximately 1-2 μ g of the sample nucleotide was dissolved in 0.5 μ l of a 1:1 mixture of glycerol (containing 10% water) and thioglycerol and placed on the FAB target. Mass spectrometric analyses were carried out on a Finnigan MAT 90 mass spectrometer equipped with an Ion Tech 11NF saddle field gun. Xenon (99.995%) was used as the primary beam gas and the FAB Gun was operated at 8 kV potential and 2-4 mA emission current. Low resolution spectra (Res. 2000-2500) were recorded at ambient temperature with a scan rate of 20-30 s/decade.

The spectra of these nucleotides exhibited strong quasimolecular ions $(M+H)$ or $(M-H)$ in addition to other characteristic fragment ions. The positive ion FAB spectra (Table 1) showed strong peaks for $(M+H)^+$ and for $(B+H)^+$, S^+ , unmodified compound+H (5'-AMP or 3',5'-cAMP), adenine+H and in many cases a dimeric peak $(2M+2H)^+$. The negative ion spectra (Table 2) showed a very strong $(M-H)^-$ peak (which in most cases was the base peak in the spectrum after subtraction of the matrix peaks). In addition to that other peaks in the negative ion spectrum were due to B-H, unmodified compound-H (5'-AMP, 3',5'-cAMP), adenine-H and in some cases a dimer peak at $2M^-$. The fragmentation pattern were in general agreement with that shown earlier^{1,2}. In general the FAB spectra in the negative ion mode were much cleaner and showed less fragmentation than the spectra in the positive ion mode. The negative ion spectra did not show any adduct ions such as $(M-H+Na)^-$ or $(M-H+K)^-$. The FAB spectra of the NH_4^+ salts of these 5'-nucleotides or 3',5'-cyclic nucleotides generally lost NH_3 and ionized as the free acid.

This paper describes the FAB mass spectra of some of the modified nucleotides present in tRNA, some other analogous compounds and the corresponding 3',5'-cyclic nucleotides.

COMPARISON OF THE MAJOR LIPIDS OF SCENT GLAND SECRETIONS FROM THE
WESTERN DIAMONDBACK RATTLESNAKE (*CROTALUS ATROX*)
AND DUMERIL'S GROUND BOA (*ACRANTOPHIS DUMERILI*)
BY GAS CHROMATOGRAPHY-MASS SPECTROMETRY:
EVIDENCE FOR TAXONOMIC AND EVOLUTIONARY VARIATION.

Jeannie K. Wright, Michael J. Tanner, John T. Simpson and Thomas R. Sharp
Departments of Chemistry and Biology
Texas A&M University
College Station, Texas 77843 U.S.A.

When disturbed by predators, many snakes secrete foul-smelling substances from two glands located at the base of the tail. Little is known about the biological significance or the chemical composition of these ubiquitous snake secretions. Several studies have described the chemical classes of compounds present in them. Electrophoretic analysis indicates taxonomic differences in scent gland proteins¹. The thin layer chromatograms of boid, colubrid and viperid scent gland secretions displayed bands consistent with sterols, sterol esters, and free fatty acids². In separate studies, gas chromatography³ and mass spectrometry⁴ have identified free fatty acids and cholesterol. Finally, we have identified cholesterol and a number of fatty acids and fatty amides in the scent gland secretions of Dumeril's ground boa (*Acrantophis dumerili*) by gas chromatography-mass spectrometry (GC-MS)^{5,6}. Extending our studies on the composition of these secretions, we report here a comparative study of the scent gland secretions from the western diamondback rattlesnake (*Crotalus atrox*) and Dumeril's ground boa.

After extensive experimentation with the boa secretion, the following standard method was adopted. Chloroform extracts of secretions were fractionated by preparative thin-layer chromatography (TLC). A representative TLC, with the standard fractions indicated, is shown in Figure 1. The TLC fractions were scraped, eluted with ether, and analyzed with a Hewlett-Packard 5995C quadrupole GC-MS. Following initial analysis, the fatty acids (fraction 3) and sterols (fraction 2) were derivatized and reanalyzed. The fatty acids were converted to methyl esters with ethereal diazomethane. The sterol fraction was trimethylsilylated. Three capillary columns were evaluated; a DB-1, a DB-5, and a DB-1701 (all 30 m x 0.32 mm i.d., 0.25 μ film thickness, J&W Scientific). Best overall resolution of components was obtained with the DB-1701. Chromatographic conditions were, in general: 30:1 split injection, 100°-300°C @ 10°C/minute, and hold. Mass spectrometric conditions were: 70 eV, scan m/z 20-620 for 0.71 sec cycle time, ion source temperature 200°C, transfer lines 300°C.

Free fatty acids and cholesterol constitute the major components of the chloroform-soluble fraction of the scent gland secretions from both species. There was no definitive evidence for sexual variation in the composition of the secretions. The fatty acids identified in *A. dumerili* included the even carbon number saturated acids from C_{16} to C_{26} , the C_{17} acid and a $C_{18:1}$ acid. Lactic, phenylacetic and 3-phenylpropanoic acids were also identified as minor constituents after derivatization. Hexadecanoic (palmitic) and octadecanoic (stearic) acids were the major fatty acids found. The fatty acid composition of the *C. atrox* secretions ranged from C_{16} to C_{25} , with C_{20} and C_{22} being the major acids.

Cholesterol was the most abundant lipid found in the secretions of both species. This sterol accounted for appx. 30% or more of the total ion current in injections of unfractionated $CHCl_3$ extracts. A cholestadiene isomer was also identified in the secretion of *A. dumerili*. This steroid was a minor component, but the exact structure is yet to be determined. Trace amounts of some other steroids were detected, as well as thermal degradation products of cholesterol occurring in the GC injection port. Both species contained several fatty amides. The C_{16} , C_{18} , C_{20} and C_{22} amides were found in *A. dumerili*, while the C_{18} , C_{20} , C_{22} and C_{24} amides were found in the *C. atrox* secretion. Shifts in the abundance of the fatty amides from C_{16} and C_{18} in *A. dumerili* to C_{20} and C_{22} in *C. atrox* reflect the shift in the abundances of the corresponding fatty acids.

While the lipid composition profiles of the secretions from these two species are qualitatively similar in that the major constituents are fatty acids and cholesterol, there is a quantitative difference in the distribution of the fatty acids found and in fatty acid/cholesterol ratio. In *A. dumerili*, the fatty acid distribution is broad -- from C_{16} to C_{26} , with C_{16} and C_{18} dominating. In *C. atrox*, the fatty acids range from C_{16} to C_{25} , but the quantitative distribution is narrower, with C_{20} and C_{22} dominating. Compare Figures 2 and 3. This finding is consistent

Figure 1: TLC of total lipid extract of scent gland secretion from *A. Dumerilii*. Lane 1: standards. Lane 2: pooled male secretion. Lane 3: pooled female secretion.

with the results reported⁴ for two species from the family Viperidae and one from the family Crotalidae, in which the vipers showed C₁₆ and C₁₈, whereas the crotaline (similar to our findings with *C. atrox*) showed only C₂₀ and C₂₂. Our results, taken with these other reports,^{3,4} suggest that fatty acid distributions in these secretions may reflect taxonomic differences. Data on a wider variety of species is needed, however, before it will become clear whether this suggestion will hold true, and to what extent it will support current snake systematics.

Of more immediate interest is the function of these secretions. The majority of evidence suggests involvement in predator-prey interactions, although most of this evidence is anecdotal. The foul odors associated with these secretions suggest a defensive role. Some evidence for this role exists from studies involving the Texas blind snake (*Leptotyphlops dulcis*)⁸, and interactions between the kingsnake (*Lampropeltis getulus*) and carnivores⁹. Our efforts at describing the chemical constituents of these snake secretions is preparatory to studies aimed at identifying the specific chemical(s) involved in such interspecies interactions. While it is clear that the major components are fatty acids and cholesterol, it is also probable that these are not the odoriferous "defensive" components, but are probably the "perfumer's base" extenders used to decrease the volatility of the active trace ingredients and prolong the efficacy of the secretion. This is in contrast to the observation that a 1:1 mixture of oleic and linoleic acids possessed an odor "nearly the same" as the secretion of *Leptotyphlops dulcis*.³ Close coordination of studies on the chemical composition of fractions and the behaviors which those fractions elicit in test subjects will be required to identify active ingredients.

Figure 2: TIC of *A. dumerili* secretion total lipid extract. DB-1701 column. 1 hexadecanoic acid (17%); 2 heptadecanoic acid (<1%); 3 octadecanoic acid (3%); 4 octadecanoic acid (25%); 5 hexadecanamide (<1%); 6, 7, 10, 11, 12 unknowns; 8 eicosanoic acid (1%); 9 octadecanamide (<1%); 13 eicosanamide (<1%); 14 cholestadiene isomer (<1%); 15, 18, 19 cholesterol degradation products; 16 docosanamide (<1%); 17 cholesterol (31%).

Figure 3: TIC of *C. atrox* secretion acid fraction. DB-1701 column. 1 hexadecanoic acid (<1%); 2 octadecanoic acid (5%); 3 eicosanoic acid (19%); 4 unknown (2%); 5 docosanoic acid (7%); 6 docosanamide (4%); 7 C_{24:1} acid (1%); 8 tetracosanoic acid (2%); 9 cholesterol (58%); 10 C₂₅ acid (1%).

ELECTRON IMPACT MASS SPECTRA OF STEROIDS: ANDROSTANES AND DERIVATIVES

Thomas R. Sharp, Mark Sutton, Anna Ferguson and Kenneth N. Marsh.
Department of Chemistry and Thermodynamics Research Center
Texas A&M University, College Station, Texas 77843 U.S.A.

As a continuation of the Thermodynamics Research Center Spectral Data Program -- Mass Spectra (formerly the American Petroleum Institute Research Project 44 -- Mass Spectral Data), we report the electron impact mass spectra of a group of 78 derivatives of androstane.

Methods: The androstane parent structure ($C_{19}H_{32}$, m.w. 260) is shown. All compounds were obtained from Steraloids, Inc., (Wilton, New Hampshire) and used as received. The composition of the collection is indicated in Table I. Many compounds have multiple types of functional groups as well as multiple functional groups. The categories in Table I represent types of compounds in the collection. The sum is therefore larger than the total number of compounds examined. All data were collected on a VG Analytical 70-S mass spectrometer and VG 11/250J datasystem. All the compounds were crystalline solids, which were introduced into the mass spectrometer on the direct insertion probe. The probe was heated slowly in order to distill the compound being analyzed to evaluate sample purity and to avoid thermal degradation.

Spectra have been searched against the National Bureau of Standards library available on the datasystem (42000 spectra; purity fit search, fit factor 700 or greater). The results are given in Table II. 46% of the spectra of these compounds yielded no matches of any quality. Most of the parent unesterified steroids all show high intensity molecular ions. Ironically, esterification with any of several acyl groups substantially decreases or, in some cases, eliminates the molecular ion, producing indistinguishable mass spectra. Example spectra for 5α -androst-3 β -ol-17-one ($C_{21}H_{30}O_3$, m.w. 288) and its acetate (m.w. 330) and benzoate (m.w. 392) esters are shown. While M^{+} is base peak for the parent compound, M^{+} for both esters is absent. Base peaks of the ester spectra correspond to the androstadien-17-one resulting from elimination of the carboxylic acid by rearrangement.

Full spectral data of all the compounds described here, as well as for a large number of other compounds and compound types, are available from the Thermodynamics Research Center. A list of compounds, M^{+} , and 6 largest peaks is given. Funds for purchase of instrumentation were provided in part by NSF Grant CHE-8705697.

FATTY ACID AND HYDROCARBON CONTENT OF SALMONELLA TYPHIMURIUM BY GC/MS.
Ross C. Beier, B. Anthony Oyofo, George E. Spates and John R. DeLoach,
Veterinary Toxicology and Entomology Research Laboratory, ARS-SPA, U.S.
Department of Agriculture, Route 5, Box 810, College Station, TX 77840.

Introduction. The occurrence of some unusual fatty acids in the lipids of microbial strains¹ has stimulated efforts to correlate these unusual molecules with virulence and disease.² The presence of both 2-OH-14:0 and 3-OH-14:0 have been associated with lipid A in Salmonella typhimurium, and appear to be incorporated into lipopolysaccharide (LPS).³ LPS is known to be associated with many aspects of the pathogenesis of Salmonellosis.⁴ Endotoxins from gram-negative bacteria stimulate interleukin 1 (IL1), and are made up of both LPS and lipid A. The lipid A component of LPS is active in inducing IL1, and hydroxylated fatty acids specifically are important for the IL1 inducing properties of lipid A.⁵

Objective. The objective of this study was to look for interesting and unusual molecules, that potentially may play a role in the virulence of S. typhimurium, in the following compound classes: 1) fatty acids or their derivatives, 2) hydrocarbons, and 3) other lipophilic components.

Instrumentation. The mass spectrometer (MS) used for these EI GC/MS measurements was a double-focussing VG 70-250 EHF spectrometer. The MS source block was directly coupled to an HP 5890 GC. The source block, interface, and GC injector temperature was 190, 260, and 250°C, respectively. A Supelco SPB-1 fused silica capillary column with a 0.25 µm coating was used. Accurate mass measurements were conducted at 2,000 resolution over a narrow mass range, encompassing two known PFK peaks at 10s/decade. Samples were injected in the splitless mode with helium as carrier gas (15 psi head pressure). The injector was purged 30 sec after injection. A double temperature ramp GC program was used: 40°C for 3 min; ramped at 10°C/min to 140°C; held at 140°C for 1 min; ramped at 5°C/min to 260°C; and held at 260°C for 20 min.

Results and Discussion. The EI GC/MS of the methylated total fatty acids are shown in Fig. 1. This chromatogram shows the two hydroxylated fatty acids, 2-hydroxy-tetradecanoic acid methyl ester (2-OH-14:0) and 3-hydroxy-tetradecanoic acid methyl ester (3-OH-14:0) with its accurate mass determined to be m/z 258.2196 (calculated for C₁₅H₃₀O₃, 258.2195). Two cyclic fatty acid methyl esters also were observed, 17-carbon cyclopropane (C17Δ) observed at m/z 282.2562 (calculated for C₁₈H₃₄O₂, 282.2559) and a 19-carbon cyclopropane (C19Δ) observed at m/z 310.2864 (calculated for C₂₀H₃₈O₂, 310.2872).

The hydrocarbons observed in small amounts during the fatty acid run are listed with their accurate mass values in Table 1. Hydrocarbons were observed from C₁₇H₃₆ to C₂₉H₆₀ in the C_nH_{2n+2} series.

Dehydroabietic acid methyl ester (DHAAME) was found with the fatty acids in the diglyceride fraction. DHAAME was observed at m/z 314.2246 (calculated for C₂₁H₃₀O₂, 314.2246). The mass spectrum of DHAAME is shown with its structure in Fig. 2. DHAA is generally considered to be a resin acid from pine wood,⁶ but it is diversely found from honey mushroom⁷ to Black Sea Bryozoa,⁸ which are minute, colonial animals. DHAA has low toxicity in rats,⁹ but, its toxicity to fish greatly changes when the pH is slightly changed.¹⁰

Conclusion. The fatty acid profiles of S. typhimurium were in agreement with those earlier reported.¹¹ The hydrocarbons are in low concentrations and do not appear unusual. Since both 2-OH-14:0 and 3-OH-14:0 have been associated with lipid A, which has been associated with virulence, the presence of these hydroxy fatty acids suggests their association with virulence by S. typhimurium. The unusual cyclic fatty acids, C17Δ and C19Δ, may play a role in virulent character. It is unusual to find a resin acid like dehydroabietic acid (DHAA) in a bacterium. Its role is not understood. But, it has low toxicity in the rat and its toxicity in fish drastically changes by slightly changing the pH. Therefore, DHAA potentially may be associated with virulence by S. typhimurium.

DETERMINATION OF ANOXIA-INDUCED PHOSPHOLIPASE A2 (PLA2)
ACTIVATION IN FRESHLY ISOLATED RABBIT PROXIMAL TUBULES
USING NICI .

Didier Portilla ; Lazaro Mandel and David S. Millington.
Nephrology Division, Departments of Medicine, Cell Biology and
Pediatrics, Duke University Medical Center , Durham N.C.

The mechanisms of ischemia induced phospholipid breakdown in kidney cells have not been completely elucidated. In the arterial occlusion model of renal ischemia several investigators have found marked increases in free fatty acids (FFA) and diacylglycerol within the first 15 minutes . These effects were accompanied by changes in lysophospholipids suggesting the action of enzyme of the phospholipase A(s) class . We have evaluated the role of anoxic injury on phospholipase(s) activation by determining changes in arachidonic acid release measured by NICI GCMS after manipulation with PLA2 inhibitors as well as protein synthesis inhibitors in rabbit proximal tubules subjected to anoxia.

METHODS : Renal cortical tubules were isolated from rabbits according to published methods.

After isolation, tubules were preequilibrated for 20 min at 37°C in a 95% O_2 /5% CO_2 atmosphere; then anoxia was maintained for 40 min under a N_2 atmosphere at 37°C and then reoxygenated for additional 40 min.

AA was extracted after addition of acidified methanol and 10 ng of octadeuterated (D8) AA as internal standard. AA is isolated on C18 columns and converted to pentafluorobenzyl esters. AA mass is determined by GCMS NICI mode monitoring m/z 303 for protium and m/z 311 for deuterium .

In alternate experiments in tubules labeled with ^3H AA, AA and diacylglycerol (DAG) were separated by TLC.

PLA2 was assayed in proximal tubules mechanically disrupted and subjected to serial high speed centrifugations to separate microsomal and cytosolic fractions. PLA2 activity was measured as the amount of AA released after incubations of the fractions with cold PC , PE and 14C 2 arachidonyl PC, PE .

RESULTS : Anoxia induced a time dependent stimulation of AA release from basal levels of 4.33 ± 71 ng/mg prot. (normoxia) to 139.03 ± 35.33 ng (after 40 min.) . AA release went up to 165.33 ± 36.41 ng/mg during 40 min of reoxygenation. Pretreatment of proximal tubules prior to anoxia with actinomycin D significantly inhibited AA release during reoxygenation from 202.66 ± 15.70 ng/mg to 108 ± 25.77 ng/mg prot.. A similar effect although less pronounced was observed with cycloheximide . Quinacrine and dibucaine did not have a significant effect on AA release during anoxia or reoxygenation . . TLC analysis of fatty acids in tubules previously labeled with ^3H AA confirmed the changes observed with AA mass determinations as well as a significant formation of 1,2 DAG in anoxic conditions. We conclude : 1) Anoxia stimulates AA release in proximal tubules through activation of phospholipases presumably PLA2 . 2) Activation of the enzyme (s) responsible for AA release require protein synthesis. Further studies are required to elucidate substrate specificity and other factors associated with this activation.

Location of double bond and other substituents in long-chain fatty acids (FA) has been a topic of continuing interest in organic and biomedical analysis. Of the numerous methods so far advanced, the approach that first suggested by Vetter in 1971 [1] on the basis of "remote functional group modification" is particularly attractive. In this way, it is possible to handle complex mixtures of unknown acids by derivatization of the COOH group ("remote site") followed by MS or GC-MS of the reaction products.

Most often FA were converted to N-acyl pyrrolidides [2], picolinyl esters [3], or heterocycles (eg., benxoxazoles, BOX [4]; or 4,4-dimethyloxazolines, DMOX [5]) that would afford more specific spectra regarding the chain structure. The main advantage is peak identification without the use of standards that are not available for the "unknowns". The significantly improved diagnostic power of these derivatives aroused immediate interest to test them in direct analysis without prior chromatographic separation. Thus, Deterding [6] reported, collision activation (CA) of the $(M+H)^+$ in fast atom bombardment (FAB) spectra of the unsaturated FA (UFA) derivatized as picolinyl esters was able to reveal typical fragmentation, from which the site of double bonds was readily apparent. Usually, the assignment is possible for cases of di- and trienoic acids, but becomes more difficult for samples with higher degrees of unsaturation.

We wish to report here a very simple and efficient technique for direct analysis by using B/E-linked scan coupled with in-beam electron-impact (IBEI) mass spectrometry of DMOX derivatives (cf. ref. 7 and 8).

DERIVATIZATION

DMOX were prepared by condensation of FA with 2-amino-2-methylpropanol (AMP) according to the procedure reported earlier [5].

MASS SPECTROMETRY

Instrument: MAT 711 coupled with SS 166 data system. Operating parameters: accelerating voltage 8 kV, electron energy 70 eV, emission current 0.8 mA, source temperature 20°C, resolution 1000.

IBEI: the sample (ca. 1 μ g) in $CHCl_3$ was loaded on the stainless steel target of the FAB direct inlet probe and then inserted into the ion source 3-4 mm away from the electron beam.

B/E-linked scan: performed by using a Finnigan-MAT Metascan unit, linear scanning speed 128 sec/decade, the spectra were registered on a UV-recorder. The measured daughter ion m_2 was calculated according to the equation $m_2 = (m \times m_1)^{1/2}$, where m_1 = mass of the precursor, m = apparent mass of the marker.

RESULTS AND DISCUSSION

Good reproducibility in mass measurement (deviation <0.2 amu) can be obtained based on a calculation from the results of repeated scanning starting from m/z 335 [DMOX of 18:1(9)].

The daughter ion spectra originating from the molecular ions of nine UFA, two acetylenic, and five hydroxy acids have been obtained. The site of unsaturation (and substitution) can be deduced according to the empirical rule outlined before [5,8].

One important implication of the use of this technique is related to the analysis of mixtures. Usually, when going from EI to IBEI mode, a pronounced increase in intensities occurs for the molecular ion peaks (200-1000 % enhancement), while the increase for other peaks are relatively less significant (10-30% enhancement). The predominating feature of the results allows easy distinction of the odd-mass molecular ions from the even-mass fragment ions in the spectra resulting from mixture samples.

CONCLUSION

The method described above provides an alternative means for direct location of unsaturated bonds (for polyenes with up to 6 double bonds) and hydroxyl groups in long-chain FA. It will be beneficial for the analysis of samples which are not amenable to GC-MS due to poor volatility or scanty MS information attainable by other means. Artifact peaks can arise from unrelated species that fall within the mass window of $\pm 2.5\%$ with respect to the target precursors. Nevertheless, this drawback can be overcome by using tandem mass spectrometry.

CHARACTERIZATION OF FATTY ACYL HYDROXYLATION OF TUMOR CELL GANGLIOSIDES BY FAB-CAD-MS/MS

Douglas A. Gage¹, Charles C. Sweeley¹, Heber Becker² and Stephan Ladisch²

¹Department of Biochemistry, Michigan State University, East Lansing, Michigan 48824

²Department of Pediatrics and Oncology, UCLA School of Medicine, Los Angeles, California 90024

Many tumor cells are known to express glycosphingolipids structurally distinct from those of cells from analogous normal tissue. Often these differences are located in the oligosaccharide portion of the molecule (1). However, structural variation has also been found in the ceramide (lipid) portion of the both gangliosides (2,3) and neutral glycosphingolipids (4,5) of some tumor lines. Ceramide composition has usually been determined by methanolysis and subsequent analysis by GC-MS of the derivatized sphingoid base and fatty acid.

Although negative ion FAB-MS analysis provides oligosaccharide sequence information, direct characterization of the ceramide structure by examination of the prominent $[\text{CerO}]^-$ fragment (representing the total ceramide composition) in the spectra of gangliosides is not possible because of potential structural isomerism (e.g., d18:1 sphingoid base, C18:0 fatty acid vs d20:1, C16:0 or d18:1, C18:0 vs d18:0, C18:1).

The introduction of FAB-CAD-MS/MS techniques in both positive and negative ion modes (6) has permitted the composition of the ceramide residue to be determined in underivatized glycosphingolipids. We have recently reported the use of this analytical approach in combination with HPLC purification of individual ganglioside molecular species to characterize the ceramide composition of neuroblastoma (NB) GM2 and compare it to that of normal human brain (HB) GM2 (7).

The separation of individual molecular species prior to analysis by FAB-CAD-MS/MS allowed the ceramide structure of minor GM2 components to be determined, even though they do not produce sufficient parent ion intensity in a mixture of ceramide species.

The FAB-MS spectra of oligosaccharide homogeneous normal human brain (HB) and neuroblastoma (NB) GM2 differ dramatically in the molecular ion region, indicating the ceramide molecular species pattern of GM2 from each tissue is distinct. This conclusion is confirmed by the reversed phase HPLC separation of these two samples into their individual GM2 ceramide molecular species. The NB GM2 has many more ceramide species than the HB GM2.

When the fragment ion in the negative FAB spectrum representing the ceramide moiety, $[\text{CerO}]^-$, is used as the parent ion in a CAD-MS/MS experiment, two daughter ions, S and T (8), indicative of the fatty acyl group are observed. Since the weight of the total ceramide is known, the sphingoid base present can be derived by difference.

The negative FAB-CAD-MS/MS spectra of HPLC separated molecular species are greatly improved over those obtained from the same compound in a mixture of other GM2 congeners. Two examples of FAB-CAD-MS/MS analysis of separated NB GM2 molecular species are shown in Figure 1. These two congeners, not present in HB GM2 both contain hydroxy fatty acyl residues. Examination of other NB GM2 ceramide species demonstrated that fatty acyl hydroxylation is characteristic of neuroblastoma GM2.

An alternative FAB-CAD MS/MS approach in the positive ion mode, using an analogous ceramide fragment provides complimentary information on the sphingoid base though, again, the other part of the ceramide can be easily deduced. The lack of sensitivity in the positive FAB mode for underivatized gangliosides, however, makes the negative ion mode experiment preferable.

The combination of HPLC purification of molecular species and FAB-CAD-MS/MS is a powerful technique for determining ceramide structure in underivatized gangliosides. This approach has been used to characterize the GM2 composition of normal human brain and neuroblastoma tumors. The dramatic differences observed were due to the presence of additional hydroxy fatty acyl and longer chain fatty acyl residues in the ceramide of neuroblastoma tissue.

We have now extended this analytical approach to other neuroblastoma gangliosides. The ceramide composition of NB GM1 was found to vary from that of HB GM1 in a similar manner. NB GM1 molecular species at m/z 1580, 1586, and 1642 were absent from HB GM1. These represent ceramide species containing sphingoid base d18:1 and the hydroxy fatty acids h18:0, h20:0, and h24:1, respectively. Preliminary analysis of NB GD3 and HB GD3 showed a similar pattern. Thus, it appears that fatty acid hydroxylation is characteristic of neuroblastoma tumor gangliosides.

HPLC: Extracted gangliosides (7) were separated and recovered by normal phase HPLC on a 25 cm Hilar RT Lichrosorb Si100 NH₂ column. The solvent gradient of Gazzotti (8) was used. Gangliosides were detected at 215 nm. The resulting oligosaccharide homogeneous gangliosides were then separated into their individual ceramide molecular species by reversed phase HPLC on a Hilar RT Lichrosorb Si100 RP-8 column. An acetonitrile-5mM phosphate buffer solvent gradient (7) was employed. Eluted gangliosides were then desalted on a Sephadex G-50 gel filtration column prior to mass spectral analysis.

Mass Spectrometry: Approximately one μl of a methanolic ganglioside solution (1nmol/ μl) was mixed with 2 μl of triethanolamine matrix on the FAB probe tip. Ions were produced by bombardment with a 6kV beam of Xe atoms in a JEOL HX-110 double focusing mass spectrometer operating in negative ion mode. The accelerating voltage was 10kV.

and the resolution was set at 3000. For CAD-MS/MS, helium was used as the collision gas in a cell located in the first field-free region. The helium pressure was adjusted to reduce the abundance of the parent ion, $[\text{CerO}]^-$, by 75%. A JEOL DA-5000 data system generated linked scans at constant B/E.

**EC-NI CAD MS/MS ANALYSIS OF THE FRAGMENTATION OF ABSICISIC ACID:
THE ROLE OF OXYGEN-INDUCED ACTIVATION**

Timothy G. Heath, Jan A.D. Zeevaart, Douglas A. Gage and J.T. Watson
Michigan State University, East Lansing, Michigan 48824

Electron Capture Negative Ionization (EC-NI) mass spectrometry is a highly sensitive method for detection of the methylated derivative of abscisic acid (ABA-Me), an important plant growth regulator. Use of methane or ammonia as the buffering reagent gas promotes the formation of M^- as the most intense ion in the mass spectrum. In EC-NI mass spectrometry, the presence of O_2 in the ion source can significantly alter the mass spectrum. Both gas-phase reactions and wall-catalyzed reactions involving oxygen are known to induce formation of additional ions.¹ In the spectrum of ABA-Me, oxygen enhances the formation of structurally-informative fragment ions of mass 136, 141, and 152. In a previous study² of ABA-Me by EC-NI, the oxygen-enhanced ions of mass 141 and 152 were observed without the deliberate introduction of oxygen into the ion source. However, small quantities of oxygen were no doubt present in the reagent gas or GC carrier gas.

Figures 1a and 1b are the mass spectrum with and without oxygen present in the source, respectively. The oxygen-induced fragmentation reaction is being studied systematically with a Finnigan triple quadrupole mass spectrometer (TSQ-70). Conditions for EC-NI are established in the ion source and the molecular anion of ABA-Me (m/z 278) is transmitted via Q_1 into the collision cell (Q_2) for energy-controlled reactions with $^{16}O_2$, $^{18}O_2$, or Ar. Molecular oxygen is required for formation of abundant ions of mass 141 and 152, and a minor ion of mass 136 (see Figure 2a,b). The abundance of these ions decreases as the K.E. of the M^- is increased from 0 to 10 eV/Lab; beyond 10 eV, CAD fragments dominate. In contrast, when M^- interacts with Ar in Q_2 at low K.E. (0-40 eV Lab), no peaks are observed at m/z 136, 141, or 152.

The oxygen-activated ions are formed through a pathway in which a $(M+O_2)^-$ adduct (m/z 310) is an intermediate. This short-lived adduct decomposes to produce the ions of mass 136, 141, and 152. The adduct ion can be stabilized in a high pressure CI ion source so that it can be chosen as the parent ion in a MS/MS experiment. The CAD spectrum of m/z 310 (figure 3) shows that the ions of mass 136, 141, and 152 arise from the $(M+O_2)^-$ adduct ion.

Two other prominent ions in the spectrum at mass 260 and 245 are not oxygen-activated fragments, but CAD fragments. ^{18}O - and 2H -labelled analogues of ABA-Me have enabled the determination of fragmentation mechanisms for these two significant dissociations. $(M-18)^-$ results from the loss of the tertiary hydroxyl group and a hydrogen from the side chain, presumably at the 4 or 5 position. $(M-33)^-$ arises from sequential loss of H^- from the 5' position and CH_3OH from the tertiary hydroxyl group and one of the gem-dimethyl groups from the ring as proposed by Netting et al.² MS/MS reveals that m/z 245 may also result from loss of CH_3^- from the ion at m/z 260. Figure 4 summarizes the relationship between the fragment ions formed and the collision energy. As the kinetic energy of the parent ion is increased, the formation of CAD fragments (m/z 260 and m/z 245) increases, whereas the oxygen-activated daughter ions decrease.

When $^{18}O_2$ was introduced into the Q_2 cell and M^- of ABA-Me was chosen as the parent ion, the fragment at m/z 141 shifted to m/z 143. There was no shift in mass for the other oxygen-activated fragment ions. The ion of mass 141 not only contains the two carboxyl oxygens, as shown by isotope labelling studies, but a third oxygen whose origin is molecular oxygen. The following mechanism involving a $(M+O_2)^-$ intermediate accounts for the formation of this oxygen-activated ion.

Oxygen contamination may significantly alter the mass spectrum in EC-NI. Most often addition products are observed due to reactions with oxygen impurities present in the reagent gas. The EC-NI spectrum of ABA-Me produces structurally-informative fragment ions which are a result of oxygen-induced fragmentation. The use of triple quadrupole mass spectrometry allows selective reactions to be examined in an environment free of interfering reactions. This method has been used to elucidate reactions between M^- of ABA-Me and molecular oxygen, and these fragments have proved useful in ^{18}O isotope labeling studies of ABA biosynthesis.^{3,4}

Experimental:

All spectra were recorded on a Finnigan TSQ 70 triple quadrupole mass spectrometer equipped with a Varian 3400 Gas Chromatograph. The column used was a DB-5 capillary column (30m x 0.247mm; J&W Scientific, Inc.). Source pressure was maintained at ca. 0.8-0.9 mtorr methane or ammonia, and source temperature was held at 150 C. Unless otherwise indicated, pressure of O_2 in Q_2 was 0.9 mtorr, and collision energy was 0-5 eV(Lab frame).

The metabolic oxidation of arachidonic acid leads to formation of a wide variety of biologically active molecules including prostaglandins and leukotrienes (1). Historically, mass spectrometry has played a central role in the structure elucidation of these hydroxy, unsaturated carboxylic acids. However, most experiments have involved extensive derivatization and/or chemical degradation of these molecules (2). Thus, there has been a continuing need for the development of methods to probe the chemical structure of oxygenated, unsaturated fatty acids to facilitate such characterizations. We report here studies performed on underivatized prostaglandins using fast atom bombardment mass spectrometry, using 3-nitrobenzyl alcohol saturated with BaCl₂ as matrix. Ions were desorbed from this matrix initially as (M-H+Ba)⁺. Previous work has involved the study of the decomposition of prostaglandins cationized as lithium salts (3)

The fragmentation of the bariated molecular ion upon high energy collision activation (CA) was observed to be quite different from that of the protonated form, in that charged localization due to the barium ion permitted charge-remote fragmentation to occur (4). In the case of the prostaglandins, localization of the cationic site at the carboxylic acid moiety was facilitated by the use of the divalent barium ion in the desorption matrix. Major ions were observed for the loss of water from each of the hydroxyl groups present in the prostaglandin structure. These are shown in Figures 1 and 2 with the loss of a single moiety of water (PGA₂ and PGB₂) and for a loss of two molecules of water in Figures 3 and 4 (PGD₂ and PGE₂). Two major ions were observed at m/z 209 and 263 for these prostaglandins which arose from a charge-remote fragmentation process indicating the double bond position in these prostanoid structures at C5-C6. The structures of these ions are shown below. Another structurally informative ion was observed at m/z 343 which could be rationalized as arising from the loss of the alkyl chain at carbon 12. The formation of these latter ions involve a proton loss from carbon 8, a proton that is not available in the PGB₂ structure because of the double bond in the cyclopentenone ring.

Figure 1 Collision-induced dissociation of bariated PGA₂ (m/z 471)

Figure 2 Collision-induced dissociation of bariated PGB₂ (m/z 471)

Figure 3 Collision-induced dissociation of bariated PGD_2 (m/z 489)

Figure 4 Collision-induced dissociation of bariated PGE_2 (m/z 489)

The loss of water from the various hydroxyl moieties in the prostaglandins has a negative effect on the CA spectra observed for all eicosanoids most likely because isomerization can occur along the C20 carbon chain. Also likely is an interaction of the barium ion with the double bonds or other functional groups present in these complex molecules, resulting in alternative fragmentation pathways that are not well understood at the present time. Studies of the collision-induced dissociation of the $(M-H-H_2O+Ba)^+$ may be of more value to probe the complex structure of these polyhydroxy, unsaturated fatty acids.

NEGATIVE ION FAB/MS OF PLATELET ACTIVATING FACTOR

Keith L. Clay and Joseph A. Zirrolli

Department of Pharmacology
University of Colorado Health Sciences Center
Denver, CO 80262

Fast atom bombardment mass spectrometry is a powerful method of measuring platelet activating factor (PAF, 1-O-alkyl-2-O-acetyl-glycero-3-phosphocholine). This technique is limited, however, by the necessity of separating PAF from other molecules which are chemically quite similar and may be isobaric. Hexadecyl PAF is the major species found in most biological mixtures and this PAF species is isobaric with 1-O-octadecanoyl-lyso-glycero-3-phosphocholine which can be expected to be in these mixtures at concentrations equal to or exceeding those of PAF. MS/MS procedures were investigated as a means to measure PAF in biological mixtures without extensive chromatographic separations.

METHODS: Dynamic (continuous flow) and static FAB/MS was carried out using either a VG 7070E in a normal mode or using the collision cell in the first field free region and performing B/E linked scans to study product ions or B²/E scans to study precursor ions. Dynamic FAB was performed with a microsyringe pump (Isco Inc., Model uLC-500) using a glycerol-based matrix (methanol/water/glycerol, 80/20/2) at 5 μ l/min through a 1 m X 50 μ m untreated fused silica tube. This mass spectrometer was equipped with a saddle-field fast atom bombardment gun and a commercial FAB ion source. FAB desorbed ions were produced with 8 KeV xenon atoms with a gun current of 2 mA. Collision-induced dissociation took place with helium as collision gas in the first field free region collision cell with a 10-50% suppression of the selected ion beam. B/E data from the VG 7070E were obtained using a Teknivent data acquisition system and software. Calibration of these scans was performed at each parent mass by linking the accelerating voltage with the B/E scan then linear scanning all three parameters (B/E/V) simultaneously. This arrangement permitted transmission of all source ions at their proper m/z ratios. The mass range was calibrated with glycerol cluster ions. Accelerating voltage was then unlinked and the B/E scan obtained for product ions.

RESULTS: Positive ion FAB/MS of phosphocholines are characterized by strong (M+H)⁺ ions and another intense ion at m/z 184 derived from the phosphocholine head group. Collisional induced dissociation of the isobaric protonated molecular ions of PAF and stearoyl-lyso-GPC followed by linked scanning (B/E) of the ESA and magnetic fields of a VG 7070E resulted in product ion spectra which were virtually indistinguishable between the two species. The major product ion from both compounds was m/z 184.

Negative ion FAB mass spectra of phosphocholines have been recently described to contain intense ions corresponding of M-15, M-60, M-86 as losses from the choline polar head group (Jensen et al., Lipids 21:580-588, 1986). Product ion spectra from the M-15 ion of these phospholipids contain ions diagnostic of acyl chain identity and position.

Negative ion FAB/MS of PAF was quite similar to that described for other phosphocholines, showing fragment ions of M-15, M-60 and M-86. However, the product ion spectrum from the M-15 ion revealed ions specifically related to the acetyl group, namely M-42 and M-60. These two ions were shown by isotopic labelling to correspond to the loss of ketene and acetic acid, respectively. The product ion spectrum from the M-15 ion of the isobaric lyso-GPC contained an intense ion at m/z 283, the stearoyl anion. Thus, product ions from the M-15 ion of these similar compounds gave spectra which clearly distinguished between the two structures.

During the course of these studies, a unique and interesting matrix adduct ion was observed in the negative ion FAB/MS of phosphocholines. The ion corresponds to attachment of one glycerol molecule minus a proton to the phosphocholine (M+G-H)⁻. For PAF this ion at m/z 614 was shown through CID and B/E linked scanning methods to be the immediate precursor for the ions previously described as M-15, M-60 and M-86. It may be this unusual chemistry of cluster adduct formation which allows the formation of intense negative ion from zwitterionic phosphocholines which contain a positively charged quaternary amino group.

DETERMINATION OF ENDOTHELIAL CELL DERIVED PLATELET ACTIVATING FACTOR BY FAB/TANDEM MASS SPECTROMETRY

Peter E. Haroldsen¹, Addison A. Taylor¹, C. Wayne Smith² and Simon J. Gaskell¹

¹ Center for Experimental Therapeutics, and ² Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030.

Mass spectrometric determination of lipid-derived mediators has been indispensable for structural elucidation and trace level analysis of these biologically significant molecules. The low concentrations of these agents, together with the complexity of the biological milieu, create stringent analytical demands of sensitivity and selectivity. We recently described (1) the development of a procedure for the detection of platelet activating factor (PAF; 1-O-alkyl-2-acetyl-sn-glycerol phosphoryl choline) using FAB/tandem MS with parent ion scanning on a BEQ instrument (VG ZAB SEQ). The method was rigorously validated and applied to the determination of PAF production by stimulated human neutrophils. A comparison of quantitative data obtained by the FAB/tandem MS method with values obtained by GC-MS of the dephosphorylated and derivatized analyte indicated excellent agreement.

We have recently extended the application of this procedure to the study of stimulated endothelial cells. The possible production of PAF by endothelial cells is of particular interest in defining mechanisms for their interaction with neutrophils. Cultured human umbilical vein endothelial cells (HUVEC) have been shown to produce PAF following stimulation with thrombin (2 U/ml) or calcium ionophore (10 μ M) (Figure 1). Cell extracts were fractionated by silica HPLC to separate PAF from other phosphatidyl choline species. Quantification using [²H₃-acetyl]PAF as internal standard and parent ion scanning indicated levels of hexadecyl-PAF to be (average values in ng PAF per mg protein): 5.7 for thrombin, 11.8 for ionophore and 1.7 for control (no stimulation). The demonstration of PAF production by stimulated endothelial cells qualitatively confirms earlier findings by Prescott et al. (2) who used bioassay techniques; our initial findings, however, suggest that the levels of PAF production may be lower than previously reported.

In preliminary experiments we have evaluated the use of continuous flow sample introduction and detection by selected reaction monitoring as an alternative approach to the analysis of PAF. Figure 2 shows repeat analyses of authentic hexadecyl-PAF (12 pg) with detection of the fragmentation m/z 524 $\rightarrow$ 184. A low picogram detection limit is indicated. Figure 2 also illustrates the satisfactory detection by selected reaction monitoring of PAF in extracts of stimulated endothelial cells.

Improved understanding of the role of 5-lipoxygenase products as mediators or products of cell injury and/or inflammation requires techniques for their accurate and precise quantification. We describe initial stages of our development of reference quantitative techniques based on tandem mass spectrometry. Hitherto development of analytical methods for the cysteinyl leukotrienes (LT's) has been limited by the expense and limited availability of authentic standards together with their instability.

LTC₄, LTE₄, their respective methyl esters and deuterium labelled analogues have been synthesized essentially according to published procedures¹⁻³. The collisionally activated decompositions of the $[M+H]^+$ and $[M-H]^-$ ions formed by fast atom bombardment have been studied by tandem mass spectrometry (ms/ms) using a hybrid sector quadrupole instrument (VG ZAB SEQ). Characteristic daughter ion spectra were observed for each ion studied, fragmentation pathways have been proposed and are supported by deuterium labelling. For example, the major daughter ion derived from the $[M+H]^+$ ion of ²H₂-LTC₄ (figure 1) is the formation of protonated glutathione (308), other losses include water (610), loss of [glutamine-OH] (499), loss of glutathione (321) and formation of C₁₄H₁₉²H₂ (191) (figure 2).

Initial studies using continuous flow fast atom bombardment/tandem mass spectrometry indicate low picogram quantities of cysteinyl LT's are detectable. Sample introduction conditions were: running solvent H₂O:CH₃CN:glycerol (70:20:10) at a flow rate of 3ul/min. Figure 3 shows the selected ion monitoring (SIM) chromatogram of m/z=628, which corresponds to the $[M+H]^+$ ion formed from ²H₂-LTC₄; three injections were made, each peak corresponds to 8 picograms of analyte.

LIPOXYGENATION OF POLYUNSATURATES BY HUMAN AND RAT PLATELETS:
Hee-Yong Kim, John W. Karanian and N. Salem, Jr, Laboratory of Clinical Studies, DICBR,
NIAAA, Bethesda, MD 20892

Polyunsaturated fatty acids can be oxygenated by lipoxygenases to form hydroperoxy and hydroxy derivatives. Many of these metabolites are known to possess significant biological activity, however, the type and the extent of these effects depend upon their molecular structure. In addition to arachidonic acid (20:4w6), w-3 polyunsaturated fatty acids have been shown to be oxygenated in various tissues including platelets, neutrophils and brain. However, our studies indicate that hydroxy compounds formed by rat brain homogenates are a racemic mixture, suggesting that they are formed mainly by autooxidation. In platelets, 12-lipoxygenase produces 14- and 11-hydroxy docosahexaenoic acid (HDHE) and 12-hydroxy eicosapentaenoic acid (HEPE) from docosahexaenoic acid (22:6w3) and eicosapentaenoic acid (20:5w3), respectively. The biological significance of these metabolites is not clear at this time, however, 14- and 11-HDHE are capable of inducing smooth muscle contraction and also antagonizing both the smooth muscle contractile and platelet aggregatory effect of thromboxane. 12-HEPE has also been shown to inhibit platelet aggregation induced by thromboxane.

We considered, therefore, that changes in the levels of these metabolites after dietary supplementation with fish oil, rich in 20:5w3 and 22:6w3, may result in a shift in the pattern of eicosanoid production and, consequently, in their biological actions. In our study, platelets obtained from rats fed either a fish oil or corn oil diet for 21 days were stimulated with ionophore, A23187. The various lipoxygenase products formed were characterized using reversed phase HPLC, thermospray LC/MS, chiral phase HPLC and GC/MS analysis; the levels of these lipoxygenase products were also compared. Four major peaks were observed in the reversed phase UV and thermospray ion chromatograms. These products were monohydroxy forms of 20:5w3, 18:2w6, 20:4w6 and 22:6w3, since their thermospray mass spectra contained $M \cdot NH_4^+ - H_2O$ and $MH^+ - H_2O$ at the corresponding m/z values. Monohydroxy derivatives of 20:4w6 and 22:6w3 coeluted in a chromatographic system using an Axxichrom-ODS column and a mobile phase of 0.1M ammonium acetate:methanol ramping from 40:60 to 10:90 in 60 min. These products were collected, methylated and separated on a chiral phase HPLC system using a Dinitrobenzoylphenylglycin (ionic) column and hexane:2-propanol:acetonitrile 497.5:2.5:0.5 as mobile phase. Analysis of the GC/MS/EI spectra indicated that the monohydroxy compounds formed were 12-HEPE, 13-HODD, 12-HETE and 14-HDHE. As an example, a thermospray spectrum and an EI spectrum of 12-HEPE are shown in figure 1. A decrease in 12-HETE and an increase in 12-HEPE were the most prominent changes observed in the stimulated rat platelets after a fish oil diet although there was also a significant increase in HDHE production (Table 1). These changes in the formation of lipoxygenase products seemed to correlate with the changes in the fatty acid distribution of the platelets (Table 2). Chiral phase HPLC analysis indicated that the 12-HEPE produced was in the S configuration, as we have previously reported for 12-HETE, 14-HDHE and 11-HDHE formed by human platelets.

Preliminary data indicate that 12(S)-HEPE also causes a contraction of rat aorta and antagonizes the contractile effects of a thromboxane-mimic. The observed decrease in the 20:4w6 substrate pool in combination with the increased level of w-3 fatty acids which can be metabolized to biologically active compounds may in part explain some of the effects of a diet high in w-3 fatty acids on platelet and vascular function.

NOVEL METABOLITES OF LTB₄ FROM GUINEA PIG EOSINOPHILS

F. F. Sun, C. I. Czuk, B. M. Taylor, *D. M. Guido and *W. R. Mathews

Departments of Hypersensitivity Diseases Research and *Biopolymer Chemistry,
The Upjohn Company, Kalamazoo, Michigan, U. S. A. 49001

Leukotriene B₄ (LTB₄) is a powerful chemoattractant for guinea pig eosinophils both *in vitro* (1) and *in vivo* (2). We have previously demonstrated (3) that guinea pig eosinophils, when activated either by phagocytotic stimuli or calcium ionophore, expressed an active arachidonic acid 5-lipoxygenase activity that led to the synthesis of LTB₄ and 5-hydroxyeicosatetraenoic acid (5-HETE). Furthermore, the time course of the LTB₄ synthesis indicated the presence of LTB₄ metabolic activity in these cells. Therefore, we examined the ability of guinea pig eosinophils to metabolize LTB₄.

Incubation of LTB₄ with guinea pig eosinophils generated five prominent metabolites (I-V) and two minor metabolites with UV absorbance at 270 nm that can be readily separated by rp HPLC (Figure 1). All of these metabolites incorporated radioactivity from [³H]-LTB₄. All seven metabolites retained the UV triplet of 258, 270, 285 nm indicating that all seven metabolites retain the conjugated triene system of LTB₄. When the retention times were compared with authentic compounds, peak V matched with 20-hydroxy LTB₄, and peak IV matched with 20-carboxy LTB₄.

Metabolites I-V were analyzed by GC/MS following formation of the methyl ester, trimethylsilyl ether derivatives on a VG 70SE mass spectrometer equipped with a HP 5890 gas chromatograph. A 15m DB-1 fused silica capillary column was used. The mass spectra of metabolites V and IV were identical to previously published spectra of 20-OH LTB₄ and 19-OH LTB₄ respectively (5).

The mass spectrum of metabolite III (Figure 2A) exhibits a weak molecular ion at m/z 670 and other important ions at m/z 655 (M-15), loss of CH₃, m/z 639 (M-31), loss of -OCH₃; m/z 580 (M-90), loss of Me₃SiOH; m/z 490 (M-2(90)), m/z 463 (M-207) loss of Me₃SiOH and CH₂-CH₂-OSiMe₃, m/z 383 (b), m/z 293 (b-90); m/z 219 (Me₃SiO + = CH-CH(OSiMe₃)-CH₃, y); m/z 203 (a), and m/z 117 (z). The alpha cleavage ions at m/z 117 and 219 indicate that the two additional -OH groups are located at C18 and C19. This assignment is confirmed by the mass spectrum of hydrogenated metabolite III (Figure 2B). The molecular ion at m/z 678 and ions at m/z 663 (M-15) and m/z 647 (M-31) are 8 mass units greater than before indicating the presence of 4 double bonds. The ions at m/z 203 (a); m/z 117 (z) and m/z 219 (y) are at the same mass as the native metabolite. Fragment ions at m/z 389 (b), m/z 299 (b-90) are shifted up 6 daltons with respect to the corresponding ions in the native metabolite consistent with hydrogenation of three double bonds. Three new alpha cleavage ions are seen in the spectrum of the hydrogenated compound at m/z 577 (M-CH₂-(CH₂)₂-COOCH₃, w), m/z 391 (M-CH₂-(CH₂)₅-CH(OSiMe₃)-(CH₂)₃-COOCH₃, x) and m/z 561 (M-CH(OSiMe₃)-CH₃, c). These fragments lose Me₃SiOH to give rise to ions at m/z 487 (w-90); m/z 471 (c-90); m/z 397 (w-2(90)); m/z 381 (c-2(90)) and m/z 291 (c-2(90)). The spectrum of hydrogenated metabolite III confirms the position of the hydroxyl groups to C5, C12, C18 and C19. This metabolite is identified as 18,19 dihydroxy LTB₄.

The mass spectrum of methyl ester, trimethylsilyl ether derivative of metabolite II is shown in figure 3A. This spectrum shows a molecular ion at m/z 508 and ions at m/z 493 (M-15), loss of CH₃; m/z 477 (M-31), loss of OCH₃; m/z 418 (M-90), loss of Me₃SiOH; m/z 383 (b); m/z 293 (b-90); m/z 203 (a) and m/z 129 (base peak), Me₃SiO + = CH-CH=CH₂. The ions at m/z 383 (b), 293 (b-90), and 203 (a) are characteristic of the C1-12 portion of the leukotriene B₄ molecule and are consistent with the UV data which indicates that the triene chromophore of LTB₄ is intact. The mass spectrum of metabolite II after hydrogenation is shown in figure 3B. The molecular ion is not seen but abundant ions at m/z 501 (M-15) and 485 (M-31) indicate that the mass of metabolite II has been increased 8 daltons by hydrogenation, indicating the presence of 4 double bonds. The b ion is not shifted while the a and a-90 ions are shifted up 6 daltons consistent with hydrogenation of the three double bonds of the C1-12 portion of LTB₄ (6,8,10). Additional ions at m/z 415 (M-101, w), loss of CH₂-(CH₂)₂-COOCH₃ and m/z 229 (M-287, x) are seen. Based this information, metabolite II is proposed to be 19-oxy LTB₄.

Four of the five major eosinophil metabolites have been identified as 20-OH LTB₄, 19-OH LTB₄, 18,19-diol LTB₄ and 19-oxy LTB₄. Guinea pig eosinophils possess an active omega oxidation system capable of metabolizing LTB₄.

CAD STUDIES OF ALKYL- AND HYDROXY-SUBSTITUTED AROMATIC IONS FOR THE
STRUCTURAL ELUCIDATION OF HYDROXYLATED METABOLITES OF AROMATIC COM-
POUNDS

The use of collisionally activated decomposition (CAD) to determine the structure of ions, based on comparison with the CAD spectra of known ions, has been well established. Judicious selection of compounds used in generating precursor ions, taking basic principles of ion chemistry into account, allows one to generate standard CAD spectra which can be used with reasonable confidence to assign the structure of ions arising in the mass spectra of unknown molecules. We report here on the use of this principle towards determination of the A-ring hydroxylation of Vitamin D.

Although not intrinsically an aromatic compound, Vitamin D gives rise in its mass spectrum to an aromatic methylstyryl cation of m/z 118 following the loss of H_2O from m/z 136 (Scheme 1) [1]. A-ring hydroxylated metabolites of Vitamin D would thus incorporate the extra hydroxy group on the ion of m/z 118 shifting it to m/z 134. The position of substitution of the extra OH-group on a metabolite could thus be ascertained by comparing the collision spectrum of its m/z 134 fragment to those of the four possible hydroxymethylstyryl cations generated from synthesized authentic compounds. The hypothesis was tested using readily available 1,25-dihydroxyvitamin D_3 .

Scheme 1

Different approaches to the generation of these ions were pursued. It was soon realized that preparation of styryl compounds bearing the structure represented by ion a was complicated by their facile polymerization. We thus decided to explore the production of such ions in situ via the McLafferty rearrangement of trifluoroacetyl (TFA)

derivatives of the corresponding hydroxyphenyl-ethanols. We found, however, that the four isomeric hydroxy-2-methylstyryl cations of interest gave identical CAD spectra. In order to circumvent this problem, methylation of the aromatic hydroxy group was considered. CAD spectra were thus acquired for the four isomers of the methoxystyryl cations of m/z 148 which were generated from the TFA derivatives of the appropriate isomeric methoxy-2-methylphenyl ethanols (Scheme 2). Consistent with this approach, 1,25-dihydroxyvitamin D_3 was also permethylated and its mass spectrum gave rise to the analogous methoxystyryl ion of m/z 148. Significant differences in the CAD spectra of the four isomers were observed. This behavior is in contrast to that of the corresponding hydroxy analogs and is, in part, due to resonance processes through the aromatic ring to form benzoquinone type cations in the *ortho* and *para* isomers following the loss of a methyl radical. Moreover, as expected, only the CAD spectrum of the 3-methoxy-2-methylstyryl ion matched that of the m/z 148 ion from 1,25-dihydroxy vitamin D_3 . The CAD spectra of the different isomeric ions are partially summarized on Table I. This method provides a viable approach for the characterization of A-ring metabolites of vitamin D as well as for related aromatic systems in general.

Scheme 2

Structural Determination of Modified Chlorophylls By Using Tandem Mass Spectrometry

R.P. Grese and M.L. Gross, Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska 68588

Improved methods for structural determinations are needed to further elucidate chlorophyll biosynthesis and photosynthetic mechanisms. We present here the first application of MS/MS to investigate a series of structurally modified chlorophylls. To evaluate MS/MS, we chose bacteriochlorophyll *a*, chlorophyll *a* and *b*, chlorophyll *a* and *b* allomers (10-*HO*-, 10-*HO*-lactone-derivatives) and the pheophytins as model systems.

In addition, we examine the application of MS/MS to study the intrinsic reactivities of chlorophylls with alkali metal ions, and chlorophyll dimers. The study of dimers is especially interesting because of their role as the "special pair" in the photosynthesis reaction center.

FAB of *chl a* in a matrix of 3-NBA produces an abundant molecular ion cluster and fragment ions consistent with previously reported spectra. (Figure 1a) (1) The predominant molecular species is the radical cation. The loss of the phytyl chain gives the most abundant fragment ion (*m/z* 614).

The FAB matrix offers both advantages and problems for analysis of chlorophylls. The FAB matrix acts to modify the strong aggregation of *chl a*; thus *chl a* is desorbed with less internal energy and the "explosive" fragmentation observed in 252Cf-PD(1)(2) and LD(3) techniques is not observed by FAB. Reactions of chlorophyll with the FAB matrix, however, are problematic for accurately determining their purity. Oxidation products of *chl a* and *Bchl a* (10-*HO*- and 10-*HO*-lactone-derivatives) and chlorophyll-matrix adducts are observed in the FAB spectra (Figures 1a and b). Their relative abundances increase with continued bombardment of the sample.

Demetallation of chlorophyll upon addition of hexafluorobutyric acid (HFBA) to the FAB probe yields the corresponding pheophytin (Figure 1c). This is analytically useful as the pheophytins yield more abundant structural information upon CA (e.g. charge-site-remote fragmentations).

The CAD of the $M^{+\bullet}$ of the chlorophylls studied are similar to that of *chl a* (Figure 2a). Product ions in the range *m/z* 400-620 are similar to source-produced fragment ions in the full scan spectrum. The MS/MS experiment, however, is less ambiguous because only the decomposition of a single species is measured. Detection limits for acquiring good quality MS/MS spectra is ~10 pmoles (10 ng). The energy loss accompanying CAD with He limits the accuracy of mass assignments in the MS/CA/MS spectra. Mass assignments were confirmed by comparison with MS/MS metastable and CA B/E linked scan experiments. The energy loss accompanying CA with He associated with the ion of *m/z* 614 was 23.4 ± 0.1 eV, which is in good agreement with the value reported by others.(4)

CA of the pheophytins produce more abundant structural information than the chlorophylls. A series of regularly spaced peaks are assigned to charge-remote losses of the elements of C_nH_{2n+2} from the phytol chain. Branch points are identified by interruptions in the series of alkane losses. The ion of m/z 838 is produced by loss of methanol and formation for the stable ketene ion.(5) The loss of methanol is not seen upon CA of the chlorophyll derivatives in which the C-10 hydrogen has been replaced by -OH. The ion of m/z 811 arises by loss $\cdot COOCH_3$ and is an abundant ion for all the chlorophylls studied.

CA of chlorophylls cationized with alkali metal ions is complementary to the M^+ ion. CA of Chla $[M + Li]^+$ produces an ion of m/z 545 resulting from loss of the phytol chain and subsequent losses of methanol and CO_2 (Figure 3a). Metal ion attachment and enol formation at C-9 are consistent with chla solution chemistry. The above fragmentation is not produced in the CA of the $[M + Li]^+$ ion of chla RCI(6) because the C-10 hydroxyl prevents the loss of methanol(Figure 3b). Loss of HCl confirms the presence of Cl in this derivative.

An interesting ion produced by CA of the $[M + K]^+$ species of HO-lactone-chla, is the ion of m/z 821(Figure 4). The metal ion is being lost possibly by a mechanism in which the K^+ is chelated by the oxalic acid methyl ester. Subsequent loss of 278 amu (phytyl) from this ion produces the ion of m/z 543.

In addition to producing abundant M^+ ions, FAB of chlorophyll produces a less abundant dimer $[2M]^+$ (Figure 5a and b). CAD of chlorophyll dimers has not been reported.

Ions corresponding to M^+ and $[M - phytol]^+$ are the most abundant ions in the CA mass spectra. More revealing are the higher mass ions due to losses of CH_3OH , $\cdot COOCH_3$, and phytol from the dimer. The ions of m/z 1189 and 1153 from Bchla and chla respectively are proposed to result from successive losses of the two phytol groups and CH_3OH and CO_2 in a mechanism similar to that of the CAD of the $[M + Li]^+$ adducts.

It has been shown that coordination of the C-9 carbonyl of one chla to the Mg of the another chla is responsible for dimer formation in solution.(7) The higher mass ions demonstrate that the $C=O \cdots Mg$ interaction between the two chla molecules is weaker than but comparable to the critical energy for cleaving off the phytol chain. If our mechanism is correct, the ions of m/z 1189 and 1153 lend support to the $C=O \cdots Mg$ interaction.

CAD of mixed chlorophyll adducts allows us to qualitatively order the ionization potentials (IP) of the various chlorophylls by measuring the relative abundances of the M^+ species(Figure 6). These results suggest, in order of increasing IP: Bchla < Chla < Pheoa < Chlb.

DERIVATIZATION OF GANGLIOSIDES AND THEIR ANALYSIS BY HIGH PERFORMANCE TANDEM MASS SPECTROMETRY J. E. Vath, B. Doman and C. E. Costello, Dept. of Chemistry, Mass. Institute of Technology, Cambridge, MA 02139

Derivatization of gangliosides shows promise for improved analysis by MS/MS, by increasing the parent ion abundance and creating groups which direct fragmentation toward structurally significant daughter ions. Permethylated-reduction has been very successful for EIMS characterization of glycolipids and permethylation has also been shown to increase FAB/MS signal. We have explored the use of similar derivatives for FAB/MS analysis of these compounds, with the expectation that the secondary amines (generated from the amides by reduction) would serve as sites for charge localization and therefore strongly influence the CID fragmentation pattern.

Permethylating using CH_3I and solid NaOH in DMSO followed by borane reduction using condensed reagent vapor comfortably allows one to derivatize 1-10 μg of ganglioside for MS/MS analysis. A comparison of the CID spectra of the permethylated, permethylated-amide reduced and permethylated-ceramide-only reduced derivatives for the lower weight homologs of GM₁ are shown in Figures 1, 2 and 3, respectively. The FAB/MS spectrum of the permethylated compound exhibits ions resulting from protonation and cleavage of the glycosidic linkage (B and Y ions). The CID spectrum of the permethylated-amide reduced GM₁ offers stronger fragment ions that characterize the carbohydrate and aglycon portions at a glance, after one becomes familiar with the derivatives' fragmentation. Typically the ${}^n\text{A}_n$ ion, where n is the number of sugars in the longest chain, (m/z 1191 for GM₁) is the base peak in the spectra of these derivatives and reveals immediately the size of the carbohydrate moiety. The sequence of the sugars can be deduced from the B and C ions. Sialic acid strongly directs B ion formation in all derivatives, which is useful in confirming parallel or serial attachment of multiple sialic acids. There is also usually an ion, labeled E (m/z 1293 for GM₁), which is due to elimination of the long chain base beyond C2 and the entire reduced acyl chain. The fact that the ceramide amide is reduced more easily than the N-acetyl moiety is exploited to give one another choice concerning permethylated-reduced derivatives. Reduction at the ceramide only (Fig. 3) yields a complete series of X ions (which clearly show the carbohydrate sequence), a dependable U ion (which characterizes the base and fatty acid portion of the aglycon) and some selective eliminations in the sugars which can give clues pertaining to the substitutions about the rings. The conditions used to bring about these transformations, and the effects on all of the functional groups in the gangliosides studied are shown in the Table. As found with the CID spectra of peptides and with the reduced cerebroside and ceramides we initially studied, fragmentation is strongly influenced by the presence of basic sites. As the number of basic sites in a molecule increases, so does the number of directing influences and these factors alter the information in the CID spectra. Besides the effects on fragmentation, derivatization also brings about an improvement in sensitivity which is about 50-fold upon permethylation and becomes about 100-fold with subsequent reduction.

The availability of a number of derivatives for the analysis of gangliosides is necessary for a completely reliable determination. Many of the ambiguities present in the spectrum of one derivative can be answered by another. A combination of permethylation and reduction allows the flexibility to control the analysis of gangliosides by FAB/MS. The sensitivity increase observed and the ability to conduct the reactions on nmol amounts is extremely important since mass spectrometry often represents the only method to characterize these compounds at that level.

EXPERIMENTAL Gangliosides (5-10 μg) were permethylated by the method of Ciucanu and Kerek [Carbohydr. Res. (1984)131:209] and the samples were dried in the bottom of a melting point capillary. The tubes were placed inside an apparatus which allows the reaction of small amounts of sample with reagent vapor (ASMS 1988 p. 167). After the reactions were complete 10 μl of 10% NBA in 2:1 $\text{CHCl}_3/\text{MeOH}$ was placed into the capillary and the sample was concentrated *in vacuo*. An 0.5 μl aliquot of the above solution on the FAB probe of a JEOL HX110/HX110 high performance tandem mass spectrometer was used for analysis.

REACTIVITY OF CARBOXYSE FUNCTIONAL GROUPS	
First Reaction CH₃COOH + DMSO to form HT CH₃-CH₂-CH₂-CH₂-COOH CERAMIDE CH₃-CH₂-CH₂-CH₂-CH₂-COOH 16:0 Ceramide CH₃-CH₂-CH₂-CH₂-CH₂-CH₂-COOH 18:0 Ceramide	Second Reaction HT HT + HT⁺ 2 HT₂ at 25°C CH₃-CH₂-CH₂-CH₂-CH₂-CH₂-COOH HT⁺ CH₃-CH₂-CH₂-CH₂-CH₂-CH₂-CH₂-COOH HT⁺ CH₃-CH₂-CH₂-CH₂-CH₂-CH₂-CH₂-CH₂-COOH HT⁺

This reaction is followed by catalysis with HCl/NaOH for 3 hr at RT and oxidation with 1:1 $\text{H}_2\text{O}_2/\text{NaOH}$ for 10 hr at 45°C. The entries shown reflect the final products after these additional steps.

INTRODUCTION

High consumption of certain foods abundant in carotenoids has recently been associated with a reduced incidence of several types of human cancer. Additionally, it has been suggested that carotenoids, along with vitamin E, protect the vascular system against development of arterial plaques. These considerations, among others, prompted an examination of methods for the analysis of carotenoid compounds.

While molecular weight data are available from electron ionization spectra of many carotenoids, there are classes of carotenoids, for example bis-fatty acyl esters of carotenediols, for which data indicative of the molecular weight are absent or extremely weak. Further, improvements in the sensitivity would be an advantage for analysis of biological samples where there is a paucity of available sample.

EXPERIMENTAL

Carotenoids bearing a variety of functional groups were obtained either from commercial sources or by extraction from vegetables and subsequent purification.

Electron capture negative ion (ECNI) spectra (one second cycle time) were obtained from a Finnigan-MAT model 4510 equipped with a direct exposure probe and a 5 KV conversion dynode. Except where noted, methane (0.25 Torr) was used as the reagent gas.

Under yellow light, samples were deposited onto the desorption probe wire loop and solvent (benzene) removed by a gentle stream of room temperature air. The probe was immediately inserted, heated by application of an increasing current (50 ma/sec) and negative ion spectra collected. Electron ionization and chemical ionization spectra were obtained using parameters detailed in table 1.

RESULTS

Under conditions for ECNI, hydrocarbons (alpha-carotene, beta-carotene), aldehydes (beta-apo-8'-carotenal) and ketones (canthaxanthin) yielded single ions corresponding to the molecular anions M^- . The increase in sensitivity (table 1), compared to electron ionization, ranged from 25 (beta-apo-8'-carotenal) to 490 fold (canthaxanthin). The low value for beta-apo-8'-carotenal can be rationalized based on its less extensive system of conjugation.

In addition to molecular anions, two carotenediols (lutein and isozeaxanthin) yielded ions reflecting the sequential elimination of two molecules of water. In the case of lutein which possesses both an epsilon ring and a beta ring, the molecular anion was the base peak. In contrast, for isozeaxanthin, which possesses two beta rings, the $M-2H_2O$ ion was the most abundant. A possible explanation for this inversion of abundance ratios is the resulting conjugation provided by elimination from the beta ring. ECNI provides an increase in sensitivity of approximately two orders of magnitude for the determination of molecular weight when compared to electron ionization.

ECNI mass spectral analysis of lutein using deuterio-ammonia (0.27 Torr) provided simultaneous deuterium exchange and electron capture, thereby demonstrating, at high sensitivity, the presence of two exchangeable hydrogens.

Two carotenoid dihydroxy epoxide compounds, lutein epoxide (a mono-epoxide) and violaxanthin (a di-epoxide), were examined. For both compounds, the molecular anion was the base peak. In the case

of lutein epoxide, however, the allylic hydroxyl group promotes an abundant ion reflecting the loss of water which was not observed in violaxanthin. Again, ECNI yields an increase in sensitivity of two orders of magnitude for the detection of ions indicative of molecular weight when compared to EI.

Under conditions of electron ionization, the di-ester isozeaxanthin dipelargonate yields a spectrum characterized by an abundance of low mass to charge ions. Absent are molecular ions and abundant ions diagnostic for the size of fatty acyl groups. In contrast, the electron capture negative ion spectrum provides not only ions indicative of the molecular weight, but also abundant ions reflecting the losses of fatty acyl groups as well as confirmatory carboxylate anions.

**SENSITIVITY^a FOR DETERMINATION OF MOLECULAR WEIGHT
(RELATIVE TO ELECTRON IONIZATION)**

COMPOUND	MW	EI ^b	NH ₃ ^c	CH ₄ ^d	ECNI ^e

^g No M⁺ ions were observed
^h Sensitivity calculated relative to methane positive ion

CONCLUSIONS

ADVANTAGES

1. Electron capture negative ion MS provides greater sensitivity for determination of molecular weight (ca. two orders of magnitude when compared to EI).
2. Non-electron capturing contaminants are invisible.
3. Presence of contaminating carotenoids readily apparent.
4. Number of exchangeable hydrogen can be determined at high sensitivity.
5. Size of fatty acyl moieties of esters easily determined.

DISADVANTAGES

1. Mode of introduction subjects sample to air oxidation.
2. Production of carotenoid anions quenched by gross amounts of contamination.
3. Lack of ions diagnostic for carotenoid end groups.
4. Sensitivity is highly dependent on source cleanliness.
5. Requires an instrument capable of detecting negative ions.

ETHANOL INDUCED CHANGES IN CENTRAL NERVOUS SYSTEM PROSTAGLANDIN PRODUCTION:

James A. Yergey, Laboratory of Clinical Studies, DICBR, NIAAA, Bethesda, MD, 20892,
Melvyn P. Heyes, Laboratory of Neurophysiology, NIMH, Bethesda, MD, 20892.

INTRODUCTION

In recent years, a relationship between the central nervous system (CNS) effects of ethanol and central production of prostaglandins has been suggested, based primarily upon the finding that behavioral effects of ethanol can be modulated by pre-administration of prostaglandin synthetase inhibitors. It has also been hypothesized that the etiology of alcoholism may be linked to aberrant fatty acid and prostaglandin metabolism. Direct evidence for ethanol induced changes in CNS prostaglandin production has been contradictory. We developed a sensitive and specific assay based on selected-ion-monitoring, electron-capture negative ionization GC/MS detection of the N-methyl methoxime, pentafluorobenzyl ester, tris-trimethylsilyl ether derivatives of PGE₂, PGD₂, PGE₁, PGF_{2α}, PGF_{1α}, TXB₂, and 6-keto-PGF_{1α}. We previously reported significant improvements in the assay procedure and results which indicated that the concentrations of PGE₂, PGE₁, PGF_{1α}, and 6-keto-PGF_{1α} were below 15 pg/mL in lumbar CSF of healthy humans and abstinent alcoholics. In order to investigate other means of measuring CNS prostaglandins, we explored both an *in vivo* microdialysis method and an *in vitro* tissue slice method.

METHODS

***In Vivo* Microdialysis:** Four male Sprague-Dawley rats, studied on separate days, were anesthetized with pentobarbital, immobilized in a stereotaxic frame, and the microdialysis probe inserted into the striatum following surgery. The dialysis membrane was perfused at 2 µL/min with Ringer's solution, and samples collected as six one hour aliquots. Eicosanoid levels were measured in the 120 µL samples, and expressed as pg / sample, from which extracellular levels can be calculated knowing the dialysis probe *in vitro* recovery.

***In vitro* Tissue Slices:** Male Sprague-Dawley rats were sacrificed by decapitation, their brains rapidly removed to an iced stage, and 1 mm slices of frontal cortex prepared and placed in ice cold 1 % bovine albumin in Krebs's buffer. The slices were then incubated at 37°C for 30 min, the buffer removed, and again washed with albumin for 30 min. Slices were then incubated in Krebs's alone (Control) or Krebs's plus 200 mg/dL ethanol for 30 min. Eicosanoid levels were measured in the buffer, and expressed as pg produced / mg tissue / hour.

Eicosanoid Assay: Prostaglandins E₂, D₂, F_{2α} and 6-keto-F_{2α} and thromboxane B₂ were determined by GC/MS using a slight modification of previous methods. Briefly, tetradeuterated standards were added to aqueous samples, which were treated overnight to produce the N-methoxime of the ketone containing eicosanoids, extracted with C₁₈ solid-phase cartridges using gravity flow, derivatized to the pentafluorobenzyl ester, trimethylsilyl ether, and dissolved in a final volume of 10 µL dodecane. All drying steps were accomplished using vacuum rotary evaporation. Samples were injected on-column at 215°C into a 1 m, 0.53 mm i.d. retention gap, attached to a 15 m, 0.25 mm i.d. DB-5 analytical column housed in a Carlo-Erba gas chromatograph. Heating to 315°C over 2 min allowed elution of measured eicosanoids in less than 4 min. The Kratos MS-80RF mass spectrometer was operated in negative electron-capture ionization mode, and set to switch between the predominant [M-PFB]⁻ ion in the spectrum of each eicosanoid using selected-ion-monitoring. Results are presented as mean ± SEM, and statistical analysis was done using a one-way analysis of variance and Dunnett's t-test.

RESULTS AND DISCUSSION

***In Vivo* Microdialysis:** Extracellular fluid levels of PGE₂, PGD₂, PGF_{2α}, 6-keto-PGF_{1α} and TXB₂ were sampled *in vivo* in the rat striatum (See Table 1 & Figure 1). Calculated extracellular concentrations ranged from 1.8 to 51 nmol/L. The lowest calculated concentrations were similar to levels reported in the literature for undamaged tissue. *In vivo* microdialysis may, therefore, allow sampling of baseline eicosanoid production in the brain. The results demonstrated that tissue damage induced by the probe's insertion resulted in elevated levels of PGD₂, PGF_{2α} and TXB₂ recovered from the area of damage in the first hour of sampling compared to later sampling times. This is consistent with the notion that arachidonic acid was rapidly released and metabolized to these specific eicosanoids. The increase in PGE₂ in the sixth hour of sampling relative to earlier time points suggests that selective production of this eicosanoid may occur as the damage process proceeds. Until the model is extended to chronically implanted animals, the study of ethanol's effects on the brain cannot be attempted by *in vivo* microdialysis, since exposure of anesthetized animals to ethanol would almost certainly kill the animals.

***In Vitro* Tissue Slices:** Study of brain eicosanoid production *in vitro* requires that tissues be sufficiently washed with albumin prior to incubation, in order to remove arachidonic acid released during decapitation and tissue preparation (See Figure 2). Ethanol at a level of 200 mg/dL induced a small decrease in eicosanoid production in central nervous system tissue *in vitro*, as measured in rat brain frontal cortex (See Figure 3).

BACTERIAL PHOSPHOLIPID ANALYSIS BY FAB/MS/MS: CHARACTERIZATION OF THE EFFECTS OF GROWTH CONDITIONS

Mark J. Cole and Christie G. Enke
Michigan State University, East Lansing, MI 48824

Fast atom bombardment mass spectrometry (FAB/MS) shows promise for bacterial detection and identification based on analysis of desorbed phospholipids. Although providing information on phospholipid content and distribution, FAB/MS suffers from a high level of chemical background noise which produces a peak at every mass throughout the spectrum. This background noise can obscure important information useful for bacterial analysis, and raise the detection limit of the method. FAB in conjunction with tandem mass spectrometry (FAB/MS/MS) overcomes much of the chemical noise and detectability problems through the increased selectivity afforded by the tandem mass selection.

We are taking advantage of the increased scan modes available with MS/MS to develop a detection scheme based on the combination of conventional, neutral loss, and daughter spectra which fully profiles the phospholipid content and distribution in bacteria. An automated method is easily programmed into the instrument control to produce these profiles quickly, and in a single run. We are using these profiles to assess the effects of different growth conditions on the phospholipid content and distribution in bacteria.

When phospholipids undergo CID, they cleave at specific points which are common to all classes of phospholipids. These cleavages produce a neutral loss characteristic of the phospholipid class, and two fragment ions - each characteristic of a fatty acyl group contained in the phospholipid.

The phospholipid distribution in the bacteria showed wide variance over different growth temperatures. An example is shown in figure 2. In all of the bacteria studied, maintaining a constant growth temperature was found to be important to spectral reproducibility.

**LIPID ABUNDANCE VS. GROWTH TEMPERATURE
FOR B. SUBTILIS AFTER 1 DAY GROWTH TIME**

Figure 2

For bacteria not grown at their optimal growth temperatures, differences in growth time cause wide variability in lipid distribution (Fig. 3). However, we found that for bacteria grown at their optimal temperature, time differences between harvesting have little effect for most of the lipids (Fig. 4).

**LIPID ABUNDANCE VS. GROWTH TIME FOR
E. COLI AT 24°C**

Figure 3

**LIPID ABUNDANCE VS. GROWTH TIME FOR
E. COLI AT 37°C**

Figure 4

Therefore it is important, for spectral reproducibility, for bacteria to be grown at their optimal temperature. However, differences between harvesting times have a much reduced effect on reproducibility.

ANALYSIS OF BACTERIAL CELL WALL GLYCOLIPIDS BY LASER DESORPTION AND PLASMA DESORPTION MASS SPECTROMETRY

W.B. Emary, R. Wang, L. Chen and R.J. Cotter, The Johns Hopkins University, Baltimore, MD 21205;
N. Qureshi and K. Takakura, VA Hospital, Madison, WI 53705

INTRODUCTION

Glycolipids are important components in the cell walls of bacteria. The cell wall provides structural support and protection for the bacteria and the structures on their surface act as potentiators of immune responses in a host environment [1].

For the work presented here, laser desorption (LD) and plasma desorption (PD) ionization methods are used to analyze this class of compounds. The goal is to obtain both molecular weight and structural information about glycolipids.

Laser desorption mass spectra were obtained using a Tachisto (Needham, MA) model 2156 pulsed CO₂ laser with a CVC (Rochester, NY) model 200 time-of-flight mass spectrometer.

Plasma desorption mass spectra were obtained using a Bio-Ion Nordic (Uppsala, Sweden) model BIN-10K instrument with Californium²⁵² ion source. Samples were electrosprayed onto aluminized mylar foil.

RESULTS

(1) Trehalose Mycolates

Trehalose mycolates are glycolipids of the outer cell wall in bacteria. Mycolates (C₂₂-C₈₀, alpha-alkyl, beta-hydroxy fatty acids) have been found to play an important role in the immune response [1].

Corynebacteria frequently contain trehalose corynemylates on their outer cell wall surface. The positive ion laser desorption mass spectra shown in Figure 1 of trehalose monocorynemylate shows intense molecular ion peaks (MNa⁺, MK⁺) and little fragmentation. The molecular weight has been determined to within ± 0.5 amu with internal calibration standards.

Lithium cation attachment was shown in other studies with CO₂ laser desorption to result in increased fragmentation and structural information for oligosaccharides and peptides [2]. Here, LiBr was added to a glycolipid (trehalose monocorynemylate). The result shown in Figure 2 was an intense peak at 479 corresponding to the mycolate fatty acid acylium ion along with other fragments from the sugar (359, 376).

(2) T-Boc CAP Derivatives of Monophosphoryl Lipid A

Derivatization of hexaacyl monophosphoryl lipid A (MPLA) was performed with the goal of preparing intermediates with an amino group. The LD mass spectrum (Figure 3) of H₁ shows a molecular ion (MK⁺) at 1971 with corresponding weight of 1932. A peak 245 daltons less than the molecular ion corresponds to loss of t-Boc CAP+OCH₃. This loss indicates t-Boc CAP was added to the 6' position of the distal sugar. Loss of R₃ is the next major fragment at 1524, corresponding to a hydroxy myristate group from the reducing sugar. A number of other peaks appear at lower mass/charge resulting from neutral losses of fatty acids on the non-reducing (or distal) glucosamine. These peaks indicate the fatty acids on R₁ and R₂ are C₁₂ and C₁₄ groups. The plasma desorption mass spectrum of H₁ is characterized by neutral losses of R₃ and R₁. The PD mass spectrum shown here does not contain peaks corresponding to two bond ring cleavages in contrast to laser desorption.

(3) Plasma Desorption of Diphosphorylated Lipid A

Diphosphoryl lipid A (DPLA) analogs have now been isolated from *R. sphaeroides* and methylated at the hydroxy group of the phosphates. PDMS was used to determine where the second phosphate was added to monophosphoryl lipid A. The positive ion PD spectrum (Fig 4) of one of the two major fractions is shown below. The spectrum shows that the second phosphate is added to the reducing sugar of lipid A and not as pyrophosphate.

TANDEM MASS SPECTROMETRY OF ERGOSTEROL AND RELATED COMPOUNDS

T. Kinoshita, Y. Ohki, H. Nagaki and T. Nakamura

Analytical and Metabolic Research Laboratories, Sankyo Co., Ltd.,
Hiromachi, Shinagawa-ku, Tokyo 140, Japan

Fast atom bombardment (FAB) usually produces $(M+H)^+$, $(M+Na)^+$, $(M+K)^+$, $(M+H+X)^+$ (X ; molecule of matrix used for FAB ionization), etc. rather than $M^{+\bullet}$ itself in the positive ion mode. However, in the course of the study on FAB mass spectrometry, we have found that the positive ion FAB mass spectrum of α -tocopherol gave an unusual radical cation $M^{+\bullet}$ instead of the expected ion $(M+H)^+$.¹⁾ Recently, similar phenomenon was found in the FAB mass spectrum of ergosterol in 3-nitrobenzyl alcohol (3-NBA) which has been used as a matrix for FAB ionization of relatively low-polar compounds (Fig. 1a). The electron impact (EI) mass spectrum of ergosterol also showed $M^{+\bullet}$ as expected (Fig. 1b). Therefore, a comparison between $M^{+\bullet}$ ions produced by FAB and EI ionization methods was carried out by tandem mass spectrometry (MS/MS) for ionic structure study.

Fig. 2 shows the collisionally activated dissociation (CAD) spectra of $M^{+\bullet}$ ions (m/z 396) in the FAB and EI mass spectra of ergosterol. These two MS/MS spectra are very similar to each other. Furthermore, the MS/MS (CAD) spectrum of $M^{+\bullet}$ in the FAB mass spectrum of ergosterol obtained from an EB/EB type instrument (Fig. 3) well corresponds to the EI mass spectrum of ergosterol (Fig. 1b). Consequently, it must be presumed that the ionic structure of $M^{+\bullet}$ produced by FAB ionization of ergosterol is very similar to that of the corresponding $M^{+\bullet}$ generated by EI ionization. MS/MS spectra of other ions, such as m/z 397, 395, 377, 363 and 337 produced from FAB ionization of ergosterol were also measured to examine the fragmentation pathways of $(M-H)^+$, $M^{+\bullet}$ and $(M+H)^+$ ions.

7-Dehydrocholesterol also showed $M^{+\bullet}$ (m/z 384) in the FAB mass spectrum (Fig. 4). On the other hand, the FAB mass spectra in 3-NBA of cholesterol, desmosterol, fucosterol and cholestanol gave $(M-H)^+$ and $(M+H-H_2O)^+$ as the main peaks. The reason why $M^{+\bullet}$ ions predominate over $(M+H)^+$ and $(M-H)^+$ ions in the FAB mass spectra of ergosterol and 7-dehydrocholesterol must be due to the conjugated double bonds in the B-ring. The MS/MS spectra of $M^{+\bullet}$ ions in the FAB and EI mass spectra of 7-dehydrocholesterol were also very similar to each other.

From the above data, it must be assumed that the precursor ions with the same structure give almost same MS/MS (CAD) spectra, regardless of ionization methods.

**CONTROLLED FRAGMENTATION OF OLIGOSACCHARIDES IN 252CF
PLASMA DESORPTION MASS SPECTROMETRY**

Subhodaya Aduru and Brian T. Chait
The Rockefeller University, New York, NY-10021

The fragmentation of underivatized and derivatized malto-oligosaccharides containing four to seven glucose residues has been studied using positive ion plasma desorption mass spectrometry (PDMS). A rapid and simple method to control the nature and extent of fragmentation of derivatized oligosaccharides and related glycoscompounds has been developed.

Peracetylation of the malto-oligosaccharides was carried out using a 2:1 (v:v) mixture of trifluoroacetic anhydride and acetic acid. Sample preparation for mass spectrometric analysis was done in two ways. 1) By electrospray deposition on to a metallized mylar foil. 2) By adsorption on a nitrocellulose backing. Underivatized malto-oligosaccharides prepared by electrospray deposition gave spectra containing an intense (M+Na)⁺ ion peak and weak fragment ion peaks. Peracetylation of malto-oligosaccharides resulted in a 10 to 100 fold increase in the mass spectral sensitivity compared with that for the underivatized compounds. Peracetylated malto-oligosaccharides prepared by electrospray deposition gave spectra consisting of a very intense quasimolecular (M+Na)⁺ ion and relatively weak sodium containing fragment ions. The spectrum obtained for an unwashed peracetylated maltoheptaose sample containing sodium is shown in figure 1a. A closer look at the fragmentation is presented in figure 2a. The fragmentation pattern is complex and involves many channels and the fragment ion peaks are sharp. Most of the fragments contain one Na. The most intense peaks are identified and marked in figure 2a. When the same sample is gently washed by dipping the sample foil in water the mass spectrum that results is shown in figure 1b. Water washing effectively removes sodium. The spectrum therefore does not show an (M+Na)⁺ ion peak. It is interesting the (M+H)⁺ ion is also absent. At the same time, the fragment ion intensities are enhanced. A closer look at the fragmentation (figure 2b) shows that there are only two fragmentation channels and the fragment ion peaks are broad and metastable. These fragment ions which do not contain sodium are identified and marked in figure 2b.

The results obtained for peracetylated maltoheptaose when prepared by adsorption on a nitrocellulose backing are similar to the above results of the electrospray deposited sample.

We have applied this method to a permethylated and reduced ganglioside Neu.Gc-GM3. The sample with added sodium gave a spectrum consisting predominantly of (M+Na)⁺ and sodium cationized saccharide fragment ions. Water washing removes these ions and enhances the non sodium containing fragment ions.

In summary, this rapid and simple method provides us a means of obtaining mass spectra consisting of either the intense (M+Na)⁺ ion peak or intense fragment ion peaks from the same sample by controlling the amount of sodium in the mass spectrometric sample. We can therefore, selectively enhance either the molecular weight information or fragment ion information from the same sample.

Strategies to Distinguish Carbohydrate Sequence Ions

by

R. Orlando, C. Murphy, and C. Fenselau

Structural Biochemistry Center
Department of Chemistry and Biochemistry
University of Maryland, Baltimore County Campus
Baltimore, Maryland 21227

New strategies for the rapid elucidation of carbohydrates are being developed, in which mass spectrometry and NMR are applied directly to the intact polymer, without recourse to chemical hydrolysis. Molecular weights obtained by mass spectrometry provide information about the complexity of a carbohydrate or glycoconjugate, and also about the heterogeneity of polymer mixtures. Plasma desorption, laser desorption and fast atom/ion bombardment have been used successfully for these purposes (1,2). More detailed structural information should be available from fragment ions, including achiral sequences. Tandem mass spectrometry coupled with collisional activation is expected to provide extensive fragmentation of the mass-selected parent ions. We are evaluating high energy collisional activation for this purpose.

This poster illustrates the use of tandem mass spectrometry for the structural analysis of minor components of mixtures of carbohydrates. Also, the sensitivity of this technique has been demonstrated to exceed 50 picomoles for several compounds. Several regioisomers have been found to be distinguishable from first principles, without the need for standards, see for example figures 1 and 2.

In addition, tandem mass spectra were obtained for both protonated and natriated molecular ions of carbohydrates. The collisionally activated fragmentation of these two species were found to be very different and provided complimentary information, as can be seen by the comparison of figure 3 (natriated) with figure 1 (protonated). It should be noted that these structural isomers can be distinguished in both the protonated and natriated spectra.

Experimental

All spectra were obtained on a JEOL HX 110/110 operated at full accelerating voltage (10 kV). Data were collected by a JEOL DA5000 data system. The FAB gun was operated at 6 kV with Xenon as the FAB gas. Conventional magnetic scans were performed on MS I. The Tandem experiments (MS/MS) were four sector experiments using a collision cell floated at 2 kV between MS I and MS II. Helium was used as the collision gas, with a precursor ion attenuation of 70%. All experiments were performed on positive ions.

Acknowledgement

The authors would like to thank Dr. Alan Bush for providing several of the samples.

LSIMS ANALYSIS OF OLIGOSACCHARIDES AS NEOGLYCOLIPID DERIVATIVES

A.M. Lawson, W. Chai, G. Cashmore, M. Stoll*, E.F. Hounsell* and T. Feizi*; Section of Clinical Mass Spectrometry and *Section of Glycoconjugate Research, MRC Clinical Research Centre, Watford Road, Harrow, Middlesex, HA1 3UJ, UK.

Introduction. The neoglycolipids produced by reductive amination of oligosaccharides with phosphatidylethanolamine dipalmitoyl (PPEADP) have been developed to study oligosaccharide recognition and have been used as solid phase probes in ligand binding assays with antibodies and with carbohydrate binding proteins of plant, animal and microbial origins [1-5].

The object of the present study was to assess the sensitivity of detection and degree of structural information obtainable by LSIMS of neoglycolipids on the conventional target probe and directly from the surface of silica plates following TLC.

Experimental. Neoglycolipids were derived from malto-oligosaccharides, chitin oligomers and a range of deoxyhexose-, hexose- N-acetamidohexose- and sialic acid-containing mammalian oligosaccharides by a procedure described previously [3] and represented in Fig 1. PPEADP conjugates were analysed by a VG Analytical ZAB2-E mass spectrometer (caesium gun: 35keV, 0.5 μ A emission) from the normal target using a DEA/TMU/NBA matrix (2:2:1) or from strips of silica (1.5 x 5mm) cut from the TLC plate together with the aluminium backing foil with addition of solvent (MeOH/CHCl₃/H₂O, 25:25:8) and the DEA/TMU/NBA matrix.

Results. a) Structural Information. Similar spectra were observed in both positive and negative mode but the latter were preferred due to lower background noise. Intense molecular ion species enabled molecular weight to be established and hence saccharide composition, while fragment ions, although of lower relative abundance, gave clear compositional and sequence information. Examples of negative ion spectra of PPEADP conjugates are shown in Fig 2 which are representative of the neoglycolipids studied. In addition to the ion series indicated, and formed with hydrogen rearrangement, were three other series at -18, -2 and +28 daltons to these ions that were confirmatory of saccharide sequence.

b) Sensitivity. Exceptionally high sensitivity was achieved for [M-H]⁻ detection of maltopentaose-PPEADP from the normal target. 100fmol produced a signal (S/N 12:1) from a complete mass scan. However, approximately 5pmol were needed to give clearly defined sequence-determining ions while ionization directly from the TLC silica surface to give fragment ions could be obtained from 50pmol. A biantennary octasaccharide PPEADP derivative required 200pmol for a full spectrum from TLC but gave a [M-H]⁻ ion from 2pmol (S/N 8:1) on the conventional target.

Conclusion. This study has demonstrated the useful structural information that can be obtained with very high sensitivity from neoglycolipids by LSIMS on both normal target and a TLC surface. The ability to provide compositional and sequence data on these oligosaccharide derivatives from a TLC surface permits individual components to be analysed from mixtures of oligosaccharides. This has immediate relevance to studies of oligosaccharide recognition.

Introduction. Human gastrointestinal mucins are large glycoproteins which are thought to act as a defensive barrier of the mucosal epithelium against chemical and bacterial attack. The oligosaccharide structures are also differentiation and tumour associated antigens and hence are of potential use as tissue markers. Pronounced heterogeneity of mucin oligosaccharides, however, makes their structural elucidation difficult and can hinder assignment, particularly of minor components. The present report discusses the identification of oligosaccharides in partially purified fractions using the direct TLC/LSIMS analysis of phosphatidylethanolamine dipalmitoyl (PPEADP) derivatives.

Experimental. Following release by mild alkali/borohydride degradation from mucin glycoproteins, oligosaccharides were purified by Bio-Gel P4 chromatography and HPLC [1,2]. Tri- to hexasaccharide fractions were treated by mild periodate oxidation before conjugation to PPEADP. The reaction products were fractionated on silica TLC plates and then subjected to LSIMS (ZAB2-E mass spectrometer; caesium gun) using a VG Analytical automated TLC target stage. The TLC strip (5 x 75mm) was coated with a DEA/TMU/*m*-NBA (2:2:1) matrix and the target stage driven at 0.25mm/sec over a distance of 60mm with negative ion spectra acquired at 2 sec/decade.

Results. The ion profile of m/z 937 and 997, which represents the $[M-H]^-$ ions of the principal PPEADP derivatives obtained from a trisaccharide from meconium are shown in Fig 1 together with their spectra (scans 58 and 63). Fragment ions from loss of GlcNAc and Gal respectively allowed the carbohydrate branching sequences to be deduced together with the assignment of the core linkage position. These data were obtained by TLC/MS of approximately 2nmol of oligosaccharide and demonstrate the resolution of closely migrating bands and their integrity during analysis. The ion plot (m/z 997 and 1099) shown in Fig 2 was obtained from a tetrasaccharide fraction. The spectra of scans 34 and 64 shown gave fragment ions arising from loss of Gal.GlcNAc and Gal respectively and permitted selected components to be identified. Fig 3 includes the TLC chromatogram of a penta- and hexasaccharide fraction and the TIC output from direct ionization from silica surface. High quality spectra were obtained from all the carbohydrate related bands at scan numbers 22, 28, 40, 51, 64 and 70 which allowed the identification of oligosaccharide sequences. Reagent peaks (scans 96 and 111) were also readily distinguished.

Conclusions. It was possible in combination with the isolation and derivatisation strategy to identify by TLC/MS all the major and many minor components in the oligosaccharide mucin preparations studied. TLC proved to be an excellent means of separating mixtures of PPEADP derivatives and with the automated TLC target stage permitted data to be obtained on complete fractions providing individual spectra of components and the ability to detect the presence of selected oligosaccharides.

ORIGIN OF THE $[M-H]^+$ IONS IN THE FAST ATOM BOMBARDMENT MASS SPECTRA OF SOME CYCLIC SUGARS

Qingmei Zha and Michel J. Bertrand

Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal Canada H3C 3J7

It is well established that FAB ionization of polar compounds usually produces protonated molecular ions $[M+H]^+$. These energetically stable species provide essential information for the determination of molecular mass and identification. It is worth mentioning that any unusual behavior in the generation of FAB mass spectra may cause incorrect assignment of molecular mass and therefore misinterpretation of the spectrum. Recently, considerable interest has been focused on the observations that for certain groups of compounds, the predominant peaks observed in the molecular ion region of positively charged FAB mass spectra are $[M-H]^+$ rather than $[M+H]^+$. This behavior has potential danger in the interpretation of the mass spectra of unknown samples. Two reaction pathways have been proposed to determine the origin of the predominant $[M-H]^+$ ions. It was suggested¹ that this phenomenon is a result of the transfer of redox equivalents between neutral molecular species during the bombardment desorption event, namely, the net loss of H $\cdot$ would result in the formation of $[M-H]^+$, or of the hydride abstraction from molecular ion, similar to that observed in gas-phase chemical ionization occurring from the hydrocarbon chain remote from the oxygen in long chain ethers².

To investigate the origin of $[M-H]^+$ ions formed in fast atom bombardment and to elucidate its reaction mechanism, derivatized cyclic sugars methyl-2,3,5-tris-O-benzyl-D-ribofuranose (1), S-phenyl-2-deoxy-3-O-methyl-5-O-benzyl-D-ribofuranose (2) and methyl-2,3-di-O-benzyl-erthiofuranose (3) were studied by FAB mass spectrometry. Gas-phase chemical ionization (CI) was also performed to compare with the FAB data. Positively charged FAB mass spectra of compounds 1-3 using thioglycerol as matrix are shown in Figure 1. These spectra can be characterized by: I) the predominant peaks observed in the molecular ion region for these compounds are $[M-H]^+$ rather than $[M+H]^+$, and the peak intensity of $[M+H]^+$ is very weak compared to that of $[M-H]^+$, II) besides the sodium adduct $[M+Na]^+$, there is also a unique adduct ion that can be observed at $[M+13]^+$, and III) the abundances of the parent-molecular and adduct ions are relatively low in comparison with those of fragment ions. Pertinent sections of the FAB mass spectra of these samples which detail the mass region of the molecular ion and adduct ions are shown in Figure 2. The CI (isobutane) mass spectra of the sugar derivatives also gave predominant $[M-H]^+$ ions except for compound 3 which showed abundant peaks at $[M-H]^+$ and $[M+H]^+$. However, no detectable adduct ion of $[M+13]^+$ was observed in CI.

Relative abundances for peaks at $[M-H]^+$, M^+ and $[M+H]^+$ are listed in Table I and are compared with theoretically calculated isotopic distributions. In the FAB mode, the observed ratios of $[M-H]^+/M^+$ are very close to theoretical predictions. This seems to indicate that the M^+ ions are mostly due to isotopic contributions and that there is almost no molecular ion M^+ formed in our experiments. The residual abundances of $[M+H]^+$ ion are very low after subtracting isotopic contributions to this peak. This would imply that the formation of $[M-H]^+$ in the FAB spectra of these cyclic sugars is highly favored to the expense of $[M+H]^+$. An important feature which reveals the differences between FAB and CI regarding the formation of $[M-H]^+$ is obtained from the fragment ions. An isobutane CI spectrum of compound 1 is shown in Figure 3 where a peak at m/z 107 corresponding to benzyloxy ion $C_6H_5CH_2O^+$ is observed. In the FAB spectrum of this compound, the fragment at m/z 107 appears to be replaced by an ion at m/z 105. This peak at m/z 105 is observed in the FAB spectra of all compounds using glycerol, thioglycerol or in the absence of a matrix and is not formed via m/z 107 as demonstrated by MIKES experiments. A plausible assignment for the peak at m/z 105 would be the benzoyl ion $C_6H_5CO^+$ whose formation obviously involves rearrangement-dissociation processes.

The results described above indicate that the ether linkage in the side chain of derivatized cyclic sugars may be the source for the rearrangement-dissociation observed under FAB conditions. Furthermore, the ether oxygen which provides a site for protonation may also be significant in bringing about the formation of predominant $[M-H]^+$ ions. The formation of $[M-H]^+$ is not a simple hydride abstraction process but is a result of a protonation induced process. The molecular ions are firstly protonated under FAB conditions and the protonated molecular ions, being very unstable, rearrange immediately to form $[M-H]^+$ ions by loss of two hydrogens. That is why the $[M+H]^+$ peak is

very weak and $[M-H]^+$ is the predominant ion in the FAB mass spectra of these compounds. This proposal may also apply to the formation of $[M+13]^+$, which is observed in the FAB spectra of these cyclic sugars with or without matrix. In this case, the attachment of a methyl CH_3 group to the molecule followed by the loss of two hydrogens can explain the formation of $[M+13]^+$, or more precisely, of $[M+15-2H]^+$.

Heparin, a polydisperse, sulfated polysaccharide of 1 $\rightarrow$ 3 linked glucosamine and uronic acid residues, has been used clinically as an anticoagulant for half a century, yet the exact chemical structure of heparin remains unclear.¹ The sequence of the polysaccharide chains comprising glycosaminoglycan (GAG)-heparin is of considerable interest (as this is heparin's drug form), thus heparin lyase is used to enzymatically depolymerize GAG-heparin into smaller oligosaccharides more suitable for structural analysis.

Reinhold and Green, et al., reported on the negative ion FAB-MS analysis of heparin-like oligosaccharides prepared by chemical synthesis.² The dominant molecular ions observed were of the type $[M + Na_x - H_{x+1}]^-$ (where M is the fully protonated, acid form of the oligosaccharide and x = 2-9) and in all cases the observed spectra contained little or no structurally significant fragment ions.²

The studies reported here were performed using a VG ZAB-HF, in the fast atom bombardment (FAB) ionization mode. Negative ion spectra were obtained using triethanolamine as the negative ion FAB matrix. Sequence specific fragment ions, of these highly sulfated enzymatically prepared (from porcine lung heparin) oligosaccharides, were observed. For example, the negative ion FAB-MS spectrum and structure of a heparin derived tetrasaccharide, TS-I, is shown in Figure 1. The molecular ion is observed at m/z 1205 and corresponds to a sodiated adduct ion of the type $[M+6Na-7H]^-$. The ion at m/z 923 is assigned as loss of the sugar residue from the nonreducing terminus of TS-I, whereas the ion at m/z 840 is assigned to loss of the sugar residue from the reducing terminus of TS-I. The ion at m/z 642 is the result of loss of two sugar residues nearest the reducing end of TS-I.

The utility of this technique is clearly dependent on the ability to aid in the prediction of unknown sample structures. The structure of hexasaccharide HS-II (Figure 2), isolated from a partial enzymatic depolymerization of bovine-lung heparin was determined, and confirmed by NMR experimentation, through the use of this mass spectral technique.³

**PORPHYRIN PYRROLE SEQUENCING BY LOW ENERGY
COLLISION INDUCED DISSOCIATION OF (M+7H)⁺ GENERATED
IN SITU DURING AMMONIA CHEMICAL IONIZATION**

G. J. Van Berkel¹, A. A. Tuinman², G. L. Glish¹, and S. A. McLuckey¹

¹Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831

²Department of Chemistry, University of Tennessee
Knoxville, TN 37996

High pressure NH₃ CI-MS promotes *in situ* reduction and decomposition of the porphyrin macrocycle producing a relatively complex pattern of mono-, di-, and tripyrrolic fragment ions that can be used, in principle, to determine the pyrrole sequence of the porphyrin (1). The CI mass spectra are complicated, however, by a plethora of peaks, most of which are not structurally informative (Figure 1a). A prominent peak in the CI mass spectrum is (M+7H)⁺, the reduced porphyrin species produced *in situ*. We have shown that high energy CID of (M+7H)⁺ on a BE geometry instrument produces a structurally informative daughter ion spectrum (2,3). The utility of such spectra is limited, however, because of poor daughter ion resolution and fragmentation of substituent groups from the individual pyrrolic units.

Low energy CID (30-100 eV (lab), argon target gas at 2 x 10⁻⁴ torr) of (M+7H)⁺, using a hybrid mass spectrometer of BEQQ geometry (VG-ZAB-EQ at the University of Tennessee), was found to yield simple, reproducible patterns of unit mass resolved daughter ions from which the mass of the pyrroles and pyrrole sequence of the porphyrin could be readily determined.

In contrast to the CI mass spectrum, the CID spectra of (M+7H)⁺ contain relatively few peaks, all of which are structurally significant (Figure 1b). Mono-, di-, and tripyrrolic daughter ions are observed and can be distinguished based on peak patterns and the nitrogen rule: monopyrroles occur as peak "triplets" of even mass, dipyrroles occur as peak "quadruplets" of odd mass, and tripyrroles occur as peak "quadruplets" of even mass. Fragmentation of the substituent groups on the individual pyrrolic units is observed in the 100 eV CID spectrum. The 70 eV CID spectrum contains all the daughter ions necessary to determine the mass of the individual pyrroles and deduce the pyrrole sequence of the porphyrin. The monopyrroles are of low abundance or not observed in the 30 eV CID spectrum.

The utility of the CI-MS/MS technique for pyrrole sequencing is best illustrated by the analysis of porphyrins with an asymmetrical pyrrole sequence. The CI mass spectra of porphyrins of this type are extremely complex and virtually impossible to interpret (Figure 2a). In contrast, the CID spectrum of (M+7H)⁺ from such a porphyrin is relatively simple and easy to interpret (Figure 2b).

A further advantage of the CI-MS/MS technique is the capability to pyrrole sequence porphyrins within a simple mixture of non-isobaric porphyrins. In such a case the EI mass spectrum is used to determine the molecular weight of the individual components present in the mixture. Ammonia CI of the mixture produces abundant (M+7H)⁺ from each of the porphyrins present (Figure 3a). The 70 eV CID spectrum from each of the (M+7H)⁺ species in the mixture (Figure 3b) is identical to the CID spectrum of (M+7H)⁺ acquired when analyzing the respective pure compounds.

class of compounds, wastes are created and discarded as wastewater and solid residues. Azo dyes are made by the classical diazotization reaction, followed by coupling of the diazonium cation with reactive aromatic compounds. In recent years a number of azo dyes have been removed

from the list of substances approved for use in foods, drugs, and cosmetics, and a number of others are under study in regard to potential adverse health effects. In addition, azo dyes can be reduced in the environment and in vivo to produce amines that are known carcinogens.

WHERE RA = various organic and inorganic reagents
= anaerobic bacteria (sediments, flooded soil, landfills)
= reducing enzymes, intestinal bacteria, etc.

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

Azo dyes of particular concern are the water soluble Acid and Direct dyes that contain aromatic amine residues that are known or suspected carcinogens. Wastes from the manufacture and use of azo dyes present two

CARCINOGENS (SUBSTANTIAL EVIDENCE)	POSSIBLE HUMAN CARCINOGENS
benzidine	aniline
3,3'-dichlorobenzidine	4-chloro-2-methylaniline
3,3'-dimethoxybenzidine	2,4-dimethylaniline
3,3-dimethylbenzidine	2-methoxy-5-nitroaniline
4-(dimethylamino)azobenzene	2-methylaniline (probable)
1-naphthylamine	2-methyl-5-nitroaniline (mice)
2-naphthylamine	1-amino-2-naphthol

challenging and important analytical problems: (1) the determination of carcinogenic and suspected carcinogenic aromatic amines; and, (2) the determination of azo dyes in environmental samples.

The mass spectrometry of azo dyes has been investigated in recent years using some of the newly developed sample introduction and ionization techniques. Capillary column gas chromatography/mass spectrometry is applicable to certain azo dyes used in the petroleum industry (1). The separation and measurement of some water insoluble disperse azo dyes using liquid chromatography/thermospray/mass spectrometry has been studied (2,3). The desorption ionization spectra (SIMS) of several azo dyes have been reported (4). A liquid chromatography/ion spray/atmospheric pressure ionization (API)/negative ion mass spectrometry method for the determination of the acid soluble sulfonated azo dyes in environmental samples has been developed (5). And capillary zone electrophoresis (CZE) has been used in connection with the ion spray/negative ion API mass spectrometric method for acid azodyes (6).

POSSIBLE WIDESPREAD ENVIRONMENTAL CONTAMINATION BY BROMO AND
BROMOCHLORO DIOXINS AND DIBENZOFURANS

G. Wayne Sovocool and Joseph R. Donnelly,* US EPA, EMSL-LV, P.O.
Box 93478, Las Vegas, NV 89193-3478 and Lockheed-ESC, 1050 E.
Flamingo Rd., Suite 120, Las Vegas, NV.

Major sources for brominated compounds in the environment may be the bromine containing flame retardant additives in plastics and combustion products of the plastic formulations, and the bromination, *in situ*, of materials during the combustion process. Plastics are ubiquitous in the environment because of their versatility, durability, and low cost. Many products were formerly made from such materials as wood, paper, metals, glass and ceramics. By volume used, plastics now exceed the amount of steel used in the United States. Plastic resin production has increased from 6.3 billion pounds annually in 1960 to 57 billion pounds in 1988. As the development, use, and availability of these materials to consumers have increased so have the rate and quantity of plastic articles entering the municipal solid waste stream also increased: from 800 million pounds in 1960 to 20.6 billion pounds in 1986. In 1960, plastics made up less than one percent by weight of the total waste stream, increasing to more than seven percent in 1986, with a projected rise to nine percent by the year 2000. Most plastic products degrade very slowly in the environment because they are in general biologically and chemically stable. Until recently, plastics waste was not seen as a threat to the environment.

Disposal of municipal solid waste has become an issue of increasing importance in the United States. The infamous 1987 voyage of the garbage barge from the town of Islip, New York, focused national attention on the difficulty encountered in disposing of municipal solid waste. Some major cities have run out of landfill capacity and must ship their wastes to remote sites at great cost. Incineration and subsequent landfilling of residues (fly ash, bottom ash) provide increased capacity for disposal of plastics and other solid waste. However, the environmental impacts of the residues and stack emissions, must be controlled. Leaching of potentially harmful chemicals is the other major pathway of concern for environmental release of plastics or plastic additives from landfills. Additives to plastics are used to provide enhanced strength, stability, color, resistance to fire, etc. Fiberglass, dyes, and other materials may be added for strength, color, or other commercially desirable properties. At least 36 million pounds of brominated flame retardants are used per year in the U.S. It is expected that plasticizers, flame retardants and other additives have the greatest probability of leaching from plastic products.

Brominated flame retardants such as polybromodiphenylethers (PBDPE) are routinely added to a variety of commercial products such as carpets, textiles, and plastics. Typical plastic resins into which PBDPE are blended include polyethylene terephthalate (PET), polybutylene terephthalate (PBT), high-impact polystyrene (HIPS) and acrylonitrile-butadiene-styrene (ABS). Generally 5-20% of flame retardant by weight is added to the plastic resin.

Concerns exist regarding the possibility of environmental contamination by polybrominated dibenzofurans (PBDF) from such formulations, either as a result of impure starting materials or

from reaction of the PBDPE during the extrusion processes, or upon other thermal processes including fires. We recently completed a study which determined that detectable levels of brominated furans were present in some typical commercial polymer products, prepared by heat extrusion manufacturing processes, and containing brominated diphenyl ether flame retardants. A pyrolysate of a PBT resin was found to contain PBDF and PBDD. Parts per billion (ppb) levels of PBDF were formed in the flame retardant materials and significantly higher levels of PBDF and PBDD formation were found in the pyrolysate of a PBT resin. A fume sample taken during resin extrusion was also analyzed and was found to contain low levels of PBDF. Thus, the possibility exists that manufacturing plant workers could be exposed to brominated flame retardants and PBDF by inhalation. The analytical methodology used for this study was based upon existing EPA methodology for chlorinated dioxins and dibenzofurans, RCRA method 8280 and CERCLA method IFB-WA84-A002. Modifications to these methods were made for extraction of analytes from the resin matrices and for GC/MS monitoring of the brominated analytes. The GC retention indices of PBDF and PBDPE are shown in Fig. 1. The GC separation of PBDF analytes from residual PBDPE interferences was important for confirmation of the PBDF because of their similar mass spectra with overlapping ion clusters.

Municipal incinerators have been extensively investigated as a source of chlorinated dioxins and furans. Our findings indicate that brominated polycyclic aromatic hydrocarbons (PAH) dioxins and dibenzofurans are also produced, usually as monobromopolychloro species. These cross-halogenated analytes were found at much lower concentration than the chlorinated species. Presumably, the flame retardants which are widespread among various domestic products serve as a major source of bromine during the incineration process. The negative ion chemical ionization (NCI) mass chromatogram of a fly ash extract for Br⁻ is shown in Fig. 2.

"Fluff" is the ground-up waste residue from junked cars and consumer appliances remaining after the bulk metals have been reclaimed. Three million tons of this waste are produced annually. Initial analysis of fluff extracts has shown the presence of polychlorinated biphenyls (PCB), other chlorinated aromatics such as naphthalenes and terphenyls, and brominated flame retardants in this highly complex matrix. We also initiated a leaching study to assist in determining whether land disposal of fluff is a potential source of environmentally significant compounds in ground water. Preliminary results indicate that significant levels of organics do leach from fluff.

Investigations of incinerator fly ash, of plastics which are also potential feedstocks for municipal incinerators and of the organic waste, "fluff", have shown a commonality in that brominated compounds including bromofurans and dioxins can be introduced into the environment by a variety of processes in general use today.

Tributyltin; good for antifouling paint, not so good for oysters

J. Greaves
Virginia Institute of Marine Science
College of William and Mary
Gloucester Point, VA 23062

The organotins are a family of compounds that have found wide application in the chemical industry. Their uses include being intermediates in organic synthesis, heat and light stabilizers for PVC, and as biocides. It is this last use that has been implicated in environmental problems. The toxicity of the biocides is dependent on the number and nature of the substituent groups with the tri-substituted state being the most toxic. Trialkyltins (R_3SnX , where, typically, R = alkyl or phenyl and X = halide, -OH, -OSnR₃, or a polymer) have been used as preservatives for wood, textiles, leather and paper because of their activity as biocides against molluscs, bacteria, algae, insects and arachnids. The inclusion of TBT in marine antifouling paints has been the application with significant environmental impact. TBT in antifouling paint occurs either in free association where the TBT is mixed with the paint or covalently linked to the polymeric backbone of the paint. In both cases it is the leaching of the TBT, probably as TBT⁺, that provides the biocidal activity. TBT containing paints were introduced in the 1960s and their use increased until, by 1985, approximately 30-50% of vessels were painted with these paints.

Toxic effects of TBT have been reported for many species. Among the most obvious, and commercially serious, are the shell deformation of the oyster Crassostrea virginica and the induction of imposex in the dogwhelk Nucella lapillus. These effects occur at submicrogram/liter TBT concentrations. In oysters the shell becomes laminated and the organism becomes round or "balled" resulting in little space remaining for the soft tissues. In the dogwhelk the female develops a penis and vas deferens. The formation of the latter eventually closes off the oviduct thus preventing the reproduction of the affected individuals and populations.

The demonstrated link between environmental problems and TBT has led to the need to monitor the occurrence and behavior of TBT and its breakdown products dibutyltin (DBT) and monobutyltin (MBT) in the environment. Because of the low concentrations at which toxicity is encountered, analytical methodologies are required that measure TBT at the ng/L level in water and at the ug/kg level in sediments and biota. Capillary GC with flame photometric detection (FPD) and GC-MS are methods used at the Virginia Institute of Marine Science (VIMS). The GC-FPD uses a >600 nm pass filter to provide the needed specificity. GC-MS is by both full scanning and SIM with positive chemical ionisation (PCI). Preparation of aqueous samples is by extraction with hexane containing 0.2% tropolone. Sediments and biota are chemically dried and Soxhlet extracted with hexane. After volume reduction the sample is derivatised with hexyl magnesium bromide to form tetraalkyltins which are then cleaned up on a Florisil column. Triphenyltin chloride, which is added prior to extraction, is the internal standard. Extraction efficiencies from water for this method were TBT > 90%, DBT ~ 55% and MBT ~ 33%. The lower efficiencies for DBT and MBT are a result of the increased polarity of these compounds. Other laboratories which utilize GC or GC-MS are using similar techniques with variations such as tripropyltin chloride as the internal standard and derivatisation with pentyl magnesium bromide to form the pentyl derivatives. When atomic absorption is the analytical technique, hydride formation is the normal derivatisation technique.

The PCI mass spectra of the tetraalkyltins are dominated by the loss of an alkyl group. For hexylTBT this gives ion clusters around m/z 319 and m/z 291. These correspond to the loss of a butyl group and a hexyl group, respectively. The reason for the ion clusters is that tin has multiple isotopes, the most common of which have masses of 116 (14%

frequency), 118 (24%) and 120 (33%). There are seven other isotopes with frequencies of up to 9%. There is no quasimolecular ion, and the fragmentation favors the loss of the heaviest alkyl group. PCI with full scanning is the method of choice for confirmation of the identities of TBT and its derivatives in environmental samples. EI spectra show progressive removal of the alkyl groups until an $[\text{SnH}]^+$ ion is formed. There is no molecular ion. FAB-MS gives spectra that are the same as those obtained in PCI; again there is no molecular ion. The isotope clusters are useful for searching for organotin in complex mixtures such as environmental samples. The limited fragmentation in PCI means that there are ions of relatively high mass that are suitable for SIM, m/z 319 is used for monitoring TBT and DBT, and m/z 347 is used for DBT, MBT and the internal standard, triphenyltin. The two assay methods, GC-FPD and PCI GC-MS SIM have been compared using environmental samples. The results of the two techniques were directly comparable.

VIMS has monitored occurrence of TBT in the water column at a number of locations over the last four years and has surveyed the southern portion of the Chesapeake Bay for TBT in oysters and sediment. In addition, samples have been submitted from other parts of the country for analysis. TBT contamination is correlated with proximity to marinas and shipyards. Concentrations found were up to 1300 ng/L, well above those required for toxic effects. In the marinas it was noted that there were peaks in mean TBT concentrations in late spring and to a lesser extent in the fall. This corresponds to the times of year when recreational boats are painted and thus when there are highest inputs of TBT into the environment. Rapid fluctuations of TBT concentrations in marinas have been observed with concentrations varying by as much as an order of magnitude over a 1 week period. Reasons for this variation include factors such as tidal flushing and inputs from freshly painted boats. Multiple sampling is therefore required so that trends can be analysed.

In general, sediment concentrations are 10^3 greater than those of the surrounding water reaching up to 4000 ug/kg at ship repair facilities. This means that the sediments are acting as a sink for the TBT. It remains to be determined whether, as fresh inputs of TBT are reduced, the sediment will become a source of future contamination of the water column.

TBT has been found in all areas from which oysters have been obtained and tested. These areas include the Elizabeth, James, York and Rappahannock rivers and various stations on the Delmarva peninsula, both the bay and ocean sides. Concentrations encountered were up to 5600 ug/kg (dry wt.). Bioconcentration factors were of the order of 10^5 . TBT was encountered in oysters even in areas where it could not be found in the sediments.

In 1988 the use of TBT in antifouling paints was restricted. It was banned for vessels under 25 m, except for those with aluminum hulls. Its use on larger vessels is permitted provided that the leaching rate of the TBT is < 4 ug TBT/cm²/day. This should reduce the amount of TBT in the water, particularly around marinas, that is derived from recreational vessels over the next 2-3 years as vessels are repainted. There are, however, other sources to consider. In addition to the desorption of TBT from sediments mentioned above, a major source of TBT may be the paint chips that are scraped from vessels. In addition, the widespread use of organotins in applications other than antifouling paint and the low concentrations at which toxicity is encountered means that there is a need to be aware of these compounds as potential environmental contaminants in the future.

The tributyltin (TBT) project at VIMS has involved many individuals whose efforts must be acknowledged. These include Mike Unger, Bill MacIntyre, Francois Espourteille, Charles Rice, Donna Westbrook, Ellen Travelstead and Bob Huggett. In addition, though this brief review has been concentrated on the work conducted at VIMS, it is inevitable that

the work of other researchers has been mentioned. Below is given a list of references which the interested reader may wish to consult.

THE ROLE OF MASS SPECTROMETRY IN THE ANALYSIS OF EXPLOSIVES

Scott A. McLuckey and Gary L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-8121

Mass spectrometry, with its wide applicability, high specificity, and high sensitivity, has played, and will continue to play, an important role in the analysis of explosives. In addition to the fundamental study of the reactions that occur during an explosion, the analysis of explosives is important in environmental, clinical, forensic, and security applications. Explosives are of environmental concern at munitions facilities where the storage and manufacture of explosives has led to contamination of soil and water. Adverse physiological effects due to exposure to many of the commonly encountered organic high explosives has been documented making the analysis of explosives and their metabolites important in a clinical setting, particularly for munitions workers. The importance of explosives analysis in forensic investigations, such as the analysis of post-explosion debris, has long been recognized. And finally, the detection of hidden explosives for security applications has become a pressing problem since the bomb is now the terrorist's weapon of choice. Mass spectrometry has been employed in all of these areas. The mass spectrometry of explosives up through the early 1980s has been thoroughly reviewed [1,2]. This paper selectively reviews work described in the last seven years to illustrate recent applications of mass spectrometry in the analysis areas mentioned above with particular emphasis on LC/MS and MS/MS studies.

Table 1 shows some of the commonly encountered organic high explosives. Most high explosives in current and past use fall into one (or perhaps, two) of three compound classes, viz. nitroaromatics, nitrate esters, and nitramines. The most common nitroaromatics are 2,4,6-trinitrotoluene (TNT) and 2,4-dinitrotoluene (DNT). The latter is frequently found as a contaminant in TNT and is often used as a sensitizer in smokeless powders. Nitrate esters, such as nitroglycerine (NG), are widely used in dynamites. Pentaerythritol tetranitrate (PETN) is commonly used in plastic explosives. The most commonly encountered nitramines are the heterocyclic nitramines RDX and HMX which are used in military explosives. It is important for explosives analysis that many of these compounds (e.g. PETN, RDX, HMX, and to a lesser degree, TNT) are involatile, thermally labile, and strongly adhere to surfaces. These properties can pose problems both in sampling from a matrix and in the introduction of the sample to the mass spectrometer ion source.

Results have been reported in explosives analyses using a wide variety of ionization methods. These include electron ionization, field ionization, field desorption, low pressure electron capture, high pressure electron capture, chemical ionization (both positive and negative), atmospheric pressure ionization (both positive and negative), and thermospray. One clear observation in surveying these results is the wide variety of different explosives-related ions that have been reported. Even when using the same nominal form of ionization, mass spectra are frequently not well reproduced between laboratories. This is due to a number of factors. Among these is the fact that many explosives readily fragment under collision-free conditions and the mass spectra can be very sensitive to temperature and electron energy. Another factor is that the highly polar explosives tend to form complexes under conditions where third body collisions can occur. This makes the mass spectra highly dependent upon the gaseous matrix in the ionization region. Different approaches to ionization employ different pressures, temperatures, residence times, reagent species, etc. The point here is that the literature is useful only as a guide as to what ions might be expected in the application of a new approach to ionization. However, if the new approach does not closely resemble the conditions used in other approaches, completely different explosives ions may be observed.

GC/MS is frequently used in explosives analyses and in many applications is clearly the method of choice, particularly for the volatile and semi-volatile explosives. A recent example has been described by Fetterolf et al. [3] where GC/MS using electron capture ionization was applied to the detection of firearms discharge residue (principally NG). However, HPLC is a more appropriate means for separating the less volatile explosives, particularly when they are present in water and biological fluids. Indeed, HPLC has been used extensively in explosives analyses with one of a variety of detectors. The relative strengths of mass spectrometry as a detector are obvious but only relatively recently has HPLC/MS been applied to explosives. The LC/MS interface has been a limiting factor in the sensitivity of this approach.

Early examples of HPLC/MS of some explosives involved the use of direct liquid introduction into the ion source [4,5]. For example, Yinon et al. [4] reported the HPLC/MS of TNT using methanol positive chemical ionization. The sensitivity of the approach, however, was limited by the fact that only 1% of the effluent could be directed into the ion source. A sample size of 1-10 µg injected onto the column was required. More recently, these same workers have shown improved performance using direct liquid introduction by using a micro-bore column [6,7]. The results were demonstrated with this system via application to TNT metabolites in body fluids of animals and humans.

Thermospray (TSP) has become a leading LC/MS interface and has recently been applied to the analysis of explosives [8,9]. For example, Berberich et al. [9] have analyzed the negative ions formed from a variety of low volatility explosives by HPLC TSP/MS in the filament on, filament off, and discharge modes. Detection limits at the picogram level were demonstrated. These results constitute the best limits of detection published thus far for explosives analysis by HPLC/MS.

MS/MS has also recently been applied to explosives analysis. One use for MS/MS is to obtain a better understanding of the unimolecular chemistry of the explosives related ions than can be obtained from a single stage of MS alone. MS/MS can provide parent-daughter ion relationships and information regarding the mechanisms for decomposition is often revealed by kinetic energy analysis of the fragment ions. Further information can sometimes be obtained by the use of labelled parent ions. For example, Carper et al. have acquired MIKE/CID spectra for the molecular cations of several labelled versions of TNT [10]. Yinon et al. [11] and our group [12] have also reported MIKE/CID data for a variety of explosives related ions formed by several ionization methods.

We have also studied the mechanisms for several of the commonly observed fragmentations of the nitroaromatic anions using MS/MS. For example, we have reported on the mechanism for the "ortho effect" loss of OH⁻ from nitroaromatic cations and anions [13] and have rationalized why some anions do not lose OH⁻ while the corresponding cations do. We have also discussed the loss of NO⁻ from nitroaromatic anions [14], the structures of the ions resulting from NO⁻ loss [15], and substituent effects in the CID spectra of nitroaromatic anions [16].

Perhaps the most important application for MS/MS in explosives analysis is in the detection of vapors of hidden explosives. This is a targeted compound analysis problem that requires speed, sensitivity, and specificity. A number of mass spectrometric approaches have been applied to explosives vapor detection but the most successful have employed some sort of direct air sampling ion source and MS/MS [17,18]. We have developed an atmospheric sampling glow discharge ionization source [19] which is well-suited to ionizing explosives in air. We have coupled this ion source to a quadrupole/time-of-flight instrument [20] and, more recently, to a Finnigan ion trap mass spectrometer [21]. We have demonstrated sub-picogram detection limits for explosives with these devices. The discharge source/ion trap

combination is still in an early stage of development. We therefore anticipate that explosives vapor detection via MS/MS will reach higher levels of performance.

IDENTIFICATION AND DETERMINATION OF *TERT*-ALKYLPHENOLS IN CARP FROM THE TRENTON CHANNEL OF THE DETROIT RIVER, MICHIGAN, U.S.A.

Hiroaki Shiraishi, Donna S. Carter, and Ronald A. Hites*, School of Public and Environmental Affairs and Department of Chemistry, Indiana University, Bloomington, IN 47405

Introduction. We have previously reported on the analyses of four major classes of organic contaminants (polycyclic aromatic hydrocarbons, polychlorobiphenyls, polychloronaphthalenes, and polychloroterphenyls) in sediments of the Trenton Channel of the Detroit River (1). The purpose of the present study is to identify previously unrecognized pollutants in fish from the Trenton Channel and to compare these levels to those of nearby sediments. Since the most polluted site is located near the middle of the Channel, carp and surface sediment samples were taken from the north, the middle (near Monguagon Creek), and the south of the Trenton Channel and analyzed by gas chromatographic mass spectrometry (GC/MS).

Experimental. Fish were sampled in the fall of 1985 by electro-shocking. Whole carp were ground with a clean, commercial meat grinder. Four carp from the same location were combined into composites, which were stored in clean glass containers and frozen until analysis. A single surface sediment sample was collected at the middle and south fish sampling sites using a Ponar grab sampler. Sediment samples were homogenized and stored in clean glass jars at 4° C.

A thawed aliquot of ground carp (about 15 g) was mixed with pre-extracted Na₂SO₄ anhydrate until a powdery texture was obtained. This mixture was placed in a pre-extracted cellulose thimble. The mixture was Soxhlet extracted for 24 hours with 250 ml of a 1:1 solution of hexane and acetone. The final extract was concentrated by rotary evaporation and made up to 10 ml with hexane. Known amounts of d₂₁-2,4-di-*tert*-butylphenol and d₁₃-4-*tert*-butylphenol were added to 5 ml of this hexane solution for use as internal standards.

Gel permeation chromatography was used to separate the lipids from the low molecular weight, anthropogenic, chemicals (2). Fish extracts containing less than 500 mg of fat were loaded onto a Biobeads SX-2 (200-600 mesh) column (2.5 cm i.d. x 35 cm) and eluted with a 3:2 mixture of cyclohexane and dichloromethane at a flow rate of 4 ml/min using a FMI pump. An UV flow detector (Alltec) operating at 254 nm was used to differentiate between the lipids and anthropogenic chemicals. Lipids appeared in the first 130 ml of eluate which were not collected; the subsequent 80 ml, containing the anthropogenic compounds, were collected. The fractions were concentrated by rotary evaporation and chromatographed into two fractions on a silica gel column using dichloromethane and methanol as eluants.

Sediments were homogenized by stirring, and an aliquot was removed for percent water determination. Another aliquot was mixed with clean, anhydrous Na₂SO₄ to absorb sediment pore water. Samples were spiked with known amounts of the internal standards. Each sample was Soxhlet extracted for 24 hours with isopropanol, followed by dichloromethane for an additional 24 hours. Sample volumes were reduced by rotary evaporation, combined, and solvent-exchanged to hexane. Combined, hexane-exchanged extracts were chromatographed on columns containing 20 grams of 1% deactivated silica-gel, with HCl-rinsed copper at the bottom to adsorb elemental sulfur and a Na₂SO₄ "cap" at the top to absorb residual water. Samples were charged to the column in 3 ml of hexane and eluted sequentially with 45 ml of hexane, 45 ml of 10% dichloromethane in hexane, 45 ml of dichloromethane, and 45 ml of methanol. All fractions were collected separately, but prior to analysis, all fractions except the methanol were combined.

The identification of new pollutants was based on their electron impact mass spectra obtained on a Hewlett Packard 5995 GC/MS system, operating at an ion source temperature of 250°C. The temperature of both the GC injector and the transfer line was 280°C. A DB-5 fused silica column (30 m x 0.25 mm, J & W Scientific, CA) was used with He as the carrier gas. Quantification of the alkyl phenols was done using selected ion monitoring; the most abundant ions were used for quantification, and the second most abundant ions were used for confirmation.

Results and Discussion. PCBs and chlorinated pesticides, such as chlordane, were plentiful in fish from all three sites. This is not surprising; contamination of the Detroit River by organochlorine compounds is well documented (3-6). There were, however, several compounds which were not abundant in the fish sampled from the north and south of the Trenton Channel but were in those sampled from the middle site.

Figure 1. Mass spectra (and GC retention indexes) of *tert*-alkylphenols found in the Trenton Channel. A: 2-*tert*-pentylphenol (1360), B: 2-chloro-6-*tert*-pentylphenol (1376), C: 4-chloro-2-*tert*-pentylphenol (1574), D: 2,4-dichloro-6-*tert*-pentylphenol (1546), E: 4-*tert*-pentylphenol (1394), F: 2-chloro-4-*tert*-pentylphenol (1417), G: 2,6-dichloro-4-*tert*-pentylphenol (1622), H: 4-*tert*-butyl-2-*tert*-pentylphenol (1588), I: 2-chloro-4-*tert*-butyl-6-*tert*-pentylphenol (1614), J: 2,4-di-*tert*-pentylphenol (1681), K: 2-chloro-4,6-di-*tert*-pentylphenol (1703), L: 2-*tert*-butyl-4-*tert*-pentylphenol (1600), M: 2-chloro-6-*tert*-butyl-4-*tert*-pentylphenol (1625), N: 2,4,6-tri-*tert*-pentylphenol (1815), O: 2,2'-dihydroxy-3,3',5,5'-tetra-*tert*-pentylbiphenyl (2641).

The electron impact mass spectra of these compounds resembled each other; they are shown in Figures 1A to 1O. (The figure caption also gives their GC retention indexes.) $(M-C_2H_5)^+$ fragment ions were always very abundant. The spectra also showed fragment ions due to the loss of C_2H_4 from the $(M-C_2H_5)^+$ ion. Elemental compositions of the fragment ions were confirmed by high resolution mass

spectrometry on a Kratos MS-80 mass spectrometer. The $(M-C_2H_5-C_2H_4)^+$ ion was shown to result from two sequential losses by tandem mass spectrometry on a VG 30-250 triple quadrupole instrument operating in the parent and daughter ion modes. We suggest that these ions are formed by the route given in Scheme 1. These $(M-C_2H_5-C_2H_4)^+$ ions were of high to medium abundance when only one *tert*-pentyl group was present in the molecule (see Figures 1A to 1G). This ion was very abundant in the spectrum when the *tert*-pentyl group was substituted at the ortho-position (see Figures 1A to 1D); this is true regardless of the position and number of chlorine substitutes. The $(M-C_2H_5-C_2H_4)^+$ ion is much smaller or even missing when two alkyl groups are present (see Figures 1H to 1M); if it is of modest abundance when a *tert*-pentyl group is in the ortho-position but missing otherwise. Presumably, the presence of more than one alkyl group increases the abundance of ions due to losses, such as $(M-C_2H_5)^+$ and $(M-CH_3)^+$, relative to the $(M-C_2H_5-C_2H_4)^+$ ions. In effect, this suppresses the latter ion, in some cases, rather dramatically. Note that when there are three or more alkyl groups, the $(M-C_2H_5-C_2H_4)^+$ ion is not present at all (see Figures 1N and 1O).

With a few exceptions, the compounds identified here are not commercially available. Thus, these compounds were synthesized, and the identifications discussed above were confirmed by comparison of GC retention times and mass spectra. The concentration of 24DP in the middle fish was 140 ug/g fat; in the middle sediment it was 130 ng/g dry. 4P was 40 ug/g fat in the middle fish, and 18 ug/g dry in the middle sediment. The dimer compound (22'DM) was 2.4 ug/g fat in the middle fish, and 27 ug/g dry in the middle sediment. The other compounds were all less abundant. The total alkyl phenol concentrations were 1.9 ug/g fat in the north carp, 270 in the middle, and 0.11 in the south. In the sediments these values were 220 ug/g dry in the middle and 0.19 dry in the south.

The ratio of concentrations in the fish relative to those in the sediment crudely represents the partitioning of the alkyl phenols between sediment and fish. These ratios are all similar to one another (within a factor of 2 to 3) except for 246TP and 22'DM, which are highly hindered alkyl phenols. Clearly, the alkyl phenol levels in carp are affected by the contamination levels of the sediments, at least when the sediment levels are high. Why are the fish/sediment ratios for 246TP and 22'DM dramatically different from the other values (about 40 times lower, on average)? This may be another example of the dependency of biological availability on molecular weight: very high molecular weight, hydrophobic compounds are often less available to biota (7, 8). These highly lipophilic compounds may not be bio-available due to their loss of permeability through cell membranes (8).

The source of 24DP and 4P is apparently the chemical plant where these chemicals are manufactured. This plant is located very near where the middle fish were collected. The origin of the other compounds is still mysterious. There are two possible ways to form these compounds: (a) formation in the plant as reaction by-products from the production of 24DP or (b) formation in the aquatic environment by microbial and chemical degradation of 24DP. In order to differentiate these two possible sources, the commercial product (24DP, technical grade) was analyzed. 2P, 2B4P, 4B2P, 246TP, and 22'DM were found as impurities in this commercial product. We also found that the ratio of the two butylpentylphenol isomers (2B4P/4B2P) in the commercial product (0.19) was about the same as in the carp (0.25) and in the sediment (0.23) sampled near the manufacturing plant. We conclude that these unchlorinated alkylphenols in the Trenton Channel did not come from the degradation of 24DP in the environment but from the discharge of chemical wastes from the plant. The source of the chlorinated alkylphenols is unclear.

LASER IONIZATION MASS SPECTROMETRY (LIMS): TECHNIQUE AND APPLICATIONS

Robert W. Odum and Charles A. Evans, Jr., Charles Evans & Associates, 301 Chesapeake Drive, Redwood City, CA 94063, USA

Introduction

Laser microprobe mass spectrometry is a microanalytical materials analysis technique employed in the characterization of a material's elemental and, in some cases, molecular composition.¹ The laser microprobe technique is based on performing a mass and intensity analysis of the ionic species formed in the high power density laser irradiation of a solid sample. The microanalytical feature of the laser microprobe technique is achieved by utilizing a finely focused (~ 1 micrometer in diameter) laser pulse to initiate the vaporization and ionization of a materials constituents. The laser microprobe technique generally employs a pulsed, Q-switched, frequency quadrupled Nd:YAG laser ($\lambda=266\text{nm}$) and a time-of-flight mass spectrometer (TOFMS). The combination of this finely focused, high irradiance (variable between $\sim 10^8$ and 10^{12} Wcm^{-2}) laser pulse with the "simultaneous" mass detection capabilities of TOFMS enables one to perform microanalytical survey analysis of a wide range of sample materials. The laser microprobe technique is referred to by several acronyms including LAMMA, LIMA, LAMMS, and one that has found favor in our laboratory, LIMS, which stands for Laser Ionization Mass Spectrometry.

In terms of analytical utility, the microanalysis of sophisticated materials is playing an ever important role in modern materials research and development. Analysis techniques which have sensitive elemental and/or molecular detection capabilities within analytical areas on the order of a few micrometers (or less) in diameter are being increasingly utilized for the characterization of materials such as semiconductor devices, integrated optical components, novel metallurgical alloys, ceramic composites, as well as biological materials. The LIMS technique is finding increasing utilization in these types of materials analyses because of its unique microanalytical capabilities which include the following:

1. Rapid, sensitive, elemental survey microanalysis
2. Ability to analyze electrically insulating materials, and
3. Potential of providing molecular or chemical bonding information from the analytical microvolume.

The only practical limitations to performing a qualitative laser microprobe analysis are the requirements that the sample material be reasonably vacuum compatible and that the Nd:YAG laser beam can be focused onto the analytical area of interest. In our laboratory, we have performed informative laser microprobe analyses on sample materials ranging from dehydrated sewage solids to liver tissues to a variety of sophisticated semiconductor materials and devices.

Figure 1 illustrates a schematic diagram of a reflection mode laser microprobe mass spectrometer. This particular instrument is the model LIMA 2A originally manufactured by Cambridge Mass Spectrometry, Ltd (Cambridge, England) which is now a part of Kratos Analytical. A similar instrument is manufactured by Leybold Heraeus and is referred to as the LAMMA 1000. Leybold also manufactured a transmission mode laser microprobe system (LAMMA 500). Vacuum Generators (East Grinstead, England) has recently introduced a TOFMS/SIMS system which can be equipped with a focused laser beam for laser microprobe analyses. The basic instrumental configuration permits one to identify the mass and measure the intensity of the ionic species produced in the high power density laser irradiation of a materials surface.

The laser microprobe can be operated under laser irradiance conditions which provide either or elemental or molecular microanalysis capabilities. Elemental analyses are generally performed at relatively high irradiance values ($\geq 10^9 \text{ Wcm}^{-2}$) and the ionization

produced at these irradiances is primarily composed of atomic and or atomic cluster ions. This mode of operation is referred to as laser ionization (LI) and part-per-million atomic (ppma) elemental detection sensitivities have been observed under these irradiance conditions.² "Molecular" LIMS analyses are typically performed at irradiances on the order of 10^8 Wcm^{-2} and this mode of operation is referred as laser desorption (LD). The ionization produced at these lower irradiances often includes molecular or pseudo-molecular (protonated, de-protonated, cationized) ions and structurally significant fragment peaks.³ Both the LI and LD ionization conditions can be employed to analyze for positive or negative ions emitted from the sample. The choice of analysis polarity depends on the sample composition and the efficiency of ion formation from the various analyte ions. For example, the elements in groups 1 through 13 form almost exclusively positive ions (with the notable exception of H) while the group 14 through 17 elements readily form negative ions.

Laser Microprobe Mass Spectrometry Applications

A large proportion of practical materials analyses are concerned with determining the materials' surface or in depth elemental composition. Examples of these survey analyses include measurements of the major, minor and trace element composition, chemical stoichiometry, and the presence or absence of chemical contaminants. Examples where these types of survey analyses are important include chemical certification of various starting materials used in semiconductor, optical, metallurgical, and polymeric materials processing, evaluation of the chemistry of various processing steps, failure analysis studies of products in which "chemical" problems are suggested as the causative factors of the failure and in the study of various environmental and biological processes. Microanalytical survey techniques address these same analysis areas while performing the analysis in analytical volumes on the order of 1 cubic micrometer or less.

Contamination Microanalysis

Figure 2 illustrates an example of contaminant microanalysis which is readily performed with the laser microprobe. This figure is a negative ion LIMS mass spectrum produced from the $4 \mu\text{m}$ square window etched through a photoresist layer deposited onto a HgCdTe substrate. An aluminum layer was deposited onto this window in order to make electrical contact with the substrate; however a number of the Al contacts on certain devices exhibited poor adhesion. The spectrum illustrated in Fig. 2 was produced from a window region on one of these devices which exhibited poor Al adhesion. The HgCdTe substrate in this spectrum contains relatively high Cl^- and Br^- signals which are not observed in spectra produced from similar regions on devices exhibiting good Al adhesion. Since this photoresist was etched with solutions containing Cl and Br, the analysis indicates that these contaminated surfaces were incompletely cleaned after the etching. This example illustrates several unique features of the laser microprobe technique including its ability to perform a near-surface microanalysis within an electrically insulating material (photoresist).

Organic Microanalysis

The laser microprobe technique has the potential for performing a sensitive molecular microanalysis of a vast number of organic materials including polymers⁴ and biological specimens.⁵ The characterization of a materials organic composition could also find extensive application in the analysis of a whole host of suspected organic thin film contaminants introduced during various materials processing steps. Organic LIMS analysis could easily become the most common application for the technique because of its unique combination of the microanalytical feature with the high mass detection capability of TOFMS. The recent very high mass capabilities ($m/z > 100,000$) of the laser microprobe technique demonstrated by Hillenkamp and Karas⁶ show exciting possibilities for the organic microanalysis of biological materials.

With regard to typical analyses performed in our laboratory, Figure 3 illustrates positive and negative ion spectra produced from a commercial photoresist (PR) layer on a

semiconductor device. The spectra produced from this type of polymeric sample is of particular interest to many of our clients because potential causes of device failure could originate with problems in the photoresist. Such factors as incomplete curing, non-uniform coverage, chemically contaminated materials, or incomplete photoresist removal could all lead to device performance problems. The spectra illustrated in Fig.5 were obtained by focusing a relatively high irradiance ($\sim 10^8 \text{ Wcm}^{-2}$) pulse onto the underlying device which produced the distorted crater shape at the photoresist surface. The positive ion mass spectrum exhibits a number of C based fragment ion peaks, several of which may be structurally significant signals of the photoresist. In particular, the peaks at masses 91 and 115 could be various reaction products of this particular PR formulation. The negative ion mass spectrum in this example exhibits an intense signal at mass 107 which is undoubtedly formed from the Novolak resin in the photoresist. This resin represents about 10% by weight of the PR composition. Although this is only one example of the qualitative organic microanalysis capability of LIMS, it represents a very pertinent one.

Acknowledgments

The authors wish to thank Mr. Charles J. Hitzman, Ms. Ilsabe C. Niemeyer and Dr. Filippo Radicati di Brozolo for their contributions. Support for portions of the LIMS research performed at Charles Evans & Associates was provided by the National Science Foundation (Grants ISI 8560203 and ISI 87000019) and the National Institutes of Health (Grant GM3123-03). This support is gratefully acknowledged.

CO₂ AND EXCIMER LASER DESORPTION AND PHOTODISSOCIATION IN AN FTMS

Lydia M. Nuwaysir and Charles L. Wilkins
University of California, Riverside
Riverside, CA 92521-0403

Laser desorption (LD) has certainly earned its place as a soft desorption/ionization technique amenable to high molecular weight, intractable, and thermally labile samples such as polymers, porphyrins, and biomolecules. Thus far, studies in our laboratory have utilized a pulsed CO₂ laser for desorption of samples up to m/z 9,700 with subsequent detection in a Fourier transform mass spectrometer (FTMS) (1). Recent literature reports describe the laser desorption of compounds up to m/z 100,000 (2)(3). Common to these studies is the use of a sample matrix to aid desorption and increase ionization yields of high molecular weight compounds. Accordingly, we have been investigating the effect of different matrices on the CO₂ and excimer laser (operating at 308 nm) desorption of various middle range molecular weight compounds.

CO₂ laser desorption of polymers and organometallic species with masses in the 1,000 to 11,000 dalton range have also been of recent interest. Exceptionally high mass resolution is obtained for some compounds as is illustrated in the partial spectrum of the tungsten-containing organometallic species presented in Figure 1. The resolving power of FTMS

can be used to advantage to obtain detailed distributions as is evident in Figure 2, which presents a portion of the CO₂ laser desorption spectrum of a methyl methacrylate-styrene

Figure 2.

copolymer. With respect to matrix effects, it is of interest that LD spectra of non-polar olefinic polymers can be obtained if a methanol-gold oxide solution is added to the sample on a stainless steel probe tip and the solvent removed, prior to laser desorption. In the absence of this treatment, no oligomer distribution spectra are obtained.

When a *p*-methoxycinnamic acid matrix of Gramicidin D was prepared and subjected to ultraviolet laser desorption using 308 nm excitation from a XeCl excimer laser, some evidence of matrix-assistance was obtained. Furthermore, use of carbon dioxide laser desorption to examine a 1:1 CsI-sucrose mixture resulted in results similar to those reported earlier by Hillenkamp using a frequency quadrupled Nd-YAG laser for a similar sample (Figure 3). Thus, there is some promise that matrix-assisted LD may be adaptable to FTMS conditions, although optimum parameters have yet to be established.

Figure 3.

A second set of studies has focussed on the use of an excimer laser for photodissociation of laser desorbed ions. Frequently, laser desorption alone does not afford enough useful fragments for structure determination. Preliminary studies have shown that laser desorption/photodissociation-FTMS may be a viable technique for analysis of various alkaloids and porphyrins (4). The use of metal ion attachment to aid photodissociation at 308 nm is currently being investigated.

MECHANISTIC STUDIES IN LASER IONIZATION MASS SPECTROMETRY

C.W. Wilkerson, S.M. Colby, M. Yang & J.P. Reilly
Dept. of Chemistry, Indiana University
Bloomington, IN 47405

Ultraviolet laser light can be effectively utilized to ionize a variety of compounds in the source region of a mass spectrometer. Quantitative studies of ion yields are facilitated by the use of a gas chromatograph sample inlet system. This enables known amounts of different compounds to be introduced in a reproducible fashion and it separates impurities from sample compounds. The latter property is particularly helpful since impurities that laser ionize with high probabilities may provide larger ion signals than compounds that are of primary interest.

In a number of previous investigations, we have found that structurally similar molecules ionize with efficiencies that differ by up to two orders of magnitude. We hypothesized that this was due to variations in their gas phase absorption characteristics and excited state dynamics. An example of this variation is displayed in a laser ionization chromatogram of a mixture of polyaromatic hydrocarbons which is displayed in Figure 1A. A 10 nanosecond laser was used to record these data. In agreement with previous results, the naphthalene:biphenyl relative ionization efficiency at a laser wavelength of 239.5 nm is about 10:1, even though biphenyl's gas phase absorption coefficient is approximately six times larger than naphthalene's at this wavelength. This result suggests that biphenyl's poor ionization yield must be due to ultrafast excited state relaxation. This theory was tested by recording a chromatogram of the same mixture of compounds using the same laser wavelength but with light pulses of 20 picosecond duration. The result is displayed in Figure 1B. Biphenyl clearly ionizes much more efficiently than does naphthalene (due to its higher absorption coefficient) as long as it is not given enough time to relax from its excited electronic state.

FIG. 1: Gas chromatograms of a mixture of polyaromatic hydrocarbons detected by laser ionization mass spectrometry. (A) 10 nanosecond light pulses (B) 20 picosecond pulses.

We are now developing a general rate equations model to predict the laser ionization efficiencies of different compounds as a function of their absorption coefficients, excited state lifetimes and the laser pulse duration. The results obtained for a model compound having an excited state lifetime of 10 nsec, and ground and excited state absorption cross sections of 10^{-17} and 10^{-19} cm², respectively, are displayed in Figure 2. The predicted time dependence of the excited state population and the ion yield are depicted for both 10 nanosecond and 10 picosecond light pulses. The most noteworthy result is that even though the photon fluence of the picosecond pulse is ten times smaller than that of the nanosecond pulse, almost five times more ions are produced in the former case. In summary, shorter laser pulses can effectively compete with excited state relaxation.

LASERS AND QUADRUPOLE FOURIER TRANSFORM MASS SPECTROMETRY
APPLIED TO PROTEIN SEQUENCE ANALYSIS

Jeffrey Shabanowitz, Donald F. Hunt, Patrick R. Griffin, and Nian-Zhou Zhu
University of Virginia, Department of Chemistry
Charlottesville, Virginia 22901

New methodology development for protein sequence analysis continues to be a major goal of our research. The need for molecular weight determination at high mass, high mass resolution, and higher sensitivity are all important to protein sequence analysis. The ability to analyze oligopeptides for amino acid sequence at lower levels is becoming more and more challenging. Our approach to protein sequencing relies, in part, on the use of quadrupole Fourier transform mass spectrometry (QFTMS) for the mass analysis. QFTMS is routinely used to generate molecular weight determinations of oligopeptides up to 6 kDa at the pmol level (1,2). Lasers can now be employed as an integral part for ionizing extremely small amounts of very large proteins (3). The laser has also been used to directly photodissociate molecules, MS/MS/MS...(ad infinitum). Sequence analysis by photodissociation of peptides up to 29 amino acid residues in length and on as little as 10 pmol of sample using the QFTMS and an ArF excimer laser has been demonstrated (3,4).

Laser photodissociation by QFTMS has significantly contributed to the amino acid sequencing of proteins. However, complete sequencing information is usually only obtained when the oligopeptide cooperates, in part, by unimolecularly decomposing. A single laser pulse from an unfocused ArF (193 nm, 6.4 eV) excimer laser results in such efficient photodissociation of the oligopeptide, that most of the photofragments produced are the lower mass fragments (illustrated in Fig. 1). A study of photofragment yield vs. photon flux indicates a linear dependence with no change in ion distribution or fragment species. Experiments using surface induced dissociation (SID), pioneered by Cooks (5), were performed on several oligopeptides using the QFTMS (6). The ArF photodissociation spectrum and the SID spectrum yield virtually the same fragmentation, confirming the quantity of energy deposition and fragmentation pathways to be similar.

To enhance the higher mass sequence ions and better control the amount of absorbed energy, different wavelengths were tried. KrF (248 nm, 5 eV) gave very poor photofragmentation yields with no higher mass fragments and XeCl (308 nm, 4 eV) was not absorbed at all by the peptides. This is not surprising since the cross-section of peptides at these wavelengths is not very large. Excimer pumped dyes around 500 nm (2.5 eV) also proved unsuccessful. However, the photon flux was insufficient to pump up the ions using an unfocused laser beam. When the beam was focussed down to <1 mm, the photons no longer physically interacted with the majority of the ions stored in the ICR cell. Experiments using an unfocused Nd:YAG laser at 532 nm are planned.

Vibrational excitation of ions using a pulsed CO₂ (10.6 μ m, .11 eV) laser is also possible. Glycerol proton bound oligomers and small oligosaccharides had been dissociated using multiple CO₂ laser pulses (4). The pulsed CO₂ laser enhanced the dissociation of Gramicidin S (Fig. 2) yielding a series of the sequence ions but was unsuccessful on other oligopeptides. Increasing the photon flux by using a continuous wave (cw) CO₂ laser to pump up and dissociate small peptide ions has been demonstrated (7). Controlling the photofragment distribution and yield from large oligopeptides by pumping up the ions in small increments should be possible.

Ions formed by different ionization modes offer another means to control the net internal energy of the photo-excited oligopeptide ions. Laser desorption of high mass proteins from solid matrices has been successful (3) and should provide a reasonable ionization alternative to LSIMS. So far we have been unable to implement this ionization technique using the QFTMS due to difficulties in extracting and/or trapping the ions.

An alternative ionization mode, which provides internally "cold" ions, is electrospray ionization (ESI). It has been demonstrated that multiply charged ions can be successfully collisionally dissociated (8) and should also be amenable to photodissociation. Preliminary results interfacing ESI and QFTMS (9) are promising and are illustrated in Fig. 3. The left spectrum (Fig. 3a) has only one ion signal at m/z 571 and it is the doubly charged molecular ion from Gramicidin S. The right spectrum (Fig. 3b) results from a single unfocussed ArF pulse to photodissociate the $(M+2H)^{++}$ ion. Predicted sequence ions, as well as, a $(M-H)^+$ ion at m/z 1140 are observed.

Lasers may prove to be useful in a more abstract manor for dissociating ions. Collisional-activated dissociation of ions remains the most widely used means to generate fragment ions. Collision gas pressure, interaction time with the collision gas, and initial collision ion energy can all be controlled to finely tune the amount and type of fragmentation desired. The collision gas pressure for FTMS experiments is usually regulated by a series of pulsed valves, which only coarsely controls the pressure in the ICR cell. The collision gas pressure, necessary for collisional decomposition, in the pressure sensitive ion cyclotron cell can be rigorously controlled and placed using lasers. A liquid N_2 cold finger is used to condense a collision gas, such as carbon dioxide, near the ICR cell. A laser pulse or series of pulses are employed to desorb the solid carbon dioxide off of the cold finger to give a finely controlled burst of collision gas. This apparatus has undergone preliminary tests using the QFTMS and should provide an effective means of controlling collision gas pressure in the ICR cell.

Lasers offer an effective means of ionizing, as well as, dissociating oligopeptides and will continue to develop as an integral part of mass spectrometry.

PHOTOINDUCED ION-MOLECULE REACTIONS IN THE GAS PHASE USING FTMS.

J.R. Gord and B.S. Freiser,

Department of Chemistry, Purdue University, W. Lafayette, IN 47907

In the mature area of solution phase photochemistry, a limitless number of examples exist in which a species, activated by the absorption of a photon, undergoes a reaction not observed in its ground state. In contrast, under the conditions used to study gas phase ion-molecule chemistry at low pressures (10^{-5} to 10^{-9} torr), examples of photo-induced or photo-enhanced reactions have been surprisingly sparse. In this environment, the time between reactive collisions is sufficiently long that internal conversion, photodissociation, or radiative and collisional relaxation of photo-excited ions significantly reduce the possibility of photo-induced reactivity.

Only one example of a photo-enhanced ion-molecule reaction in this pressure regime has been reported to date [1]. Bomse and Beauchamp observed selective enhancement of k_r by $>10^3$ during an ion cyclotron resonance (ICR) study of the effect of infrared irradiation ($10.6 \mu\text{m}$) on reaction 1. In this

paper we discuss several strategies for generating long-lived intermediates and report the second and third examples of photo-induced reactivity in the ICR pressure regime and the first such examples involving organometallic ions. The first example involves RhC_5H_6^+ [2] which was prepared through reaction of laser-desorbed Rh^+ with cyclopentane. Thermalized RhC_5H_6^+ reacts with cyclopentane to produce $\text{RhC}_{10}\text{H}_{12}^+$, reaction 2. However, photo-excited RhC_5H_6^+

reacts with cyclopentane to produce the rhodocenium ion, reaction 3. In

addition irradiation results in photodissociation, reaction 4. The fact that

reaction 3 competes favorably with reaction 4 implies that the photodissociation pathway proceeds slowly, either because the photon energy is near the dissociation energy or because multiple photon absorption is required to produce photodissociation at this wavelength.

The mass spectra produced with and without laser irradiation are displayed in Figure 1. $\text{RhC}_{10}\text{H}_{12}^+$ photodissociates to produce $\text{RhC}_{10}\text{H}_{10}^+$,

reaction 5, so double resonance techniques were employed to ensure that the suspected photo-induced reaction product was not produced via this pathway.

The second example involves Co_2NO^+ . Klaassen and Jacobson recently identified two forms of this ion, one which reacts with $^{18}\text{O}_2$ by nitrosyl displacement, reaction 6, and a second which is unreactive with O_2 [3]. The

absence of isotope scrambling in reaction 6 suggests that the reactive form of Co_2NO^+ involves molecularly chemisorbed nitrosyl ligand. Further studies using H_2^{18}O indicate that the nonreactive form may involve the dissociatively chemisorbed ligand.

In this study we observed the reaction of Co_2NO^+ with O_2 as a function of time with and without irradiation. Figure 2 displays the relative abundances of Co_2NO^+ and Co_2O_2^+ under these conditions. Jacobson has demonstrated that the populations of the reactant and product ions approach an asymptotic limit with increasing time when no irradiation is present. However, when irradiated with 1064 nm (~ 27 kcal/mol) photons from a pulsed Nd:YAG laser operated at 10 Hz, the nonreactive isomer is observed to become reactive, presumably because the photo-excited species can access both the reactive and the nonreactive isomers. Relative abundances in Figure 2 do not sum to 100% due to a small photodissociation contribution not displayed.

Experiments using arc lamp irradiation at ~ 35 kcal/mol resulted in competition between the photo-induced reactivity characterized in Figure 2 and photodissociation, reaction 7. The 514.5 nm output from the Ar^+ laser

produced photodissociation products exclusively. In a continuing series of studies, we are using variable energy light sources in conjunction with this

photoinduced reaction to characterize the height of the Co_2NO^+ reactive/nonreactive isomerization barrier. In addition, photodissociation threshold studies are underway to determine $D(\text{Co}_2^+-\text{NO})$ for the reactive and nonreactive isomers as well as $D(\text{Co}_2^+-\text{O}_2)$.

Three mechanisms could explain production of the long-lived intermediate necessary to observe photo-induced reactivity: (i) generation of an ion in an electronically excited state which is forbidden to the ground state, formed directly, by intersystem crossing, or by some collisional or radiative process involving the initially photoaccessed excited state, (ii) generation of a vibrationally excited ground state ion by internal conversion, and (iii) generation of a different geometric isomer. Given the high density of low-lying electronic states characteristic of open shell organometallic species, (i) cannot be completely ruled out; however, we believe it is the least likely of the three. Photodissociation of an ion of this size, as observed in reaction 4, typically occurs following internal conversion, consistent with either (ii) or (iii). We believe reaction 3 involves a vibrationally excited ground electronic state intermediate, mechanism (ii), while the photoinduced reaction involving Co_2NO^+ proceeds by a novel photo-induced rearrangement, mechanism (iii).

Other systems currently under study in this and other laboratories suggest that rich and diverse photoinduced chemistries wait to be uncovered.

DEPENDANCE OF CAR SPECTRA OF DIASTEROMERIC MH^+
ION UPON THE USED METHOD OF ION PREPARATION.

J.C. TABET and D. DESPEYROUX

Laboratoire de Chimie Organique Structurale, UA 455, Université
Pierre et Marie CURIE, 4 Place Jussieu 75252, Paris 05, France

Recently, various studies had been investigated on the different effects of initial internal energy on low energy CAD of selected protonated MH^+ ions^{1,2,3,4}. Relative daughter ion abundances are significantly dependent on the CI reagent used to generate the precursor MH^+ ion. Such low energy CAD processes occurred in the collision cell of triple quadrupole mass spectrometer. For relatively low energy collision (under $E_{lab} < 50$ eV) these studies shown that together (i) the initial internal energy of MH^+ and (ii) the protonated site on MH^+ ion played an important role on the orientation of competitive and consecutive decompositions. These factors yield large changes on the low energy CAD spectra. For diastereomeric protonated molecules, these effects enhance strongly the observed stereochemical effects⁴.

In this report, Collisionally-Activated-Reaction (CAR) spectra of protonated diastereomeric bicyclo-(2,2,1)-heptanol-2 (1a, 1b) and derivatives (e.g. endo and exo acetates (2a, 2b) and benzoates (3a, 3b)) are investigated according to the method to prepare the MH^+ ions (e.g. protonated by different CI reagent gases). In collision cell and under very low collision energy (<3 eV), the reactivity of diastereomeric protonated molecules (containing different internal energy) towards ammonia reagent are compared.

In the collision cell, different competitive processes occur from low energetic MH^+ ions under these conditions: Solvation (adduct ions, ammonium clusters), Nucleophilic Substitution ($(M+NH_4-ROH)^+$ ion, noted MsH^+) and Proton Transfer (yielding NH_4^+). Concerning the protonated isomeric benzoates (formed in CI/NH_3), weak stereochemical effects are observed (figure 1a and 1b) and disappear when they contain larger internal energy (figure 1c). Furthermore, solvation process yields decrease in particular for the produced MsH^+ ion. This behavior often takes place for reversible processes. This suggests that likely during flight through the first analyser, $C_{7}H_{11}-O-COH^+-C_6H_5$ isomerizes into $C_{7}H_{10}..H^+..HOOC-C_6H_5$ intermediate which reacts with NH_3 yielding of $C_{7}H_{10}..H^+..NH_3$ ion rather a covalent $C_{7}H_{11}-NH_3^+$ ion such as it is produced in CI source (via S_N2 and S_N1 according to the initial configuration). The protonated acetates are characterized by a different gas phase behavior since large stereochemical effects are observed (figure 2a and 2b). Furthermore, unusual stereospecific process can take place under these CAR conditions. The latter is due to a prior isomerization of bicyclic skeleton into a reactive protonated tricyclic hemiketal such as it is occurred in solution (lactone formation). From this tricyclic form, SN and methane elimination occur and lead to the unusual $(M+NH_4-R_2O-CH_4)^+$ formation (Scheme 1). The increasing of the initial internal energy of MH^+ leads to a "levelling" of CAR spectra. Likely, from the latter species, an isomerization in protonated norbornene-acetic acid complex is preferred to this yielding hemiketal intermediate prior reactive collisions. On the other hand, from protonated esters (formed via metastable NH_3 loss from selected $(M+NH_4)^+$ ion), consecutive isomerization into any intermediate is unfavored (shorter residence time in this region) (figure 2c).

In conclusion this work shows the role plays by (i) the function stereochemistry and (ii) the internal energy of the selected ions on reactivity towards ammonia. The increasing of precursor ion internal energy on CAR spectrum can be significant on the possible ion structures.

Effective Ion Temperatures in a Quadrupole Ion Trap

B.D. Nourse, H.I. Kenttämä, R.G. Cooks
Department of Chemistry, Purdue University
West Lafayette, IN 47907

Paul-type quadrupole ion traps are rapidly gaining recognition as simple and relatively inexpensive mass spectrometers that are well-suited, for example, for chemical ionization experiments, thermochemical studies, ion-molecule reaction studies and tandem mass spectrometry involving photo- or collision-activated dissociation of mass selected ions (1). These mechanically simple devices consist of a chamber formed between three electrodes with hyperbolic inner surfaces. Radio-frequency voltages, in combination with dc voltages, are used to trap, isolate, excite and eject ions. Typically, one mtorr of helium is introduced into the ion trap to dampen the motion of the ions, thereby improving the overall performance.

The lack of knowledge of the temperature of ions in a quadrupole ion trap limits the usefulness of this device. Knowledge of the internal and kinetic energies of the ions is very important for example for comparison of experimental results obtained using different instruments and for determination of kinetic and thermodynamic parameters, such as rate constants, equilibrium constants and bond energies. One can not directly measure the actual ion temperature. However, an "effective" temperature can be determined that is related to the internal energy distribution of the ions. The "effective" temperature is here determined as the temperature that would result in a specified rate (or product distribution) for a reaction in the absence of external electric fields.

In order to obtain information concerning the actual internal energy distribution of ions in a three-dimensional quadrupole ion trap, a number of experiments have been carried out in this lab. The reaction of O_2^+ with methane is one of the systems employed as a "chemical thermometer". This reaction has been the focus of a considerable research effort and is one of the best understood bimolecular gas-phase reactions. The rate constant as well as the product distribution are temperature dependent (2,3). There is only one exothermic pathway (I) available. At higher energies two endothermic channels ((II) and (III)) dominate the product distribution (4).

Under normal trapping conditions, the rate constant for the reaction of O_2^+ with methane was determined to be $8.2 \pm 3.4 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ second}^{-1}$. The ratio of exothermic to endothermic products (m/z 47 : (m/z 15 + m/z 16)) was 1 : 0.33 (when excess methane is present, m/z 15 and m/z 16 are detected as m/z 17 and m/z 29). Both the rate constant and the product distribution indicate an "effective" temperature of 600K - 700K for ions stored in the quadrupole ion trap in the presence of 5 mtorr of helium buffer gas. This temperature corresponds to kinetic energies of approximately 0.1 eV (3/2 kT).

Other systems studied to further investigate the "effective" temperature are shown in Table 1. The excess internal energy that these ions would gain upon a temperature increase from 298K to

600K is indicated together with the dissociation thresholds for each ion. The stability of these ions under normal trapping conditions was examined by storing the ions in the ion trap for approximately 3000 msec. Spontaneous decomposition was observed for tetraethylsilane and protonated cyclohexene oxide but not for the other ions studied. These findings support the estimated ion temperature of 600K. The general equation $k(T) = k_{\text{capture}} \exp(-E_a/RT)$, where E_a is the activation energy, may be used to approximate the "effective" ion temperature using an endothermic bimolecular reaction as a chemical thermometer. The dissociation of $(C_2H_5)_3Si^+$, upon collisions with helium, gives $k_{\text{dissoc.}}/k_{\text{AOD}} = 0.0003$ which results in an "effective" temperature of 720K.

The reaction of O_2^+ with methane was examined under more energetic conditions, i.e., the O_2^+ ion was isolated and a supplementary ac voltage was employed to increase the ions kinetic energy. The ratio of m/z 47 : (m/z 15 + m/z 16) varies with the ac voltage amplitude and is 1 : 5 under the most energetic conditions. This indicates that the "effective" temperature can be as high as 1300K for this system, corresponding to 0.4 eV internal energy for O_2^+ .

In conclusion, the "effective" temperature of ions in the quadrupole ion trap can be as low as 600K - 700K under normal trapping conditions. These results apply for m/z 30 - m/z 150, $q = 0.04$ - 0.50. The dependence of the "effective" temperature on the nature of the buffer gas, the mass of the ion, and the q value will be examined in detail.

TABLE 1

	$(H_{\text{AOD}} - H_{\text{ZPE}})$ - $3/2 kT$	dissociation threshold:	reaction observed
$(CH_3CH_2)_3Si^+$	0.92 eV	0.8 eV	YES
 OH ⁺	0.53 eV	0.5 eV	YES
$(CH_3O)_2P(O)H^+$	0.34 eV	0.7 eV	NO
$(CH_3CH_2)_3Si^+$	0.69 eV	1.5 eV	NO
 OH ⁺	0.53 eV	1.6 eV	NO

MECHANISTIC AND ENERGETIC IMPLICATIONS OF KINETIC ENERGY RELEASE DISTRIBUTIONS FOR REACTIONS OF TRANSITION METAL IONS WITH ALKANES

J. Brodbelt-Lustig, P. van Koppen, M. Bowers, Department of Chemistry, University of California, Santa Barbara, CA 93106, D. Dearden, J. Beauchamp, Arthur Amos Noyes Laboratory of Chemical Physics, California Institute of Technology, Pasadena, CA 91125

The growing number of investigations probing aspects of organotransition-metal reactions stem in part from the importance of organometallics as widely proposed intermediates in many catalytic transformations. In particular, considerable effort in recent years has been directed at understanding the mechanisms and energetics of C-H and C-C bond activation of alkanes by transition metal ions. Such exothermic ion/molecule reactions typically result in elimination of molecular hydrogen, alkanes, and alkenes, cleavages which are initiated by oxidative addition of a metal ion across a C-H or C-C bond. The insertion site has yet to be determined for some of these alkane elimination reactions, for example CH_4 loss from Co^+ and Fe^+ reacting with propane.

Product kinetic energy release distributions (KERD) have proven valuable in deducing the mechanisms as well as in elucidating details of potential energy surfaces for metal-mediated reactions. Statistical theories such as phase space theory have been used successfully to model translational energy release distributions for reactions on a surface where there is no barrier, excluding a centrifugal barrier, for the the reverse association reaction. Recently, we have examined a number of reactions, including methane loss from Co^+ and Fe^+ complexes with propane, where the kinetic energy releases are narrower than predicted by statistical theory. These are unusual and interesting results since non-statistical kinetic energy release distributions are generally broader than the statistically predicted ones. The results are explained in terms of a rotational energy barrier on the potential energy surface prior to the exit channel. Labeling studies indicate that the initial C-H bond activation energy barrier is responsible for these observations.

Metastable kinetic energy release distributions were measured using a reverse geometry double focusing mass spectrometer (VG Instruments ZAB-2F) with a home built variable temperature EI/CI source. Metal ions were formed by electron impact (150 eV) of $\text{Fe}(\text{CO})_5$ and $\text{Co}(\text{CO})_3\text{NO}$. The bare metal ions react with the organic neutrals in the ion source to form the organometallic adduct ions. The ions are accelerated to 8 kV and mass analyzed using a magnetic sector. Metastable ions decomposing in the second field free region are energy analyzed by scanning the electric sector.

The KERD for methane loss from Co-propane^+ is shown in Figure 1 along with the statistically calculated distribution. The experimentally measured distribution is much narrower than the one modelled using phase space theory. This translationally cold distribution derives from the influence of angular momentum conservation on reaction dynamics. Examination of the potential surface shown in

Figure 2 reveals that the presence of an insertion barrier close to the asymptotic energy of the reactants dictates the outcome of capture collisions involving varying amounts of angular momentum. For collisions involving large angular momentum, it is possible that the system can cross the centrifugal barrier but yet be unable to approach closely enough to undergo insertion. Thus, the Co^+ /propane adduct may be formed but unable to proceed to final products. This discrimination against large angular momentum collisions is manifested as a reduction in the high kinetic energy release portion of the product kinetic energy distribution, since large values of angular momentum contribute to the higher energy portion of the distribution.

It is possible to model translationally cold kinetic energy release distributions using statistical theory by simply restricting the total angular momentum of the orbiting transition state for the reactants. The kinetic energy release distribution obtained using the restricted model is shown in Figure 1, and yields a good fit to the experimental distribution.

To determine the site of initial insertion for the demethanation of the Co^+ /propane complexes, deuterium labelled propane was used. The abundance of the loss of CH_4 from complexes formed using 2,2-propane- d_2 is the same as for the undeuterated complexes. Conversely, the loss of CD_4 from Co^+ /propane- d_8 is virtually negligible, indicating that insertion into a primary C-H bond rather than a C-C bond is the initial step for the demethanation of these organometallic complexes.

Figure 2

HYDROGEN-BONDED, σ -BONDED AND π -BONDED COMPLEXES $M \cdot X^-$ FROM M AND X^- WHERE M = SUBSTITUTED BENZENES AND QUINONES AND $X^- = F^-, Cl^-, Br^-,$ AND I^- .

Gary J. C. Paul and Paul Kebarle,
Dept. of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2.

The equilibrium constants K and complexing energies, $-\Delta G^0 = RT \ln K$, were obtained at 150°C for the complexes $M \cdot X^-$ by determining the ion-molecule equilibria:

with a pulsed-electron high pressure mass spectrometer. These complexing free energies were complemented by the measurement of X^- transfer equilibria between the substituted benzenes and quinones:

which serves as a cross-check for the complexing energies. An agreement within 0.3 kcal/mol between these two types of measurements was observed. Combining the results from the present (~fifty) measurements using principally Br^- (1) with earlier work from this laboratory (2,3) gives an insight into the variety of bonding that can occur in these complexes.

Previous theoretical work on Cl^- bonding to fluorobenzene (2) showed that hydrogen-bonding leads to the most stable complex:

The same type of bonding is expected also for $X^- = Br^-$. Further information on the nature of bonding in $M \cdot X^-$ from present measurements, where M is benzene and singly substituted benzenes and X^- is Br^- , can be gained using methods developed by Taft (4) for the separation of the substituent effects, $-\Delta G^0$, into resonance (R) and field-inductive (F) contributions by:

$$-\Delta G^0 = \rho_R \sigma_R + \rho_F \sigma_F \quad 3$$

In this case $-\Delta G^0$ is the experimentally-determined relative free energy change in bromide affinity between each substituted benzene and benzene ($-\Delta G^0 = 0$ kcal/mol for substituent = H); σ_R and σ_F are system-independent parameters compiled by Taft (4) which rank resonance and field effects for each substituent; ρ_R and ρ_F are coefficients particular to this system which indicate the magnitude of R and F effects and are determined by multiple regression analysis of equation 3 applied to each benzene substituent. Figure 1 shows a good correlation of $-\Delta G^0_{calc}$, determined with these evaluated ρ_R and ρ_F values, with $-\Delta G^0_{BFA,423K}$. Thus the substituent effects are well described by established resonance and field-inductive terms of the substituent.

Table 1

	ρ_R	ρ_F	ρ_R/ρ_F	
	6.8 ± 2.0	8.5 ± 0.5	0.8	
	14.6 ± 0.7	15.0 ± 0.6	1.0	Acidity data from (4)
	49.0 ± 1.5	18.6 ± 0.5	2.6	" " " "

The ρ_R/ρ_F ratio, see Table 1, which provides a means to compare the relative stabilizations by resonance and field effects for different systems, is similar for $Br^- \cdots H-C_6H_4Y$ and $CO_2-C_6H_4Y$ stabilization but larger for $O-C_6H_4Y$. This is to be expected from the resonance structures in Figure 2 where direct conjugation of the negative charge occurs only in $O-C_6H_4Y$ stabilization which leads to a larger resonance contribution and consequently a bigger ρ_R/ρ_F ratio. The smaller ρ_R/ρ_F ratio therefore supports the theoretical prediction of the bromide ion being hydrogen-bonded to singly substituted benzenes where resonance stabilization is a relatively small effect.

Progressive substitutions of electron-withdrawing groups on benzenes and quinones were found to cause a continued increase in the bromide affinities. Very strong bonding was observed for Br^- with perfluorobenzenes and quinones which contain no aromatic hydrogens at all. For example, the bond energy increases by ~10 kcal/mol from benzoquinone. Br^- to tetrafluoroquinone. Br^- . SCF calculations on the tetrafluoroquinone. Br^- complex (5) predict that Br^- is σ -bonding to the aromatic ring forming a so-called

Meisenheimer complex. Confirmation of this bonding can be again be obtained using the Taft methods (4) applied this time to the experimental $-\delta\Delta G_{BrA,423K}^{\circ}$ and $-\delta\Delta G_{ClA,423K}^{\circ}$ values for the singly substituted perfluorobenzenes. The results are shown in Table 2.

Table 2

	ρ_R	ρ_F	ρ_R/ρ_F
	7.4 ± 3.2	4.1 ± 1.0	1.8
	9.0 ± 2.8	2.8 ± 0.8	3.2

The larger ρ_R/ρ_F ratios obtained show, as for the phenols acidities in Table 1, that the negative charge is directly conjugated into the ring as would be anticipated for the σ -bond formation as shown in Table 2. This type of σ -bonded complex has also been previously predicted by ab initio calculations for $C_6F_6-F^-$ (6).

UNIMOLECULAR REARRANGEMENTS IN THE GAS PHASE: RING OPENING OF CYCLOPROPYL ANIONS

Phillip Chou and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

Theoretical and experimental investigations of unimolecular rearrangements are a productive and vast area for research. The elucidation of reaction mechanisms and information regarding the relationship between structure and reactivity has provided some of the impetus for these studies.

Rearrangements of positive and negative ions have been extensively examined in condensed media, but gas phase studies offer some distinct advantages. An obstacle impeding such work is that unimolecular rearrangements lead to isomeric species, which cannot be distinguished simply on the basis of their mass. Another difficulty is that energetically well defined systems are needed if rates of reaction are to be measured and activation energies obtained. These latter quantities are of fundamental importance but are generally not accessible. We now wish to report that a variable temperature flowing afterglow apparatus can be used to probe unimolecular rearrangements.

It has previously been shown by several research groups that cyclopropanes do not undergo ring cleavage upon reaction with strong bases.^{1,2} More recently, we have found that even the highly strained bicyclobutyl anion (I) can be formed without any accompanying rupture (eq 1).³ These results are consistent with liquid phase studies and molecular orbital calculations which suggest that a significant barrier exists for the ring opening of cyclopropyl anions.^{4,5}

Remarkably, the bicyclobutyl anion is unaltered by heating to temperatures as high as 300° C (eq 2). In sharp contrast to the

behavior of I, phenylcyclopropyl anion (II) begins to undergo thermolysis at a temperatures approximately 200 °C (eq 3). The

activation energies for the rearrangement of these two ions are clearly quite different. They can be estimated if one assumes a typical value, 10^{13} - 10^{14} , for the A factor in the Arrhenius equation. The results are in reasonable agreement with theory, and reveal that structural effects are of critical importance.

A THEORETICAL STUDY OF NUCLEOPHILIC SUBSTITUTION
REACTIONS IN THE GAS PHASE

Peter M. Hierl, Sally Meyer, and James Sigler
Department of Chemistry
University of Kansas
Lawrence, KS 66045

Measurements¹ of the rate constants for the exothermic gas-phase nucleophilic substitution reactions $\text{OH}^- + \text{CH}_3\text{X} \rightarrow \text{X}^- + \text{CH}_3\text{OH}$ (where $\text{X} = \text{Cl}, \text{Br}$ or I) over the temperature range 200–500 K reveal two unusual features: reaction does not occur on every collision, and the rate constants decrease with increasing temperature. We report here the results of theoretical calculations of the reaction efficiencies, and show that good agreement can be obtained with the experimental observations.

These calculations are based upon a model² which assumes a double minimum potential energy surface of the type shown in Figure 1 for the generalized ion-molecule reaction $\text{A}^- + \text{B} \rightarrow \text{C}^- + \text{D}$. Briefly stated, this model assumes that the reactants, attracted by long range ion-dipole forces, form the reactants adduct A^-B at the collision rate, k_1 . This adduct can either reform the reactants with a rate constant k_{-1} , or pass over the central barrier E_0 with a rate constant k_2 to form the product adduct C^-D . For sufficiently exothermic reactions, it can be shown that the predicted reaction efficiency is given by $k_2/(k_{-1} + k_2)$. The model further assumes that the ratio k_{-1}/k_2 (and hence the reaction efficiency) can be calculated as a function of temperature from the RRKM theory of unimolecular reactions if the properties of the relevant transition states are known and if a value is known or assumed for E_0 .

For all three reactions, the geometry of the transition state along the pathway leading to products (TSB) was optimized using AMPAC,³ a semiempirical method of optimization. For the reaction with $\text{X} = \text{Cl}$, the transition state geometry obtained from AMPAC was very similar to that reported by Ohta and Morokuma⁴ from ab initio quantum mechanical calculations. (Ab initio results have not been reported for the reactions with $\text{X} = \text{Br}$ or I .) Vibrational frequencies for TSB were then obtained from the computed structure by using the BEBOVIB IV program.

For the pathway leading back to reactants, the transition states were assumed to be orbiting transition states; the reactants were fixed at the separation corresponding to the maximum in the centrifugal barrier, and AMPAC was used to optimize the remaining degrees of freedom. Vibrational frequencies were then derived using BEBOVIB IV.

The height E_0 of the central barrier (or more directly, the energy difference ΔE between the two transition states) was treated as an adjustable parameter. Using the transition state properties obtained from AMPAC, RRKM calculations⁵ were carried out to find the value of ΔE required for the calculated efficiency to equal the experimental efficiency at room temperature. Using this "empirical barrier height," RRKM calculations of the reaction efficiencies were carried out at a number of temperatures over the range 200–500K. The results obtained for the reaction with $\text{X} = \text{Cl}$ are compared with the experimentally obtained reaction efficiencies in Fig. 2. Similar results (not shown) were also obtained for the reactions with $\text{X} = \text{Br}$ and I .

From the good agreement obtained between calculated and measured efficiencies for these three reactions, it would appear that the double minimum model proposed by Brauman and co-workers can provide a useful explanation for the rather unusual temperature dependence exhibited by nucleophilic substitution reactions in the gas phase.

A more complete account of this work is being prepared for publication elsewhere.

Figure 1. Schematic representation of the double minimum potential energy surface for the generalized ion-molecule reaction $A^- + B + C^- + D$.

Figure 2. Reaction efficiency vs. Temperature (K) for the reaction $OD^- + CH_3Cl + Cl^- + CH_3OD$. The squares represent the ratio of the measured reaction rate constant to the calculated collision rate constant. The solid line represents the results of the RRM calculations discussed in the text.

SELECTIVITY AS A FUNCTION OF ANIONIC BASE PROPERTIES IN THE REACTIONS OF DIMETHYL SULFITE

Joseph J. Grabowski and Rachel C. Lum
Department of Chemistry, Harvard University
Cambridge, MA 02138

As part of our continuing interest in understanding the intrinsic reactivity of organic sulfur compounds,¹ especially in relation to the utility of such functionality by bio-organic systems and in relation to the fate of sulfur in the atmosphere, we report here our detailed anion-molecule studies of dimethyl sulfite. The related molecule dimethyl carbonate ($\text{CH}_3\text{OCO}_2\text{CH}_3$) has been briefly examined by the ion cyclotron resonance (ICR) technique² and has been found to undergo nucleophilic attack at both $\text{sp}^2\text{-C}$ and at $\text{sp}^3\text{-C}$. In this flowing afterglow study, we report the products observed and our mechanistic interpretations of a series of anions interacting with dimethyl sulfite at 300K. We are interested in isolating the factors that define the site of reactivity (C or S) and the type of reaction ($\text{S}_{\text{N}}2$, E2 or $\text{B}_{\text{AC}}2$) that occurs. The studies have focussed on the competitive chemical processes that can occur within an ion-neutral encounter, and to a much lesser extent, the absolute rate of reaction.

We can account for the observations reported herein with four general pathways by which an anion might reaction with dimethyl sulfite (Scheme): (i) nucleophilic attack at sulfur, path a; (ii) nucleophilic substitution at the methyl group, path b; (iii) elimination initiated by proton abstraction from the methyl group, path c, and (iv) adduct/cluster formation, path d.

Consider the data from the amide reaction shown in eq 1. The major ion at m/z 79, CH_3OSO^- , can be envisioned as arising from elimination across a carbon-oxygen bond (Scheme, path c) while the m/z 64 ion, SO_2^- , is formed by a minor fragmentation during the elimination of those CH_3OSO^- ions that obtain enough of the reaction exothermicity to surmount the fragmentation barrier. Also produced in 44% overall yield from the reaction of amide with dimethyl sulfite is $\text{CH}_3\text{OSO}_2^-$, m/z 95, which arises from bimolecular substitution at saturated carbon. The two minor products are m/z 62 and 94, NSO^- and $\text{CH}_3\text{OSONH}^-$, both of which arise from initial addition of amide to sulfur to form a tetravalent species. Breakdown of the tetravalent species by extruding methoxide, followed by either elimination or proton transfer gives ultimate rise to the respective products noted.

HA ⁻	PA (kcal/mole)	Elimination	Substitution at sp ³ -C	Reaction at S
H ₂ N ⁻	403.7	48%	44%	8%
H ₂ C=CH-CH ₂ ⁻	390.8	0%	44%	56%
HO ⁻	390.8	19%	← 81% →	
Ph-CH ₂ ⁻	380.7	0%	12%	88%
CD ₃ O ⁻	381.0	0%	50%	50%
	368.5	0%	94%	6%

Several reactions are summarized in the Table, according to the type of reaction noted, E2, S_N2 and B_{AC}2, as have been discussed for amide. Inspection of the data in the Table reveals that the structures of the anionic nucleophile is of primary importance in determining selectivity and only secondarily does one need consider basicity. Strongly basic, localized heteroatomic nucleophiles yield larger amounts of elimination products compared to carbon bases of comparable basicity. While all anions yield substitution products, localized bases are much more nucleophilic at carbon than delocalized carbon bases. For nucleophilic attack at sulfur, the opposite trend is found, delocalized carbon bases being most nucleophilic at this site. The new level of chemical understanding developed from the overall reaction scheme and reactivity patterns noted above will help design future gas-phase experiments to probe specific reaction mechanisms.

GAS-PHASE NUCLEOPHILIC ADDITION REACTIONS OF NITRILES: A CA MS/MS STUDY OF THE THORPE REACTION.

R.N. Hayes and M.L. Gross, Midwest Center of Mass Spectrometry, Dept. of Chemistry, University of Nebraska-Lincoln, NE 68588-0362.

The study of gas-phase negative ion-molecule reactions has become a significant area of research in gas-phase ion chemistry. Specifically, conducting an ion-molecule reaction in the gas phase provides an opportunity to study the intrinsic properties of a possible adduct without the complicating effects of solvent. Furthermore, an adduct that is formed with excess energy under conditions of higher pressure [e.g., chemical ionization (CI)] can often be collisionally stabilized by either a buffer gas (e.g., CS_2) and/or unreactant neutrals.

In two previous studies we employed tandem mass spectrometry (MS/MS) techniques to isolate and characterize adducts formed in a CI source by gas-phase base-initiated aldol and Reformatsky condensations.^{1,2} The enolate anions $\text{CH}_2=\text{CHO}^-$ and $\text{CH}_2=\text{CC}(\text{OEt})\text{O}^-$, respectively, were shown to react with acetaldehyde and acetone to produce "stable" adducts. Differences in the relative abundances of characteristic losses from the gas-phase adducts compared to appropriate model compounds pointed to the existence of at least three adducts; viz, ion-dipole, proton-bound, and tetrahedral complexes. The major constituents are loosely-associated ion-dipole and proton-bound complexes.

In this study, we report on the gas-phase base-initiated condensations of nitriles. Nitrile condensations in solution, as a class, are known as Thorpe reactions, and are analogous to the well-known aldol reaction of carbonyl compounds.³

Figure 1.

The acetonitrile ($\text{M} - \text{H}$)⁻ anion condenses with acetonitrile to form a "stable" adduct. Upon collisional activation this adduct decomposes primarily to yield CH_2CN^- . Minor fragment ions are formed by losses of H^- , CH_2 and CH_4 . Similarly, an adduct formed by condensation of CD_2CN^- with CD_3CN undergoes the losses of D^- , CD_2 and CD_4 , and a retro reaction to reform CD_2CN^- (Figure 1).

The charge reversal spectrum of the gas-phase adduct shows that a portion of the adduct is covalently bound as evidenced by the multiple dissociation processes. Significant reversion to starting materials is also observed. Ion-dipole complex are typically transparent to charge stripping, and thus, that fraction of adduct undergoing reversion is likely to be a proton-bound complex.

A possible reference ion, $\text{NCCH}=\text{C}(\text{CH}_3)\text{NH}^-$, formed by deprotonation of the condensed phase Thorpe product of CH_3CN , undergoes fragmentation in a manner distinct from the gas-phase adduct. Presumably, the covalent portion of the gas-phase adduct that loses D^- , CD_2 and CD_4 does so not in the enamine form, but rather in the imine conformation as shown in Scheme 1.

Scheme 1

The propionitrile anion reacts with propionitrile to form an adduct that fragments upon CA in a manner analogous to that described for the acetonitrile condensation homologue. Specifically, the adduct eliminates CH_3CH and reverts to CH_3CHCN^- .

A mixed adduct of acetonitrile and propionitrile fragments in a manner that indicates that the dominant conformation of the adduct is that formed by reaction of the acetonitrile anion with neutral propionitrile. This is to say that the major fragmentation process is reversion to CH_2CN^- . A minor loss of CH_2 is also observed that is consistent with such an adduct.

The dinitrile, 1,4-dicyanobutane, was considered a potential candidate for intramolecular cyclization. We were, however, unable to show that indeed cyclization had occurred. Specifically, the major fragmentations that occur upon CA are consistent only with a linear anion.

GAS-PHASE REACTIONS OF FIRST-ROW TRANSITION METAL IONS (Sc^+ - Zn^+) WITH PHENYL HALIDES.

Asgeir Bjarnason, *Science Institute, University of Iceland,
Dunhaga 3, IS-107 Reykjavik, Iceland.*

INTRODUCTION

The reactions of Fe^+ with phenyl halides in the gas phase have been characterized (1-3) and were found to be of particular interest for two reasons. First, the iron-ligand bond energies, $D^0(\text{Fe}^+-\text{C}_6\text{H}_4)$ and $D^0(\text{Fe}^+-\text{C}_6\text{H}_5)$ could be estimated. Second, the initial steps in the metal catalyzed polymerization to produce polyphenylenes could be observed when oligomers of the form $(\text{C}_6\text{H}_4)_n^+$ were produced with $n=1-5$ from $\text{Fe}(\text{C}_6\text{H}_4)_n^+$, which in turn were produced in successive steps of dehydrohalogenations.

The reactions of the other first row transition metal ions (Sc^+ - Zn^+) have now been studied and considerable variations have been observed in the behavior of the different metals.

EXPERIMENTAL

The experiments were carried out, by using a Nicolet FTMS-2000 Fourier transform mass spectrometer. Metal ions were made by focusing a laser pulse onto a target of the pure metal, placed on the direct insertion probe of the mass spectrometer. Following isolation of the metal ion, using double ejection pulses, it was allowed to react with the sample molecule, which was incorporated through the gas inlet system and maintained at a static pressure of about $2 \cdot 10^{-7}$ torr. Reaction time was varied to elucidate reaction paths, and double resonance techniques were used for their verification. Nitrogen or Krypton was used in several cases as a buffer gas and maintained at pressures ten times that of the sample gas.

RESULTS

Sc^+ , Ti^+ , V^+ , Co^+ , and Ni^+ were found to form $\text{M}(\text{C}_6\text{H}_4)_n^+$ in dehydrohalogenation reactions with the phenyl halides, each to a different extent (up to $n=6$), depending on the metal and the halide. This behavior puts them in a group with Fe^+ , but unlike iron, was the absence of oligomer ion formation. Cr^+ , Mn^+ , and Cu^+ were relatively unreactive towards the phenyl halides and at best formed metal/molecular ion cluster ions or formed C_6H_5^+ and MX . Zn^+ , due to its high ionization potential only participated in charge transfer reactions with the phenyl halides.

Initially, two reaction channels are available:

The second reaction channel is never observed in the case of fluoro-, chloro-, or bromobenzene. Variations are observed in the case of iodobenzene. Sc^+ and Ti^+ only react with iodobenzene according to reaction 1, whereas Fe^+ and Co^+ only react via channel 2. V^+ and Ni^+ react through both channels.

The reactions of Fe^+ , Ti^+ , and Co^+ with naphthalene halides have also been studied. Dehydrohalogenation is also observed in those reactions and metal-catalyzed oligomer formation as well. Reactions of Fe^+ , for example gave products of the form $Fe(C_{10}H_6)_n^+$ with $n=1-6$, and the smaller of these were observed to lose the iron atom producing oligomers ions of the form $(C_{10}H_6)_n^+$ with $n=2$ and 3.

These studies were performed with instrument access provided through the courtesy of Nicolet Analytical Instruments, which is gratefully acknowledged. Studies are continuing with a larger selection of metal ions and a wider variety of polymerization processes.

**ELECTROSPRAY IONIZATION MASS SPECTROMETRY AND TANDEM MASS
SPECTROMETRY OF SMALL OLIGONUCLEOTIDES**

Charles G. Edmonds, Charles J. Barinaga, Joseph A. Loo, Harold R. Udseth and
Richard D. Smith
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory*
Richland WA 99352

We have carried out a preliminary evaluation of electrospray ionization (ESI) mass spectrometry for the analysis of small oligonucleotides. In addition to the qualitative and quantitative potential suggested by the success of ESI of peptides and proteins, ESI tandem mass spectrometry may also be amenable to the sequence determination of oligonucleotides. Sequence analysis of large oligonucleotides (n 10 to 10^3) is usually performed by chemical degradation according to Maxam and Gilbert¹ or by the chain termination technique of Sanger *et al.*². Smaller oligonucleotides have been analyzed by mass spectrometry with advantages in speed and simplicity of analysis³. Tandem mass spectrometry has been effectively employed for the singly charged molecular anions of oligonucleotides to a polymerization level of $n = 6^4$. Fenn and co-workers have reported the ESI of nucleotide mono-, di- and triphosphates⁵. A ESI mass spectrum of a deoxynucleotide 14-mer has also been recently reported⁶.

Mass spectra were acquired on a tandem quadrupole mass spectrometer with a sheath flow ion source which has been described elsewhere⁷. Samples prepared in deionized water at a concentration of 1-2 $\mu\text{g}/\mu\text{l}$ were introduced by continuous infusion at 0.25 $\mu\text{l}/\text{min}$. These were obtained from Sigma Chemical Co., St. Louis, MO, Pharmacia LKB Biotechnology Inc., Piscataway NJ and colleagues acknowledge below. Concentrated biochemical buffers required ethanol precipitation of the sample prior to analysis. Daughter ion experiments were performed with Ar collision gas at a thickness of 100×10^{12} atoms/ cm^2 . Lab frame collision energies were ca $100 \cdot q$ eV (where q = number of charges). Calculations of M_r were performed on peak maxima (at unit mass precision) utilizing a computer program which accepts a group of m/z values from a multiply charged distribution and combines these to calculate charge state and M_r from the maximum number of pairs for best precision.

We have examined the ESI mass spectra of a number of synthetic and biological oligodeoxyribo- and oligoribonucleotides ($n = 2-76$). We have observed the efficient collisionally induced dissociation (CID) of multiply charged molecular anions of small ($n = 2-8$) oligonucleotides. These show differences in lab frame energies required for efficient CID and minor differences in preferred modes of fragmentation.

The ESI behavior of larger oligodeoxynucleotides is illustrated in Figure 1 for the synthetic 21-mer d(AAATTGTGCACATCCTGCAGC). These spectra illustrate the increasing contribution of sodium salts to the backbone phosphate with increasing level of polymerization. Up to this level we observe that the lowest m/z member of the peak cluster for a given charge state is invariably the free acid. The ESI mass spectrum of the largest oligonucleotide so far examined, the phenylalanine isoacceptor transfer ribonucleic acid isolated from Brewers yeast (76 nucleotide residues, M_r 24,952) show three overlapping distributions of multiple charged molecular ions corresponding to the intact tRNA and apparent degradations of the native structure.

The ESI mass spectra of oligonucleotides ($n = 2-76$) show abundant multiply charged molecular anions which significantly extend the range of application of a quadrupole mass spectrometer of limited m/z range and allow the precise determination of molecular weight. These multiply charged ions are efficiently dissociated by collision with a neutral gas and afford qualitatively informative daughter fragments. These results highlight significant new capabilities for the mass spectrometric analysis of oligonucleotides. Further studies of the ESI of oligonucleotides and the CID of the multiply charged molecular ions produced by CE/ESI MS are proceeding in our laboratory.

FAB TANDEM MS OF PROTEASE AUTOLYSIS PRODUCTS

Martha M. Vestling, Catherine C. Fenselau, and Constance M. Murphy
Department of Chemistry and Biochemistry
University of Maryland Baltimore County, Baltimore, MD 21228

Despite dramatic increases in the mass range of FAB mass spectrometry, most proteins are still large and must be cleaved into smaller peptides for analysis. The cleanest most reproducible way to effect selective cleavage is to hydrolyze specific amide bonds with suitable enzymes. Trypsin, chymotrypsin, and *Staphylococcus aureus* V8 protease are the most widely used proteases for this purpose. Their molecular weights range from 23,900 to 27,000 Daltons. Generally, the protein to enzyme ratios used are between 10/1 and 200/1 (wt/wt). Unfortunately, proteases also catalyze their own hydrolysis (autolysis). The peptides produced by protease autolysis are presumably mixed in with the peptides from target proteins and thus are part of the background in HPLC analyses and in FAB mass spectra of digested mixtures. We are identifying the major peptides produced by autolysis and attempting to ascertain the extent of their background participation.

Trypsin [EC 3.4.21.4] is the most frequently used protease. It catalyzes hydrolysis of amide bonds whose carbonyls come from either arginine (R) or lysine (K). Trypsin's sequence (1) of 223 amino acids includes two arginines and 14 lysines making it a substrate for itself. When trypsin [bovine pancreas, TPCK treated, Sigma] is dissolved in 0.1 M NH_4HCO_3 /0.1 mM CaCl_2 (1 mg/mL), it completely autolyzes in two hours at room temperature (See Figure 1.) When the lyophilized reaction mixture is subjected to FAB mass spectrometry, ions accounting for most (79%) of its 223 amino acids are observed (See Figure 2) especially if the mixture is partially separated by HPLC before FAB/MS (See Figure 3.) Ions at 659 (See Figure 4.), 805, and 1154 have been sequenced using MS/MS confirming the assignments based on mapping.

In our hands, calcium chloride stabilizes an ice cold aqueous solution of trypsin. However, trypsin dissolved in 0.1 M NH_4HCO_3 alone, completely autolyzes within two hours at room temperature giving the same HPLC trace and the same mass spectrum as it does in the presence of calcium chloride.

All of the mass spectra were obtained on a JEOL HX110/110 (with a JEOL DA5000 data system) at the full accelerating voltage of 10 keV. The FAB gun was operated at 6 keV with xenon as the FAB gas. Helium was the collision gas in the MS/MS experiments.

SEQUENTIAL MASS SPECTROMETRY ON A HYBRID TANDEM INSTRUMENT OF BEqQ CONFIGURATION

G.C. Thorne and S.J. Gaskell
Center for Experimental Therapeutics
Baylor College of Medicine, Houston, TX 77030

The use of tandem mass spectrometry together with fast atom bombardment has become increasingly important in the structure elucidation of peptides. A standard technique employed on a double focusing sector/quadrupole instrument is to select a specific parent ion beam with the magnetic and electric sectors and subsequently use the quadrupole to obtain a spectrum of daughter ions derived from the chosen parent. Analyses of these type yield improved information which might be obscured by high background components in a conventional spectrum.

In principle, further improvements in structural elucidation may be achieved by incorporation of additional stages of mass spectrometry to give sequential MS.^{1,2} Modifications to our instrument (a VG ZAB SEQ) have enabled us to implement this technique in our laboratory. The ESA voltage depends on the value of its 0-10V program. Under normal operating circumstances this is linked to the 0-10V accelerating voltage program. The accelerating voltage and ESA voltage therefore usually maintain a fixed ratio. We have incorporated the option of uncoupling this link and operating the ESA supply via an independent 0-10V supply derived from a 5k ohm resistor in series with a 10-turn 10k potentiometer connected between a 0V and 15V rail. In the sequential daughter ion experiment, the initial parent ion beam is selected by the magnetic sector and subjected to collisional activation in the cell between B and E.. A specific daughter ion fragment is then transmitted through the electric sector and collisionally activated in the rf-only quadrupole. The quadrupole mass filter is scanned to obtain a spectrum of "granddaughter" ions produced by fragmentation of the transmitted daughter.

As an example of this sequential MS approach, we have determined the origin of the "internal" fragment at m/z 205 (assigned as $(B_4Y'_3)_2$) in the daughter ion spectrum derived from leucine-enkephalin MH^+ ions^{3,4} (Figure 1.). It was not possible to predict from the daughter ion spectrum whether the ion was formed via an initial B_4 fragmentation (m/z 425) or a Y'_3 fragmentation (m/z 336). However, this ambiguity was resolved by setting the magnetic sector to transmit the parent ion beam at m/z 556 and using the electric sector to select either the m/z 425 (Figure 2, upper spectrum) or m/z 336 (Figure 2, lower spectrum) daughter ion beam prior to scanning the quadrupole filter over a range to include m/z 205. It was clearly seen that the major origin of m/z 205 ions was the Y'_3 fragment at m/z 336. It can also be seen from Figure 2 that the internal fragment $(A_4Y'_3)_2$ at m/z 177 also arises via the initial Y'_3 fragment at m/z 336.

Daughter ion spectra of metal-cationised peptides have been shown to provide structural information which complements that provided by CAD of protonated species.^{5,6} The conventional FAB spectrum of the europium adduct of leucine-enkephalin, formed by the addition of $Eu(NO_3)_3$ to the liquid matrix, includes doublets at m/z 705 and m/z 707 indicating the incorporation of both ^{151}Eu and ^{153}Eu .

Tandem MS and sequential MS analyses were performed on each isotopic variant and the complementary daughter ion spectra and sequential MS data from $[M-H+^{151}Eu]^+$ and $[M-H+^{153}Eu]^+$ were recorded. Both C- and N-terminal fragments were observed, each retaining the europium. The complementary MS/MS and MS/MS/MS data suggest a multiplicity of sites of interaction between peptide and metal cation.

APPLICATIONS OF STABLE ISOTOPES AND TANDEM MASS SPECTROMETRY TO THE
CHARACTERIZATION OF REACTIVE METABOLITE-PEPTIDE INTERACTIONS.

Paul G. Pearson, J. Greg Slatter, Mohamed S. Rashed, Deog-Hwa Han
and Thomas A. Baillie.

Department of Medicinal Chemistry, School of Pharmacy, University of Washington,
Seattle WA 98195.

Covalent modification of protein or peptide amino-acid residues by electrophilic species, generated metabolically from drugs or other xenobiotics, may represent an initial event in the expression of chemical-induced toxicity. Understanding the nature of the chemical events and the target amino-acid residues involved, allows the sites of modification in toxicologically important target proteins or peptides to be predicted.

A major metabolite of the investigational anti-tumour agent, N-methylformamide (NMF) in rodents is S-(N-methylcarbamoyl)glutathione (SMG) which possesses similar structural features to reactive glutathione and cysteine conjugates of allyl- and benzyl isothiocyanate¹. Consequently, SMG may be a reactive metabolite and display the potential to covalently modify free thiol functionalities in peptides.

The objective of the present investigation was to evaluate the reactivity of two cysteine analogs of SMG *viz* S-(N-methylcarbamoyl)cysteine (SMC) and S-(N-trideutero-methylcarbamoyl)cysteine (D₃-SMC) towards oxytocin, a model thiol-containing peptide. The structures of the oxytocin adducts were established by fast-atom bombardment tandem mass spectrometry (FAB/MS-MS).

Experimental: SMC or trideuteromethyl-SMC (10 equiv.) were incubated with reduced² or oxidized oxytocin, in aqueous triethylamine-formate buffer (pH 7.7) for 6 hr, and the lyophilized incubations were analyzed directly by FAB / MS. Collision-induced dissociation (CID) daughter ion spectra were recorded on a VG 70 SEQ hybrid tandem instrument of EBQ geometry, equipped with an Ion-Tech fast atom gun, and a VG11/250 data system. CID was performed in the first (rf-only) quadrupole employing argon as a collision gas (3.5×10^{-6} Torr) and collision energies of 35 eV. Daughter ion spectra were recorded via the data system in the multi-channel-analysis mode.

Results and Discussion: The CID daughter ion spectra of reduced oxytocin, was characterized by a structurally informative (Y_n) and (B_n) series ions, with an intense B₆ ion (m/z 725) diagnostic for the reduced Cys-1 and Cys-6 residues. The assignment of sequence ions was confirmed by shifts in m/z of (B_n) series ions upon acetylation or by comparison with oxidized oxytocin. Upon reaction of SMC with reduced oxytocin, two adducted peptides were recognized by FAB/MS consistent with the formation of mono- (MH⁺ = 1066) and bis-N-methylcarbamoylated (MH⁺ = 1123) peptides. In incubations of reduced oxytocin with D₃-SMC a shift in m/z values to 1069 and 1129, for the mono- and bis-carbamoylated species respectively was observed. A CID spectra of MH⁺ = m/z 1066 revealed the presence of two mono-adducted peptides which arose from carbamoylation of either Cys-6 or Cys-1 in a ratio of 5:1; an isotopically induced shift in mass was observed for the Y₄⁺ and B₆⁺ ions when D₃-SMC was used in place of SMC.

A daughter ion spectra of the bis-adduct obtained by CID on MH⁺ = 1129 (figure 1) revealed a series of sequence ions diagnostic of modification of oxytocin at Cys-1 and Cys-6. No carbamoylation of the terminal glycinamide was observed based upon a shift in B₆⁺ ion at m/z 725 to 845, and the presence of the unchanged Y₃⁺ ion at m/z 285. In addition, the Y₄⁺ ion at m/z 448, when related to the unaltered Y₃⁺ ion (m/z 285) reports specifically upon modification of Cys-6; in each case an appropriate isotopically induced shift of 3 or 6u was observed. Reaction of oxidized oxytocin with SMC resulted in the appearance of mono- and bis-adducted species of identical mass to those observed for reduced oxytocin. The CID daughter ion spectra of these adducts compared closely with the spectra obtained upon carbamoylation of reduced oxytocin by SMC.

In conclusion, the results indicate that SMC is a reactive S-linked conjugate which may covalently modify oxytocin by specific carbamoylation of cysteinyl thiols. In addition we have demonstrated the value of MS/MS techniques and stable isotope methodology to study the interactions of a reactive metabolite with a model peptide.

Figure 1. Daughter ion spectra of bis-S-(N-trideutero-methylcarbamoyl)oxytocin obtained by CID on MH⁺ = 1129. The proposed structure of the adduct and the origin of the daughter ions, according to Roepstorff and Fohlman³ nomenclature, is as indicated.

ALTERNATE MASS SPECTROMETRIC METHODS FOR PEPTIDE SEQUENCE DETERMINATION

Mark S. Bolgar*, G.C. DiDonato, J.H. Johnson, A.A. Tymiak, S.E. Unger+ and B.M. Warrack

The Squibb Institute for Medical Research, P.O. Box 4000, Princeton, NJ 08543-4000

*current address: Glaxo, Inc., Department of Drug Metabolism, Research Triangle Park, NC 27709

Introduction In recent years the utility of tandem mass spectrometric methods for the determination of peptide sequence has been clearly demonstrated. In our laboratory we have had to sequence naturally occurring peptidic antibiotics that did not yield useful structural information using our MS/MS instruments (a VG-ZAB-HF and Finnigan TSQ 4600). Fortunately, there are other mass spectrometric techniques that aid in sequence determination. These techniques are:

1) Amino acid analysis by DCI MS/MS of an acid hydrolysate, 2) Amino acid analysis and chirality determination by GC-MS, 3) Peptide mapping of mild acid hydrolysates by FAB, 4) Identification of Edman degradation products by FAB and CI MS and MS/MS.

Amino acid analysis by DCI allows rapid identification of residues obtained by total acid hydrolysis. Daughter ion spectra are obtained from each of the molecular ions and compared to the library spectra for positive identification of the amino acids.

Since peptides produced by micro-organisms may contain amino acids in both the D and L form, GC-MS is useful for determining not only the identity of amino acids, but also their chiralities.

Knowledge of amino acid content greatly aids in interpreting FAB mass spectra obtained from a mild acid hydrolysis of a peptide. The overlapping peptide fragments obtained make it possible to determine large portions of the original sequence.

The products from an Edman degradation of the peptide can be positively identified by examination of the cleaved PTH-amino acid by CI MS/MS and by analyzing the residual peptide by FAB-MS to determine mass loss.

lation site and attach to nascent neutrals. In the TOF experiment, the strong electric extraction field clears all charged particles as they evolve, so no such attachment can take place. The phenomenon in the FTMS experiment is similar to *chemical ionization*. 3) Most spectra show at least one of three distributions of C clusters. Polyimide is the most general case, in which low (C_{9-25}), intermediate ($C_{20-40}H_{1-12}$) and high mass (C_{2n} , $25 < n < 225$) clusters are observed. The intermediate range is the most common. 4) Ion series consistent with the general formula $+HA_mB_n$ appear. That is, stable subunits which may or may not be present in the original polymer seem to condense to form series of (protonated) ions. In some cases, "B" appears to be bare carbon. 5) Spectra often evolve as a function of laser fluence and number of laser shots to the same spot. This observation is important for laser modification of polymers as well as for analytical purposes. The positive ion spectrum of poly(methylmethacrylate) (PMMA) presented here shows both protonated rearrangement products and intermediate mass C clusters.

Negative ion spectra: These spectra often exhibit far more structural ions than corresponding positive ion spectra. This is particularly true for poly(phenylene sulfide), poly(vinyl acetate), and is illustrated for PMMA.

In closing, we cite the following observations. All polymers studied by us to date can be easily distinguished based on their FTMS-LAMMS spectra, which are radically different from literature TOF spectra. From these differences and a consideration of the experimental arrangement, we can propose a number of mechanisms to explain observed the observed ions. These proposals await confirmation by high mass resolution studies which are in progress.

SELECTIVE IDENTIFICATION OF DISULFIDE-CONTAINING PEPTIDES BY ELECTROCHEMICAL HPLC AND FAB/MS

Yiping Sun, Philip C. Andrews and David L. Smith
Departments of Medicinal Chemistry & Pharmacognosy and Biochemistry
Purdue University, West Lafayette, IN 47907

Peptides containing disulfide bonds are important constituents of the extracts of many organs, and are often present in digests of many enzymes. Because of their importance, it is desirable to have rapid and definitive methods for detecting and identifying disulfide-containing peptides. A general procedure for identifying peptides containing disulfide bonds in complex mixtures involves fractionation of the mixture by HPLC and analysis of all chromatographic fractions, before and after reduction of disulfide bonds, by FAB/MS. This is not an efficient approach when only a few of the fractions contain peptides with disulfide bonds. We have extended this general method by using a dual electrode electrochemical detector to denote those fractions which contain peptides with disulfide bonds. As a result, only the fractions of interest are analyzed by FAB/MS.

Disulfide-containing peptides can be detected by using two Hg/Au electrodes in series such that the first one (upstream) is used as a generator to reduce the disulfide bond, and the second one (downstream) is used to detect the thiol produced by the upstream electrode. Chromatograms of the bovine pituitary extract recorded with tandem UV and electrochemical detectors are shown in Fig. 1. Chromatogram A was obtained by monitoring the UV absorbance at 230 nm. Chromatograms B and C were obtained with the EC detector in the two- and one- electrode modes, respectively. Since peaks 2 and 3 are not present when only one electrode is used, these peptides most likely contain disulfide bonds. Peak 1 elutes in the void volume.

FAB mass spectra of peak 3 from the chromatograms of the pituitary extract, taken before and after treatment with performic acid, are shown in Fig. 2. The spectrum in Fig. 2a has a strong peak corresponding to a protonated molecular ion at m/z 1007. The small peak at m/z 1115 is a 1-thioglycerol adduct of the molecular ion at m/z 1007. Upon treatment of this fraction with performic acid, a strong single protonated molecular ion m/z 1105 was found. This shift of 98 m/z is consistent with oxidation of the disulfide bond to two cysteic acid moieties. It was concluded that the substance comprising peak 3 is oxytocin, and peak 2 is [Arg⁸]-vasopressin. This assignment was confirmed by comparing their chromatographic retention times and FAB mass spectra to those reference samples of oxytocin and [Arg⁸]-vasopressin.

Chromatograms of the catfish pancreas extract recorded with tandem UV and EC detectors shown that it has many disulfide-containing peptides (Data are not shown.). FAB mass spectra of fraction 10 and 11 have no peaks from 2000 m/z to 3200 m/z . Upon reduction, fraction 10 gave one pair of peaks (A), which is insulin 1 chain A (m/z 2390), chain B (m/z 3119), whereas fraction 11 gave another pair of peaks (B), which is insulin 2 chain A (m/z 2381), chain B (m/z 3175). It was concluded that the substance in fraction 10 is catfish insulin 1 with average mass (MH^+) 5502, and fraction 11 is catfish insulin 2 with average mass (MH^+) 5549. These assignments were confirmed by amino acid sequence analysis, and performic acid oxidation followed by FAB/MS analysis.

In summary, the combination of RPHPLC/electrochemical detection and FAB/MS analysis may be used to identify cystine-containing peptides. This is attractive because it is rapid, specific for disulfide-containing peptides, and applicable to a variety of complex biological mixtures.

Amino-Terminal Derivatization of Peptides Yields Improved CAD Spectra

John T. Stults, Roger Halualani, and Ronald Wetzel

Protein Chemistry Department, Genentech, Inc.
460 Point San Bruno Blvd., South San Francisco, CA 94080

Mass spectrometry is now an integral tool in the protein sequencing laboratory. Peptide sequencing by tandem mass spectrometry (MS/MS) in particular is proving extremely useful for peptide sequencing. The complexity of the ion fragmentations, however, often makes data interpretation difficult and time consuming. Sophisticated computer programs to aid interpretation are generally required to determine the correct sequence in a timely manner. An alternative approach we have pursued is to modify the peptide to produce simplified, predictable fragmentation.

Attachment of a fixed positive charge to the peptide amino-terminus, to favor production of N-terminal fragment ions, is especially attractive for simplifying the spectrum [1]. The reaction described here consists of two steps (see Scheme 1) [2]. In the first step, 1-30 nmol of peptide were dissolved in 200 μ l of 0.01M MES (2-[N-morpholino]ethanesulfonic acid), pH 6, and cooled to 0°C in a 1.5 ml Eppendorf tube. To this solution was added 2 μ l of 300 mM iodoacetic anhydride (Aldrich) in dry THF. The sample was vortexed. A second aliquot of the anhydride was added after 3 min. To add the quaternary ammonium group in the second step, the pH of the solution was raised to pH 8 with 20 μ l of 0.5 M N-ethylmorpholine. Thiocholine iodide (Pfaltz and Bauer) was added and the sample incubated at 37°C for 2 hrs. The reaction was terminated by drying, *in vacuo*, or by injection of the solution into an HPLC system. The use of nonvolatile buffer and excess reagent necessitates sample cleanup after the reactions. However, if the reaction is carried out immediately after enzymatic digestion, the cleanup and separation of the proteolytic fragments are accomplished simultaneously.

The first step selectively modifies the N-terminus of an unblocked peptide by exploiting the differences between the pKa values of its α -amino group (pKa~8) and the side chain amino groups of Lys (~10.5) and Arg (~12). Although different N-terminal amino acids affect reactivity and degree of specificity, the responses of twenty model hexapeptides (X-GAKQA, X = each of the 20 common amino acids) are sufficiently similar that conditions were found which should modify any peptide containing 0-1 Lys residues with at least 80% selectivity for the N-terminus, with essentially complete conversion of starting peptide with no detectable side reactions. Because the iodoacetyl functionality readily reacts with free sulfhydryl groups, free cysteines must be protected prior to reaction. Conventional reduction and alkylation of the peptides is sufficient. The use of a two-step reaction allows the quaternary ammonium compound to be changed without altering the specificity of the α -amino attachment. For example, use of a compound with a longer hydrocarbon chain should increase the hydrophobicity of the peptide to make its desorption from a liquid matrix more favorable.

The CAD spectra were obtained with a JEOL HX110HF/HX110HF tandem double focusing mass spectrometer, operating with a JEOL DA-5000 data system. Ionization by FAB with 6 keV xenon atoms or LSIMS using 15 keV Cs⁺ ions produced positive ions that were analyzed at 10 keV accelerating voltage, 3000 resolution. Nitrobenzyl alcohol was preferred as the matrix because degradation products were observed in glycerol, thioglycerol, and DTT:DTE (5:1). The

SCHEME 1.

^{12}C -isotope peak of the precursor M^+ ions was selected at unit resolution with MS-1, the ions passed into the collision cell containing a pressure of helium sufficient to attenuate the parent ion beam to 25% of its original intensity, and the fragmentation resulting from collision-induced dissociation was measured with MS-2.

The CAD spectra of the N-terminally derivatized peptides (Fig. 1 and 2) show only fragment ions derived from the amino-terminus (a_n , c_n , d_n), the a_n and d_n ions predominating. The strong $\text{M}^+-\text{N}(\text{CH}_3)_3$ peak, and several a_n -trimethylamine ions, are likely formed by gas-phase nucleophilic attack of the sulfur on the amino carbon to form a cyclic sulfonium ion with loss of trimethylamine.

The utility of the derivative may be summarized as follows:

1. Simplified interpretation -- fewer fragments, all derived from the N-terminus, are produced.
2. Enhanced signal -- fewer fragment ion types mean ion intensity is spread among fewer channels.
3. Lower resolving power required for daughter ions -- sequence ions solely from the N-terminus produce well separated peaks.
4. Distinction of Ile and Leu -- abundant d_n ions are produced that differentiate these residues [3].

INVESTIGATION OF THE FRAGMENTATION OF PEPTIDES AS A FUNCTION OF COLLISION
ENERGY IN A FOUR-SECTOR TANDEM MASS SPECTROMETER.

S.A. Martin, Genetics Institute, Andover, MA 01810.

Over the course of the last few years we have investigated the type and extent of fragmentation of peptides undergoing high energy collisions (10000 eV). These studies lead to the characterization of three fragmentation series; d_n , v_n and w_n , which are apparently not observed in low energy collision spectra of peptides acquired with triple quadrupole mass spectrometers (1). Since these ion series are important in determining the covalent structure of peptides, we have investigated the collision energy (CE) regime in which the relative abundance of these fragment ions change. In the process of defining these transitions we have evaluated the overall information content of the MS/MS spectra of peptides as a function of CE. This information is important not only for understanding the mechanisms of fragmentation but also for determining the CE to be used with focal plane detectors which can simultaneously integrate 20-30% of the mass range. In these experiments very low collision energies are required in order to transmit the product ions, which vary in both mass and energy through the electric sector which typically has an energy bandpass of approximately four percent.

All experiments were performed on a JEOL HX110/HX110 tandem mass spectrometer in which the collision energy (E_{coll}) is continuously variable from 10000 to 150 eV. The initial energy of the precursor and final energy of the product ions is 10000 eV (V_{acc}). The resolution of MS-1 was sufficient to transmit only the $^{12}C(M+H)^+$ ion into the collision region. The peptides chosen for this study, renin substrate (1757.9), LHRH (1181.6) and β -lipotropin (950.5), represent all the major fragmentation processes observed at high collision energies: a_n , b_n , d_n , v_n , w_n , x_n and y_n . The product ion spectra were recorded at more than ten CE values ranging from 10000 to 130 eV employing both helium and xenon as the collision gas. The product ion spectra for all the peptides examined with helium gas were very similar for CE= 10000 to 2000 eV at which point the relative abundance of the d_n , v_n , and w_n ions began to decrease and were absent below 500 eV. When helium was replaced with xenon the same trend was observed, however, the relative abundance of these ion series did not begin to decrease until CE= 500 eV and were almost completely absent in the range of 150 to 200 eV. The distribution of fragment ions as a function of CE with xenon gas is shown in Figure 1 for renin substrate at E_{coll} = 750 and 130 eV, respectively. At E_{coll} = 750 eV the relative abundance of product ions is almost identical to that at E_{coll} = 10000 eV with very abundant a_n and d_n ions throughout the MS/MS spectrum. This is in contrast to the MS/MS spectrum of the same sample at E_{coll} = 130 eV (Figure 1). At this CE all the d_n ions are absent and several ions which were not observed at the higher collision energies, i.e. b_n-NH_3 , b_6 , are very abundant. This transition from one type of ion series to another as a function of CE is illustrated in Figure 2 for three product ions of renin substrate. This plot indicates that the transition occurs around E_{coll} = 400 eV, therefore, to obtain collision spectra which retain the characteristic side chain losses associated with high energy collisions an E_{coll} > 400 eV is required with xenon as the collision gas. These studies indicate that it is feasible to acquire collision spectra with E_{coll} from 10000 to 130 eV in a tandem magnetic sector mass spectrometer and that the transition from high to low energy type MS/MS spectra is dependent on the collision gas and, therefore, the center of mass collision energy.

EFFECT OF TRIFLUOROACETIC ACID ON THE REDUCTION OF DISULFIDE BRIDGES IN PEPTIDES ANALYZED BY FAB/MS

J. Visentini, J. Gauthier¹⁾, and M. J. Bertrand

Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, P. O. Box 6128, Montreal, Canada H3C 3J7,

¹⁾ BioMega Inc., 2100 Cunard, Laval, Quebec, Canada H7S 2G5.

The analysis of peptides by fast atom bombardment mass spectrometry is a good example of the extensive use and utility of desorption-ionization techniques for the characterization of polar, involatile and higher molecular weight compounds. This technique produces parent-molecular ions, which along with their isotopic clusters, can be useful in determining the molecular weight and empirical formula of the compound. Both these types of information are essential for the characterization of a peptide. However, a common problem that can be encountered when analyzing peptides by FAB/MS is that the $(M+H+n)^+$ ($n \geq 2$) peak intensities are higher than theoretically calculated. It is believed that reduction reactions occurring in the matrix are responsible for the distortion observed in the isotopic cluster which can lead to the misidentification of the peptide. The positive deviation noted in the isotopic peak ratios appears to be particularly exaggerated with the presence of a disulfide bridge in the molecule.

In order to study the effect of instrumental parameters on this phenomenon, deamino arginine vasopressin (DAVP) and arginine vasopressin (AVP), which are both neurohormonal peptides, have been chosen. The molecular structures of these peptides are shown in figure 1. In preliminary experiments conducted in thioglycerol, it was noticed that DAVP and AVP stabilized with acetic acid produced parent ions at m/z 1071 and 1086 respectively. The protonated molecular ions for these compounds should occur at m/z 1069 and 1084. The same peptides stabilized with trifluoroacetic acid, however, showed the parent ion at the correct mass. The results obtained for DAVP are illustrated in Figure 2 which shows a portion of the mass spectra of both types of acetates. Using "extended resolution multiple peak monitoring" and signal averaging techniques, later experiments were conducted to accurately measure the isotopic peak ratios. The results obtained in these experiments demonstrated that the $(A+2)/A$ isotopic peak ratio increased with time. Both the trifluoroacetate and acetate salts showed a time dependence of the $(A+2)/A$ ratio, but the rate of reduction for the acetate salt was found to be approximately 30 times faster than that of the trifluoroacetate. In other experiments, trifluoroacetic acid was added to the acetate sample prior to bombardment and it was found to decrease the amount of reduction substantially so that the parent ions for DAVP and AVP now occurred at m/z 1069 and 1084 respectively. Even though spectra obtained under these conditions provided parent ions at the correct mass, the reduction process was not completely eliminated. If the addition of trifluoroacetic acid was made after the sample had been bombarded, the reduction could not be inhibited. This observation indicates that the reduction process is irreversible under the experimental conditions used.

In order to assess the importance of solution parameters on the reduction process, the peptide DAVP stabilized with acetic acid was analyzed in different matrices. The results of these experiments are shown in Table I where the measured $A+2/A$ ratios are given as a function of the nature of the matrix. It can be seen from the data that reduction as measured by the $(A+2)/A$ ratio is most prominent when a 5:1 mixture of dithiothreitol/dithioerythritol (magic bullet) is utilized as matrix. This is not surprising since these molecules contain two thiol groups which are known to reduce disulfide bridges in solution. As would be expected, the observed reduction process is lesser with thioglycerol in which only one thiol group is found. Furthermore, samples analyzed in glycerol show reduction, but to a much smaller extent, while samples analyzed in 2-hydroxyethyl disulfide and 3-nitrobenzylalcohol exhibit the least amount of reduction. The disulfide bridge in hydroxyethyl disulfide and the nitrophenyl moiety in nitrobenzylalcohol are electron scavengers and can therefore be expected to decrease the possibility of reduction.

The results obtained in this work are useful in determining the types of reduction reactions that can occur when analyzing peptides by FAB/MS. It can be concluded that the choice of a proper matrix and addition of trifluoroacetic acid can be useful in inhibiting the possibility of reduction processes and therefore misidentification. Both of these parameters have determining effects on the accuracy of the results, since the $A+2/A$ is found to vary from 8.5, under the worst conditions (acetate salt in magic bullet), to approximately 0.28 in experiments where either TFA is added or a proper matrix is used. Thus the results obtained indicate that not only can accurate values be obtained for the isotopic ratios when analyzing peptides containing disulfide bridges but that the factors influencing reduction have drastic effects since they can change the reduction rate by a factor of 30.

Another finding in this study that is worthy of mention concerns the thiolglycerol adducts of the reduced form of the peptides. Close examination of the spectra of DAVP and AVP revealed that, in thiolglycerol, adduct ions $(M + \text{Thiolglycerol} + H)^+$ corresponding to the non-reduced form of the peptides were observed at m/z 1177 and 1192 respectively. However, thiolglycerol adducts of the reduced forms expected to be observed at m/z 1179 and 1194 were essentially absent from the spectra. This implies that either the adduct is actually a reaction product of the peptide and thiolglycerol or that thiolglycerol adducts "protect" the molecule from being reduced. Studies are presently being conducted to explain this peculiar observation and to elucidate other factors involved in the more general phenomenon of reduction of different types of peptides under FAB conditions.

A MASS SPECTROMETRIC TECHNIQUE FOR DETECTING AND LOCATING
ERRORS IN SYNTHETIC PEPTIDES

Swapan K. Chowdhury and Brian T. Chait
The Rockefeller University
New York, N.Y. 10021 USA

The utility of a new mass spectrometric technique¹ for detecting and identifying peptide by-products produced in the synthesis of peptides is demonstrated. The technique involves three sequential steps: (1) Practically nondestructive ²⁵²Cf plasma desorption mass spectrometric analysis of monolayer amounts of peptide(s) of interest bound to a thin layer of nitrocellulose. (2) Enzyme catalyzed microscale chemical reaction of the surface bound peptide(s) to produce structurally informative hydrolysis products. (3) Plasma desorption mass spectrometric analysis of these hydrolysis products. The first step determines the presence and molecular weights of unwanted by-products resulting from errors or incomplete reactions during synthesis. The subsequent two steps provide information on the precise location in the peptides where errors have occurred.

In the present paper, the technique is applied to an investigation of unwanted peptide by-products associated with the use of tryptophan, protected on the indole nitrogen with the formyl group. Results are presented on two tryptophan containing synthetic peptides in which large formyl group containing impurities are observed². The sequence of the first peptide, melittin is G I G A V L K V L T T G L P A L I S W I K R K R Q Q-NH₂. The PD mass spectrum of a 1nmol HPLC purified melittin sample, (Fig.1(a)) showed the presence of an impurity ion ($M_1^1 + H$)⁺, with mass 28u higher than that of the desired melittin ion ($M_1 + H$)⁺. The 28u mass difference indicated the retention of the formyl group on the impurity and was thought to be the result of either an incomplete deprotection of Trp(For) or a transformylation modification during deprotection. In order to locate the position of this formyl group, the sample used to obtain the spectrum shown in Fig.1(a) was removed from the mass spectrometer and treated with 10⁻¹¹ mol of trypsin for 10 minutes at 37°C. The mass spectrum of this trypsin treated sample (Fig.1(b)) exhibits a series of new peaks corresponding to the products of hydrolysis of melittin and the melittin impurity. Since all the fragments are observed as doublets (28u apart), we conclude that the formyl group in the impurity, M_1^1 , is located between residues 8-21 inclusive. To obtain more information regarding the location of the formyl group, 1 nmol of freshly deposited sample on NC was treated with 10⁻¹⁰ mol of proteinase K for 10 min. The mass spectrum of the resulting hydrolysis products is shown in Fig.1(c). The ion (20-26)⁺ clearly lacks the companion peak (20-26)⁺₁, which indicates the absence of the formyl group in the impurity melittin in residues 20-26. However, the presence of the pair (19-26)⁺ and (19-26)⁺₁ indicates that the formyl group is present in residues 19-26. Therefore the formyl group is located on Trp-19 of the impurity melittin. Supporting evidence for the location of the formyl group on Trp-19 was similarly deduced from the mass spectrum (Fig.1(d)) obtained after α -chymotrypsin treatment of the melittin sample. A summary of the observed cleavages from all three enzymatic hydrolysis is shown in Fig. 2.

A similar investigation was carried out on a sample of synthetic [Bpa-8]dynorphin A (1-17), with sequence Y G G F L R R Bpa R P K L K W D N Q, where Bpa denotes p-benzoyl-phenylalanine. The PD mass spectrum of this sample, (Fig.3) also showed the presence of an impurity ion ($M_2^1 + H$)⁺ 28u higher than the Dynorphin ion ($M_2 + H$)⁺. An investigation of the mass spectrometric fragmentation in Fig.3 and the mass spectra following digestion with α -chymotrypsin, proteinase K, and carboxypeptidase B (data not shown) demonstrated² that the formyl group is no longer present on Trp-14, but in this case has migrated to the neighboring lys-11 or lys-13.

**PULSED ION BOMBARDMENT TIME-OF-FLIGHT MASS SPECTROMETER
WITH OPTIMUM SENSITIVITY FOR PEPTIDES IN 1-2 PICOMOLE RANGE**

Viswanatham Katta and Brian T. Chait
The Rockefeller University, New York, NY-10021

Ion bombardment time-of-flight (TOF) mass spectrometry is an extremely sensitive technique. In order to obtain the best response from a sample, it is desirable that all the available sample be efficiently utilized in producing the mass spectrum. This can be achieved by concentrating the sample on a small area; bombarding it with a sufficiently intense, tightly focussed ion beam to desorb the entire sample; and analysing the secondary ion masses with an efficient TOF mass analyzer. We have designed and constructed a pulsed ion bombardment TOF mass spectrometer (PIB-MS) that utilizes this principle (1,2) and have achieved a sensitivity with this instrument such that the highest yield occurs for the peptide amounts of the order of 1 picomole. The PIB-MS is schematically shown in Figure 1. 30 keV indium ion beam from an electrohydrodynamic liquid metal ion source is focussed to a 100 micron diameter spot on the sample probe (2mm diameter) and is caused to sweep across it when pulsed. The beam is pulsed at a rate of 2 kHz and each pulse of 5-10 nanoseconds duration contains 500-1000 indium ions.

In the PIB-MS the sample utilization is quite high in the area of bombardment (100 micron x 2mm = 0.2 mm²). This is evident from Figure 2 which shows the decay of the (M+H)⁺ ion signal from arginine vasopressin (MW=1083) as a function of the duration of bombardment by indium ion beam. Here 1 picomole of the peptide was absorbed to a thin film of nitrocellulose deposited on the 'whole area' of the probe tip. The signal decreased nearly exponentially with a half life of about 23 minutes. The data shown in Figure 2 also shows that by steering the beam to a different spot on the probe tip, after a 90 minute bombardment, the signal returns to its original level. This indicates that higher sensitivities could be obtained if all the sample were concentrated in the area swept by the bombarding beam. To achieve this further increase in sensitivity the peptides were restricted to remain on a small area nitrocellulose (NC) stripe (250 um x 2mm) on the probe tip. Figure 3 compares the spectra obtained from 100 femtomoles of arginine vasopressin deposited on the 'whole area' and on the NC 'stripe'. A three fold increase in signal for the peptide on the stripe can be seen.

Figure 4 compares the (M+H)⁺ ion yield as a function of the amount of arginine vasopressin for the case of peptide deposited on the whole probe tip area versus that of peptide deposited on the NC stripe. In the former case the signal increased linearly for amounts up to 10 picomoles. For amounts in excess of 10 picomoles, the yield first levels out and then actually begins to decrease. For the sample deposited on the stripe on the other hand, the signal reached a saturation value for an amount of about 1 picomole.

Such yield maximization at the 1-2 picomoles level was also observed with other peptides in the mass range 1000-6000u (e.g. a synthetic peptide analogue of calcitonin (MW=3576) and bovine insulin (MW=5733)).

Thus the design goal of attaining 1 picomole optimum sensitivity for peptides was accomplished by efficient utilization of the available sample with the described pulsed ion bombardment time-of-flight mass spectrometer.

The Effect of Primary Ionization on the MS/MS Spectra
of Small Peptides Using a Triple Quadrupole MS

Russell H. Robins and F.W. Crow
The Upjohn Company, Kalamazoo Michigan

Recent advances in MS/MS instrumentation have fostered interest in the Collisionally Induced Dissociation (CID) daughter spectra of peptides. Structurally significant fragmentation of biomolecules induced by Collisional Activation (CA) has been shown to provide both primary sequence and modification site information. The technique has been used for peptide structural studies not applicable to classical Edman degradation.

A common perception is that MS/MS of peptides can be best performed using FAB primary ionization followed by high energy CA in multisection instruments. We have examined the utility of simpler and less expensive triple quadrupole instrumentation for this purpose.

The inherent inefficiency of CA, the low collision energies attainable (<200 eV) and poor high mass sensitivity of the quad relative to sector instruments makes acquisition of high mass CID spectra challenging. Quads, however, are uniquely suited for detection of Unimolecular Decomposition (UMD) products of the parent ion.

In both sector and quad instruments, MS/MS fragment ions are observed only if decomposition (CID or UMD) occurs in the collision cell. Consideration of ion flight times for both instruments reveals that selected parent ions reach the collision cell at nearly the same time, but reside in the quad cell ca. 500 times longer. Quad UMD fragments are readily observable due to this statistical advantage. Parent ions of sufficient internal energy to undergo UMD produce useful daughter spectra in the absence of CA. UMD must be exploited for successful MS/MS of massive parent ions using quadrupoles of limited CA capability.

The UMD and CID MS/MS daughter spectra of Pertirelin (pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-NH-C₆H₅ MW=1153), a nonylpeptide, using FAB and Thermospray (TSP) primary ionization is shown. The FAB UMD spectrum (A) shows significant fragmentation in the absence of CA suggesting FAB produces parent ions of high internal energy. Collision energies less than 2 eV were employed with no collision gas. Primary structure information is readily attainable as highlighted by the figure. The CID spectrum (B) shows improved low mass fragment sensitivity, but provides little additional structural information. This spectrum was recorded at a collision energy of 15 eV with 0.4 torr Argon collision gas.

Conversely, the TSP UMD spectrum (C) shows very little fragmentation suggesting parent ions of much lower internal energy are produced by this ionization method. A collision energy of 120 eV or greater was required to produce TSP CID fragmentation (D) similar to the FAB UMD data. Similar results have been noted for many small peptides ranging in molecular weight from 400 to 2000 daltons using a Finnigan TSQ-70 triple quadrupole spectrometer.

It is concluded that, triple quadrupole MS/MS systems are relatively sensitive to UMD fragmentation due to the statistically long sampling times. The FAB primary ionization process produces parent ions of small peptides of sufficient internal energy to undergo UMD. Below 1000 Da., CA adds little additional information to the daughter spectrum. Above 1000 Da., CA is required to obtain optimal daughter spectra. In triple quads, most of the energy required for peptide fragmentation must be provided by the primary ionization method due to the limited capabilities of low energy CA.

THREE DIMENSIONAL CELLULAR MAPPING OF ANTIBODY-ANTIGEN INTERACTIONS BY SECONDARY ION MASS SPECTROMETRY

Authors: J.J. Lee, R.W. Linton, R.D. Voyksner*, J.L. Hunter, D.C. Wilson, Dept. of Chemistry-CB3290, Univ. of North Carolina, Chapel Hill, NC 27599; * Research Triangle Institute, Research Triangle Park, NC 27709

INTRODUCTION

Colloidal gold probes are widely used for light and electron microscopic immunocytochemistry, for example, in cell surface labeling and as markers in histological samples.^{1,2} One approach for labeling fixed histological sections involves a sequential reaction, first with a primary antibody having specificity for an antigen of interest, followed by treatment with a secondary antibody linked to colloidal gold particles. The signal produced by the gold particles using backscattered electron or light microscopic imaging can be greatly enhanced using a physical silver developer to enlarge the staining particle size. This approach was utilized in this study to label antigenic sites along the basement membranes (basal laminae) of glomeruli in human kidney tissue. It provides the first demonstrated application of elemental tags with high ionization efficiency in SIMS to image sites of antigen-antibody interactions in fixed biological tissue.

EXPERIMENTAL

Human kidney tissue sections were treated with a two stage immunogold silver staining (IGSS) process. Anti-human collagen Type IV monoclonal antibodies (Chemicon International, Inc. Catalog no. MAB1910) were used to bind to antigenic sites on glomerular basement membranes. The secondary antibody was goat anti-mouse IgG conjugated with 5nm gold particles (Janssen Life Sciences Products AuroProbe EM # 23.685.17-GAM1G). The silver enhancement reaction was then used to enlarge the gold particle size by deposition of silver (Janssen Intense M kit). Control sections treated in the above manner, except for the omission of the primary antibody, did not exhibit any detectable silver incorporation. Sections which did not utilize silver enhancement provided inadequate labeling for direct imaging of the gold tags using ion microscopy. The SIMS measurements were performed using a Cameca IMS-3f ion microscope equipped with a magnetically filtered primary Cs⁺ beam and a custom digital secondary ion imaging system.³

RESULTS AND DISCUSSION

Figure 1 illustrates SIMS results for glomeruli from the IGSS labeled kidney tissue. In addition to elements characteristic of the organic constituents (H, C, N, O, S), the negative ion spectrum (Fig. 1) shows high concentrations of the Ag label and halogens with very high secondary ion yields (Cl, Br, I). The lack of Au⁻ intensity is readily explained by the difference in the relative volumes of the Au cores and Ag overlayers of about 10⁵. The Ag⁻ and Br⁻ signals are several orders of magnitude more intense in the tissue treated with the Ag. The enhanced Br⁻ may result from binding to Ag particles during H and E staining for light microscopy.

Results of digital ion imaging studies are summarized in Figure 2 for a selected portion of a single glomerulus with its associated basement membrane (Bowman's Capsule). The SIMS analytical area was confined to a circle 150 μ m in diameter centered in the ion beam sputtered area.

The tissue morphology is shown in the backscattered electron micrograph (Fig. 2A) and is correlated with the surface images of the same feature obtained by SIMS (Figs. 2B). The CN⁻ image identifies the regions containing tissue, the dark channel representing the urinary (Bowman's) space. The binary SIMS image overlay of Ag⁻ and CN⁻ in Figure 2B illustrates the predominance of Ag in surface regions associated with the basement membrane (Bowman's Capsule).

Results of SIMS 3-D or image depth profiles are shown in Figures 2C and 2D for CN⁻ and Ag⁻, respectively. Vertical slicing of the digital image stack was selected to go through the basement membrane located in the bottom right quadrant of micrographs shown in Figures 2A-2B. About 0.4 μ m were sputtered in increments between each successive set of image acquisitions. The result confirms that the Ag is confined to the outer surface of the section. That is, sputtering of the outer 0.4 μ m before acquiring the second Ag⁻ image was sufficient to virtually eliminate all detectable Ag (Fig. 2D). In contrast, the CN⁻ signal actually increases somewhat for the second and third data sets (Fig. 2C). This may reflect attenuation by remnants of a carbon overlayer in the first data set, and progressive ion beam damage effects which may influence the CN⁻ signal. It should be noted that SIMS sensitivity is such that less than 15nm depth normally is consumed to acquire a single Ag⁻ image, and about 0.1 nm for each CN⁻ image.

CONCLUSION

The immunogold silver staining process is shown to be useful for the localization of antigen-antibody interactions in biological tissues using SIMS. The 3-D image depth profiling mode provides information on the specificity and penetration of the antibodies used to label antigenic sites. Further improvements are expected in SIMS lateral resolution using focused liquid metal ion sources, in methods to display 3-D information, and in the development of chemical tags for biomolecules tailored to mass spectral detection. These are important early steps in the evolution of imaging mass spectrometries as molecular microprobes with applications to biology and medicine.

TOPOGRAPHY OF MEMBRANE-BOUND PROTEINS: PHOTOAFFINITY STUDIES OF COLICIN Ia.

A. M. Falick*, S. F. Mel**, R. M. Stroud** and A. L. Burlingame*, *Mass Spectrometry Facility, Dept. of Pharmaceutical Chemistry and **Department of Biochemistry and Biophysics, University of California, San Francisco, CA 94143.

Ion channels are membrane proteins that permit and control the transport of selected small ionic species across cell membranes. They are found in numerous cell types, playing key roles in nervous system signaling, muscle contraction, and hormone release. Molecular level studies of ion channels have focused on molecules such as the acetylcholine receptor, a large (270kD) transmembrane glycoprotein. Colicin Ia is a smaller (67kD, 626 residues) monomeric bacterial ion channel, which is an excellent model for higher eukaryotic ion channel function.

In order to completely understand the mechanism by which this bacterial ion channel forms and the details of the ion channel structure, we have undertaken to map the topography of its transmembrane form, using photoaffinity labeling followed by a combination of proteolytic digestion, HPLC, and mass spectrometric techniques. The essential feature of our experiments is that they are an attempt to specifically identify that portion of the colicin molecule that is imbedded in the membrane when colicin is functioning as a transmembrane ion channel.

Experimental

A. Preparation of Mass Map

Colicin Ia was prepared and purified according to the method of Mel and Wolberger (1). *Staphylococcus aureus* V8 enzyme was used to digest the protein. The resulting mixture of peptides was separated by reverse phase HPLC (C-4 column, water/acetonitrile/0.1% TFA solvent system). Liquid secondary ion mass spectrometry was used to identify the peptides by their molecular masses. For many of the earlier-eluting peptides, it was necessary to prepare the hexyl esters (2) in order to obtain mass spectra. In cases where the molecular masses of two different peptides coincided, MS/MS (Kratos Concept 4-sector (3)) was used to distinguish between the two possibilities. Using these methods, approximately 77% of the protein could be successfully mapped from a single digest of less than 1 nmol of protein. The remaining unmapped portions of the molecule were difficult to map due to the lack of suitable cleavage sites for the V8 enzyme, so that other enzyme digests may be required to complete the map.

B. Photoaffinity labeling

Lipid vesicles (liposomes) were prepared according to the method of Szoka and Papahadjopoulos (4). The photoaffinity label we used was 3-(trifluoromethyl)-3-(*m*-iodophenyl) diazirene (TID) (5). Upon uv irradiation, TID loses molecular nitrogen to form a carbene, which rapidly inserts into adjacent C-C and C-H bonds.

TID is lipid-soluble, and when added to a suspension of liposomes, it dissolves in and remains almost exclusively in the lipid bilayer. If a membrane-spanning protein, such as colicin, is also present in the bilayer, then the carbene formed upon uv irradiation will immediately react with adjacent portions of the protein, thus selectively tagging those residues that reside in the membrane. Isolation of the protein followed by proteolytic digestion and mass mapping should allow identification of the modified residues. In our experiments, TID was labeled with ¹²⁵I to aid in rapid identification of the modified peptides.

Results and Discussion

A 2 nmol sample of colicin Ia was labeled with ^{125}I TID as described. The labeled protein was digested with *S. aureus* V8 enzyme (1:10, 4 hrs at 37°C) and the resulting peptide mixture was separated by HPLC. Fractions were collected at 1 minute intervals using an automated fraction collector. The ^{125}I content of each fraction was assayed by gamma-ray counting. The resulting plot of counts per minute vs. fraction number is shown in Fig. 1.

It is clear from Fig. 1 that our first major goal of specific labeling of peptides was achieved. The total amount of labeling was approximately 1%, i.e., 1 TID molecule per 100 colicin molecules. This proportion is similar to other reported experiments using TID. Remaining problems include the fact that the quantities of TID-labeled peptides so far generated are too small for direct identification by mass spectrometry, and the fact that the addition of TID to a peptide affects its HPLC retention time, so that direct identification by means of this parameter is not straightforward.

DERIVATIZATION AS AN AID TO PEPTIDE MAPPING BY LSIMS.

FALICK, A.M. and MALTBY, D.M., MASS SPECTROMETRY FACILITY,
DEPT. OF PHARMACEUTICAL CHEMISTRY, UNIVERSITY OF CALIFORNIA,
SAN FRANCISCO, CA 94143-0446.

Peptide mapping by LSIMS is often complicated by the poor ionization efficiencies of some peptides, particularly small, hydrophilic ones, making them effectively invisible to LSIMS analysis. Derivatization has been shown to be useful in the analysis of such peptides (1). We have developed an improved method for the derivatization of difficult peptides which increases their hydrophobicities, thereby improving the signal-to-noise level in their LSIMS spectra. In our procedure, samples are collected in tubes, then dried and the hexyl esters formed by treatment with a hexanol/HCl mixture. The derivatized samples can be analyzed directly or they can be dried and resuspended in 0.1% TFA for analysis. The figure below shows the effect of hexyl ester formation on a heptapeptide obtained from a 500 picomole *S. Aureus* V8 digest of colicin Ia. The HPLC fraction containing this peptide was collected and divided into two equal aliquots (approximately 50 picomoles each); one was run directly on the mass spectrometer, while the second was derivatized with hexanol. This illustrates the improvement in S:N ratio and absolute signal intensity commonly found in this procedure. The utility of this method was further demonstrated when we derivatized one-half of the eluent collected from each of the first ten peaks detected on the HPLC of the colicin digest. No peptide ions were discernable in 8 out of 10 of the underivatized fractions, whereas 9 out of 10 of the derivatized fractions gave easily measured signals whose masses corresponded to hexyl esters of predicted peptides from this digest. The hexylation reaction has also been useful in the MS/MS analysis of these peptides, as C-terminus daughter ions show an 84 amu shift relative to the underivatized peptide ions. The procedure is simple, rapid and easily applied to large numbers of samples and has proven useful in the analysis of difficult peptides in our laboratory.

Introduction

Alkylation of DNA by electrophilic metabolites of xenobiotics is believed to be the major initiating process that may result in carcinogenesis. The study of hemoglobin alkylated *in vivo* by chemical carcinogens has previously been proposed as an indicator for DNA alkylation (1). Modified proteins are not readily amenable to conventional methods for amino acid sequencing. Tandem mass spectrometry, however, allows structural elucidation of chemically modified proteins (2). Styrene is widely used in the plastics industry and the major metabolite, styrene-7,8-oxide, is both mutagenic and carcinogenic in rodents (3). Human hemoglobin was modified *in vitro* with styrene-7,8-oxide and digested with trypsin. LSIMS mass mapping of unmodified hemoglobin confirmed the sequence of the protein and provided a library for the identification of modified peptides. Tandem MS of modified peptides allowed assignment of specific residues modified.

Results and Discussion

LSIMS confirmed 95% of the amino acid sequence for human hemoglobin. Hemoglobin isolated from human erythrocytes was alkylated by incubating with [¹⁴C-8] styrene oxide. Tryptic peptides were fractionated by HPLC and the radiogram indicated a number of peptides containing covalently bound styrene oxide (Fig. 1). LSIMS of fraction 13 showed molecular ion MH⁺ m/z 1269.6 as the major component and this is consistent with peptide 133-144 in the β -chain containing one hydroxyphenylethyl moiety (covalent binding of one styrene oxide molecule). The corresponding unmodified peptide eluted in fraction 9. The specific site of modification was established by tandem MS experiments. The high energy CID spectrum of fraction 13 (20 pmole) shows the of the histidine immonium ion m/z 110 (Fig. 2). The ion m/z 230 arises from the immonium ion for histidine containing a hydroxyphenylethyl moiety. This is confirmed by ions of the W, X, Y and Z series containing the histidine residue which show an analogous shift in 120u. As expected, ions of the A, B, C and D series (charge retention at the N-terminus) do not show a mass shift except for fragments containing the histidine residue, e.g. m/z 1095 (A11) compared with m/z 975 (A11) in the unmodified peptide. Other sites of covalent modification were similarly established and are described elsewhere (4). The application of high performance tandem MS to identify aralkylation of hemoglobin with styrene oxide illustrates the potential of this approach for *in vivo* biological monitoring. At present, however, the strategy outlined is not readily amenable for monitoring occupational exposure in humans, largely due to the high levels of unmodified peptides which co-elute during the HPLC fractionation and render difficult identification of modified peptides. This problem may be significantly reduced by the use of immunoaffinity chromatography in the isolation of the modified protein. This approach will be pursued for *in vivo* studies.

Oligopeptide Fragmentation Viewed as Constant Neutral Loss

C. M. Murphy, R. C. Orlando, C. C. Fenselau, R. J. Cotter*

University of Maryland, Baltimore, MD 2122

*Johns Hopkins University, Baltimore, MD 21205

The observation of preselected decompositions defined by constancy in the mass of the neutral fragment ¹ has allowed mechanism-based enhancement of signal to noise sensitivity for probing mixtures, and of specificity for characterizing target analytes in complex matrices. Working with tri- and tetra- peptides dePauw ² has suggested that the CNL scans can extend the same advantages to spectra of peptides, that contain multiple series of sequence ions.³ We have evaluated the usefulness of CNL for sequencing peptides in the mass range of 1000-3000amu. We have looked at the elimination of neutral fragments of 17, 18, 28, and 48 amu in the unimolecular and collisionally induced decomposition of bradykinin, LHRH, somatostatin, renin substrate, melittin, and glucagon. These experiments were carried out on a JEOL HX110/HX110 tandem mass spectrometer. CNL scans of anion and cation processes were compared to quadratic scans and B/E scans obtained in MS/MS experiments. The FAB gun was operated at 6keV with Xenon as the FAB gas. In the CID experiments, helium was the collision gas and the parent ion was attenuated by 80%. Among the several candidates, observation of the elimination of 28 amu provided the most information about the amino acid sequence, i.e., the most complete series. Most of the losses correspond to the process "b -> a", and their observation in the complimentary analysis permits the "a" and "b" series ions to be distinguished in the quadratic and MS/MS experiments. Some side chain cleavage processes were also detected, e.g., "d->c", "w-> x", and "z->w". The "z->w" loss is only possible with isoleucine. The CNL window for the loss of 28 amu was found to be 2-4 amu wide, with skewing of the mass window to the lower mass side. The ratio of signal to noise was improved relative to the quadratic scan. The collision gas pressure and matrix solvent are important variables in successfully obtaining sequence information from CNL scans. The width of the CNL window must also be determined for each experimental set up. Overall, the CNL of 28 provides one with a reading frame which is useful in the interpretation of quadratic and MS/MS spectra of peptides.

INVESTIGATION OF ARTIFACTS FORMED DURING CYANOGEN BROMIDE DIGESTION OF PROTEINS.

D.R. Goodlett, J. Creech, F.B. Armstrong and R.B. van Breemen,
Departments of Chemistry and Biochemistry, North Carolina State University
Raleigh, NC 27695-8204

Shively and coworkers (1) reported the formation of artifacts due to exposure of proteins to 70% formic acid during cyanogen bromide digestion, which might block the amino terminus of cyanogen bromide peptides and thereby prevent sequencing by Edman degradation. The use of positive ion fast atom bombardment (FAB) mass spectrometry in this and other laboratories (2) has confirmed this observation and has shown that the artifact corresponds to the addition of 28 mass units to the protonated molecular ion of a cyanogen bromide peptide fragment, $[M+H+28]^+$. We examined the site of peptide formylation using mass spectrometry, and measured the stability of adduct in aqueous solution as a function of pH. The effect of formylation on sequencing by Edman degradation was also investigated. Finally, conditions for the prevention of formylation during cyanogen bromide digestion, which had been suggested by Shively and coworkers (1), were confirmed.

Cyanogen bromide digestion of horse heart cytochrome *c*, bovine adrenal medulla dodecapeptide, bovine adrenal peptide E, and bacteriorhodopsin was carried out as previously described (4). Protein samples were digested for 24 hours in 70% aqueous formic acid at room temperature under argon. The formic acid solution was diluted 20-fold with water and then freeze dried. Cyanogen bromide peptide fragments were purified by high performance liquid chromatography (HPLC) using a Vydac C18 column and a gradient solvent system consisting of water and acetonitrile (each containing 0.1% trifluoroacetic acid). HPLC-purified peptides were analyzed using a JEOL HX110HF double-focussing mass spectrometer, equipped with fast atom bombardment, DA5000 data system, B/E linked scanning, and a collision cell in the first field-free region. The pressure of the helium collision gas was adjusted so that the signal was attenuated 70% during B/E linked scans. Peptide sequencing using Edman degradation was carried out using a Applied Biosystems Model 475A.

Positive ion FAB mass spectrometric analysis of cyanogen bromide peptide fragments of cytochrome *c* and bacteriorhodopsin showed formylated adducts corresponding to $[M+H+28]^+$. Bovine adrenal medulla dodecapeptide and bovine adrenal peptide E were not formylated during digestion. The molecular ion region of the mass spectrum for one of the three cyanogen bromide peptides from cytochrome *c* (CNBr-2) is shown in Figure 1. Both formylated and nonformylated ions are present in this mass spectrum. Formylated peptides could be resolved from the corresponding nonformylated peaks using reversed phase HPLC. When sequenced by Edman degradation, formylated CNBr-2 produced a sequence identical to the nonformylated peptide. This indicated that the formyl group was labile under the conditions of Edman degradation. Saponification, incubation in an aqueous buffer at pH 6.00, 37°C, for 30 minutes, or storage at pH 2.4, -20°C, for one week all resulted in conversion of formylated to nonformylated CNBr-2 from cytochrome *c*.

Figure 1. Positive ion FAB mass spectrum of the molecular ion region of CNBr-2 from cytochrome *c*.

B/E linked scanning with collisional activation was used to obtain daughter ion mass spectra of the $[M+H]^+$ and $[M+H+28]^+$ molecular ions of CNBr-2 (See Figure 2.) The most abundant daughter ions, which localized the formyl adduct, were detected at m/z 513 in the formylated CNBr-2 mass spectrum and m/z 485 in the mass spectrum of the non-formylated peptide. These fragments corresponded to x_5 carboxyl terminus sequence ions and resulted from fragmentation between isoleucine and proline. Formylation occurred in the sequence Pro-Gly-Thr-Lys-Hsl (where Hsl is homoserine lactone). Because Shively and coworkers (1) reported that lysine modified at the ϵ -amino group was misidentified during sequencing by Edman degradation, lysine was probably not formylated in this peptide.

Figure 2. B/E linked scan of protonated molecular ions of A) formylated and B) non-formylated CNBr-2 from cytochrome *c*.

These data and the instability of the adduct suggest that the hydroxyl group of threonine was the site of formylation. Furthermore, we have observed that only proteins containing serine or threonine were formylated during cyanogen bromide digestion in 70% formic acid. The use of 70% trifluoroacetic acid as a solvent for cyanogen bromide digestion eliminated formylation and generated little or no trifluoroacetylation.

The ability to qualitatively and quantitatively analyze the amino acid residues from a peptide sequencing experiment is important for the study of protein. Protein microsequencing using the Edman degradation is currently possible in the picomolar range using high performance liquid chromatography with UV absorbance to detect and identify the amino acid phenylthiohydantoin released at each cycle.

We are developing modified Edman reagents that form good electron-capturing derivatives for the detection by negative ion mass spectrometry. The use of 4-nitro-phenylisothiocyanate (4-NPITC) (1) in peptide sequencing is being explored. Amino acid 4-nitro phenylthiohydantoin (4-NPTH) derivatives have been prepared for all twenty amino acids. Coupling of the amino acid with 4-NPITC was achieved by reaction at 45°C for 40 min in a buffer system of pyridine:water(1:1) and triethyl amine, the pH of which was maintained between 8-9. Conversion of ATZ to NPTH amino acids was carried out at 55°C in 25% trifluoroacetic acid for 45 min. The resulting 4-NPTH derivatives were analyzed on an HP 5985 B mass spectrometer equipped with Vacumetrics DCI probe. EI and CI spectra were recorded at source temperatures 200°C and 100°C respectively.

For most of the derivatives NI CI mass spectra show only the molecular anion with no fragmentation (TABLE 1). Hence the amino acid residue can be identified by the diagnostic mass. PCI mass spectra show M+1, M+29, ..., and fragment ions in some cases. EI mass spectra show characteristic fragmentation including fragment ions that allow the differentiation of leucine and isoleucine (data not shown).

The use of 4-NPITC in peptide sequencing is demonstrated by sequencing the first five residues from a nonapeptide of known sequence (FIG.1). Except for arginine in the first cycle which gives some unidentified ions, 4-NPTH derivatives from other cycles were easily identified by the molecular anion.

The combination of 4-NPITC with NI CI mass spectrometry would offer the advantages of speed, since no chromatography is required and selectivity, since only electron-capturing molecules are detected. Moreover, it would also enhance the sensitivity because for most of the derivatives, ion current is concentrated on the molecular anion. Experiments to find out the detection limits and coupling yields are underway.

QUANTIFICATION OF SUBSTANCE P BY FAB-MS

Jozef Kusmierz and Dominic M. Desiderio

University of Tennessee, Memphis, Memphis Tennessee 38163

INTRODUCTION

Endogenous SP in human CSF¹ tooth pulp² was quantified in our laboratory by radioimmunoassay. Also, different RRA and RIA patterns of endogenous opioid peptides in human postmortem pituitaries³ were found. RIA provides very good sensitivity but does not provide specificity. These results prompted us to develop a method for simultaneous determination of SP and ME in human tissues and fluids by mass spectrometry, which provides almost equal sensitivity but greater specificity than RIA.

SAMPLE PREPARATION

Post-mortem human pituitaries, of known weight were homogenized in 10 ml of trifluoroacetic acid (TFA) solution (pH 1.5), and one μg of d5-ME and of d7-SPOH (free acid) as internal standard were added. The mixture was homogenized, and an aliquot (100 μl) was taken for protein determination. The homogenate was centrifuged, and the resulting supernatant was prepurified and desalted with SEP-PAK C-18 disposable cartridge. Peptides were eluted with 50% acetonitrile and 0.1% TFA solution. The extraction recovery for this procedure, established with ³H-SP, was 60%. Eluent was concentrated to 400 μl under a stream of nitrogen, and subjected to RP-HPLC for peptide separation. A C-18 $\mu\text{Bondapak}$ column (4 x 250 mm) was used. Mobile phase was 21% acetonitrile and triethylamine-formic acid (TEAF) buffer. Collected fractions were lyophilized, and reconstituted in 50 μl of 0.1% heptafluorobutyric acid (HFBA), and stored until FAB-MS analysis.

MASS-SPECTROMETRY

The FAB-MS measurements were obtained with a Finnigan MAT 731 instrument equipped with a FAB gun, which was operated at 8 keV with xenon as bombardment gas. The protonated molecular ion of SP and ME were monitored in the single ion monitoring mode. Quantitative data were acquired by an Apple II microcomputer. To optimize MH⁺ production of peptides, we examined two matrices, glycerol and 3-nitrobenzyl alcohol. A perfluorinated carboxylic acid was added to manipulate the relative hydrophobicity of the peptide in the matrix. Total ion current from glycerol increased six times using HFBA as an additive compared to TFA; in 3-nitrobenzyl alcohol, the inverse was found. The biological sample measurement was performed using 0.2 μl of glycerol and 0.1% HFBA as FAB matrix.

RESULTS

The standard curve for SP was generated from the ratio of molecular ion current SP/d7-SPOH plotted versus ng SP (Figure 1). The limit of detection of the SP MH⁺ was 0.5 ng (0.37 pmol). We always want to achieve optimal molecular specificity, so we monitored the metastable transition for SP MH⁺ (1348.7) to 1002. The detection limit is 20 ng, which is much poorer related to the molecular ion sensitivity. We rationalize that the poor SP B/E data (Figure 2) are due to the low relative intensity of the transition ion 1002, which is 0.1%. For example, the ME sensitivity for MH⁺, and for B/E (measured for the 425 fragment ion) equals 125 pg and 250 pg respectively. The relative intensity of ion 425 is 1.3%.

The measured amount of SP in human pituitaries is shown in Table 1. We also report the amount of ME in the same pituitaries (Table 2). For ME, we are able to acquire data using the molecular ion and N-terminus (m/z 425) product ions. The last data were acquired in linked-field scan mode. The amount of ME in human pituitary as determined in the linked-field scan mode, is lower, relative to the amount measured for the molecular ion. We rationalize that the B/E mode is more specific and enables us to decrease any biological matrix interference during the quantification of endogenous peptides.

CONCLUSIONS

1. In this work, endogenous SP and ME were quantified by FAB-MS./2. ME was quantified in human pituitaries by using the MH^+ and 574 → 425 transition. Both measurements are in good agreement with each other. 3. Our research on human samples requires increases in sensitivity, fragmentation, mass range, and specificity. Therefore, quantification of SP by the linked-field scan method is possible with a four sector instrument, equipped with an array photo-diode detector. 4. In the next step, we will use deuterated SP instead of d_7 -SP free acid as internal standard. This work was supported by NIH GM 26666.

QUANTIFICATION OF β -ENDORPHIN IN HUMAN PITUITARY BY FAB

Chhabil Dass, Josef Kusmierz, and Dominic M. Desiderio

University of Tennessee-Memphis, Memphis, TN 38163

β -Endorphin is an endogenous opioid peptide consisting of 31 amino acid residues with molecular weight of 3463 Da. β -Endorphin and other related peptides form one of the three known major groups of endogenous peptides; the other two being the enkephalins and the dynorphin-related peptides. β -Endorphin is synthesized biochemically by proteolytic cleavage of the large gene product precursor proopiomelanocortin (POMC). β -Endorphin forms the C-terminal segment of POMC, and is the only component of precursor peptide with agonist activity at an opioid receptor.

β -Endorphin has been implicated in several neurochemical and pharmacological functions of the body. To understand the physiological significance of endorphins, it is critical to determine their amounts in various body tissues. Highly structure-specific and sensitive methods are needed to identify and quantify endogenous peptides so that the data reflect with high fidelity the structure of the target compound.

The objective of the present study is to develop a MS method for quantification of β -endorphin in extracts of human tissues. FAB-MS is the method of choice for the analysis of highly polar and non-volatile compounds such as peptides. Three different approaches were attempted. In the first method (Method 1), the doubly-charged $[(M+2H)^{++}]$ ion of intact β -endorphin which falls into the highest sensitive mass range of VG 7070 E-HF mass spectrometer was monitored using narrow mass (10 u wide) magnet scans acquired in the multichannel analysis (MCA) mode. A variety of FAB matrices (glycerol, a 3:1 mixture of dithiothreitol=DTT and dithioerythritol=DTE, α -thioglycerol, 3-nitrobenzyl alcohol=NBA) and chemical modifiers were tested to determine their effect on the sensitivity of the method. NBA with the addition of 1 μ l of 0.1% TFA and 2.5 μ g of glutathione was the most appropriate FAB matrix. The calibration curve (Curve A) is linear in the concentration range of 2.9-100 pmol of β -endorphin. The lowest detection limit of this method is 2.9 pmol of β -endorphin.

In Methods 2 and 3, β -endorphin was digested with trypsin to provide smaller fragment 20-24 (NAIK) (see Scheme 1). The rationale of using this protocol is based on the fact that low MW compounds are more efficiently ionized. Thus, this approach will improve detection sensitivity (see reference). In Method 2, the $(M+H)^+$ ion of NAIK (at m/z 558) was monitored using narrow mass (10 u wide) MCA scans. DTT/DTE with the addition of 1 μ l of 0.1% TFA and 0.4 μ g of glutathione was found to yield the most intense ion current. A linear calibration curve (Curve B) was obtained in the concentration range 86 fmol-3 pmol of β -endorphin. The curve deviated towards the x-axis at a concentration above 3 pmol. The lowest detection limit of this method is 86 fmol of β -endorphin.

Although monitoring of the $(M+H)^+$ provides high detection sensitivity, it nonetheless lacks the molecular specificity needed for measurements of endogenous neuropeptides. A high level of molecular specificity can be achieved by use of the MS/MS technique. In MS/MS, a product ion can be correlated incontrovertibly to the mass-selected precursor ion. Method B is based on measurement of the area under the peak due to the transition $NAIK \rightarrow NAI$ (i.e., 558 $\rightarrow$ 299; see Scheme 2) acquired using multiple reaction monitoring (MRM) mode. The same combination of FAB matrix as used for Method 2 provided highest sensitivity. The calibration curve (Curve C) is linear over the concentration range 0.5-30 pmol of β -endorphin. The detection limit of this method is 580 fmol of β -endorphin.

These methods were applied to the analysis of β -endorphin in human pituitary extracts. Five human pituitaries were combined, extracted, purified by gradient RP-HPLC and then divided in two portions. Half of the amount was analyzed by Method 1. Although high ion current was obtained for $(M+2H)^{++}$ of β -endorphin, that ion could not be identified unambiguously from the background, indicating that some other biological compounds are still eluting from RP-HPLC at the retention time (73 min) of β -endorphin. The remainder of the pituitary sample was digested with trypsin, and the NAIK was separated by isocratic RP-HPLC. Amounts of 36 and 31 pmol/mg of protein were estimated by Methods 2 and 3, respectively.

In conclusion, it can be said that Method 2 is very simple and straightforward, but is less sensitive and also lacks in specificity. Method 2 provides the highest detection sensitivity,

but involves additional experimental steps such as trypsinolysis and isocratic HPLC. These two steps increase specificity and also provide cleaner sample. The most important attribute of Method 3 is high molecular specificity, which results from the combination of trypsinolysis, isocratic HPLC, and MRM techniques. The detection sensitivity of the method is also quite good.

MATRIX REACTIONS AND THEIR EFFECTS ON THE ISOTOPIC PEAK RATIOS OF PEPTIDES MEASURED BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY

J. Visentini, P. Thibault¹⁾, and M. J. Bertrand,
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada H3C 3J7,

1) National Research Council of Canada, Halifax, NS., Canada B3H 3Z1.

In recent years, fast atom bombardment mass spectrometry (FABMS) has been used extensively in the characterization of peptides. For the higher molecular weight compounds, the molecular ion cluster in the mass spectrum can provide information regarding the molecular weight as well as the elemental composition of the peptide. Unfortunately, the relative intensities of isotopic peaks obtained from the FAB spectra of organic compounds are often found to be larger than theoretically expected. The $(A+1)/A$ peak ratios, where $A=(M+H)^+$, are usually close to the predicted theoretical values within experimental error. However, subsequent isotopic peak ratios, i.e. $(A+n)/A$ ($n \geq 2$) often display substantial positive deviations. In addition to peptides, the distortion of isotopic peak ratios has been reported in the analysis of other classes of organic compounds including dyes, quinones and nucleotides^{1,2,3}. It has been suggested that reduction processes occurring either in the matrix or intramolecularly are responsible for the discrepancy between theory and practice.

Since the deviations observed in the isotopic peak ratios for peptides can vary substantially for different compounds studied under similar experimental conditions, a study was performed in the hopes of determining the factors responsible for the reduction occurring during analysis. In order to determine if the concentration of the analyte had an influence on the reduction, preliminary experiments were conducted using narrow voltage scanning and signal averaging techniques. Typical results obtained for methionine-enkephalin in a glycerol/water (2:1) matrix are illustrated in Figure 1. The $(A+2)/A$ ratio appears to be constant for concentrations above 0.03 M whereas it varies below that concentration and this is attributed to signal interferences at low S/N.

In attempts at quantifying the extent of reduction occurring in different peptides, experiments were conducted using narrow scans over the molecular ion cluster and signal averaging techniques. The results obtained in these experiments indicated that a relation existed between the extent of reduction and bombardment time. Since acids are commonly added to the matrix when studying peptides in order to increase the intensities of parent molecular ions, the effect of pH and type of acid added to the sample was investigated using methionine-enkephalin in a glycerol matrix. The results from these experiments indicated that in pure glycerol, the reduction effect was seen immediately and increased slightly with time. The addition of hydrochloric acid, a common matrix additive in peptide analysis, indicated that the initial $(A+2)/A$ ratio was higher than for glycerol alone and that the reduction proceeded at a slightly greater rate as well. Although the addition of hydrochloric acid may produce more intense spectra, it poses a limitation in the determination of isotopic peak ratios. Since earlier work with disulfide-containing peptides analyzed in thio glycerol had demonstrated that the addition of trifluoroacetic acid added to the sample prior to bombardment could inhibit reduction considerably, the effect of this acid was also evaluated. Samples containing trifluoroacetic acid tended to show a deviation in the $(A+2)/A$ ratio similar to that of hydrochloric acid, but yielded initial values lower than those obtained with hydrochloric acid.

The other factors that can influence the reduction process are structural elements contained in the peptides and in the matrix and these were studied by varying the nature of the peptide and the composition of the matrix. There are several functional groups, such as carbonyl, aromatic rings, and disulfide bridges, present in peptides which can act as reduction sites and the effect of these groups on the extent of reduction can be evaluated from the data given in Table I. The table illustrates the extent of isotopic peak enhancement for five different peptides in a thio glycerol matrix. As expected, the peptides containing disulfide bridges show the greatest reduction effect. Furthermore, pentaphenylalanine which contains more aromatic rings than either methionine-enkephalin or bradykinin exhibits more reduction than the latter. Thus the contribution of disulfide bridges to reduction is more significant than that of aromatic rings which is more important than that of carbonyl groups. In a similar way, the presence of functional groups such as NO_2 , S-S, and aromatic groups in the matrix inhibit the reduction of peptides whereas the presence of thiol or hydroxyl groups accelerate the process.

In order to determine whether the matrix composition affects the extent of reduction significantly in peptides which do not contain disulfide bridges, five different peptides were studied in

matrices composed of glycerol/water (2:1), thioglycerol, and water. The experiments conducted in water were done using continuous-flow FAB (CFFAB) in order to verify if the constant refurbishing of the sample could have an effect on the reduction process. As can be seen in Table II, there is no apparent trend to the reduction process occurring in the different matrices. However, the values measured in glycerol/water, thioglycerol or CFFAB are always higher than the theoretical values indicating that reduction is present in all cases and that it is not avoided even if a dynamic system is used. Thus this observation suggests that the reduction of peptides not containing disulfide bridges is FAB-induced. The reduction in disulfide-containing peptides, however, is accelerated during the FAB process but occurs in solution as well. Furthermore, experiments were conducted to compare the effect of the probe tip material on the reduction process. The results for a brass and gold tip demonstrated that these support materials have no significant effect on the reduction of peptides.

In conclusion, experimental results obtained in this study indicate that there are, in fact several mechanisms involved in the reduction of peptides in the analysis by FABMS and that the use of proper experimental conditions can minimize these effects which are dependent on several factors including the nature of the sample and of the matrix, the concentration of the analyte, the pH, the nature of the acids used as additives and also the time of analysis and atom beam energy.

ANALYSIS OF CANCER CELL LINES FOR THE PRESENCE OF PEPTIDE GROWTH HORMONES AND OTHER PEPTIDES BY ION EVAPORATION IONIZATION / TANDEM MASS SPECTROMETRY.

Anthony Treston, Philip Kasprzyk, Frank Cuttitta, Thomas Covey and James Mulshine. SCIEX Inc., Ontario, Canada, and NCI-Navy Medical Oncology Branch, National Institutes of Health, Bethesda, MD 20814.

Outline : Small cell lung cancers stimulate their own growth by producing both peptide hormones and receptors for those peptides. The mRNAs of several prohormones, for example insulin-like growth factor-I (IGF-I) and gastrin releasing peptide (GRP), have been sequenced, and appear to code for multiple potentially-bioactive peptides. We are attempting to determine whether peptides predicted from these mRNAs are synthesized by the cells, and whether they have activities which may be used as targets for novel therapies. We also have identified novel C-terminal α -amidated peptides by a thermospray LC/MS technique (presented at ASMS 1988; in press *J. Chromatogr.* 1989) and are purifying them to determine whether they represent novel peptide hormones. These peptides are being analyzed using ion-evaporation ionization/ tandem mass spectrometry.

Methods : A Sciex triple quadrupole TAGA 6000 E was used for all studies. Ion evaporation mass spectra were obtained using a Sciex TAGA 6000 E triple-quadrupole mass spectrometer equipped with an Ionspray interface. Samples were infused at a flow rate of 2 μ L/min. Spectra were acquired for 1-2 min. MS/MS was carried out with an argon collision gas thickness of 1.6×10^{14} atoms/cm² and an energy of 60-70 eV. Experimental samples were obtained from the spent media of cancer cell lines (NCI-N417 and NCI-H716). The media was fractionated on C₁₈ HPLC columns using acetonitrile or methanol gradients. Fractions of interest were identified by either 1) immuno-cross-reactivity to peptides predicted from the known prohormone sequences of IGF-I or GRP, or 2) a thermospray LC/MS technique for identifying C-terminal α -amidated peptides. Lyophilized samples and standards were dissolved in CH₃CN/water with 0.5% formic acid. Samples in solution were acidified with 0.5% formic acid, or were diluted 1:1 with CH₃CN/aqueous formic acid.

Results and Discussion : Peptides tend to form multiply-charged ion species under the conditions used here. This process permits accurate mass determinations on peptides with masses beyond the stated capacity of the mass filter : 1400 da. for the Sciex quadrupole (see spectra GRP₁₄₋₂₇). The peptide fragmentation patterns induced by CID MS/MS are similar to those which have been reported for EI and FAB. Ions of the B, A and Y series are formed (figures show MS/MS spectra for the (M+2H)²⁺ ion of GRP₁₄₋₂₇, and the (M+2H)²⁺ ion of bombesin). For ions with >2 charges some of the rules regarding fragmentation seem more complex, or are complicated by the formation of multiply-charged daughter ions. However, it appears that fragmentation is driven by instabilities in the peptide structure due to the presence of multiple charges. Peptides isolated from the conditioned media of cancer cell lines have been analyzed, but as yet no firm sequence assignments have been made.

ANALYSIS OF PHOSPHORYLATED AND SULFATED PEPTIDES BY
FAST ATOM BOMBARDMENT MASS SPECTROMETRY

David M. Guido and W. Rodney Mathews
The Upjohn Company, Kalamazoo, MI 49001

The characterization of phosphorylated and sulfated peptides can be difficult, especially when both qualitative (location of modified sites) and quantitative (extent of phosphorylation and sulfation at each site) information is required. We have examined the behavior of a number of phosphorylated and sulfated peptides by FAB MS. The location of phosphate groups in peptides can usually be determined from the fragmentation information available in the positive ion FAB mass spectrum (Figure 1) (1,2). Quantitative information on the extent of phosphorylation can also be obtained by FAB by determining the molecular protonated ion intensity ratio for the phosphorylated and non-phosphorylated peptide and plotting it versus mole ratio. Although the ion intensity ratio versus the molar ratio plot is linear for all peptides examined, as illustrated in Figure 2, the slope is significantly less than one and a standard curve should be prepared. Table 1 gives the slopes for the peptides studied. The method is useful for protein digests since the presence of other peptides in the sample does not appear to affect the relationship. When less than 10% phosphorylation is present, no peak may be observed for the phosphorylated peptide so one must be careful about drawing conclusions at those levels. Work published by Poulter, *et al.* indicated that a relationship is evident between hydrophobicity and ionization efficiency and that the difference in ion intensities for protonated molecular ions of phosphorylated and the corresponding non-phosphorylated peptide could be corrected for by modifying the matrix (3). In our experiments, however, addition of strong acids only complicated the spectra and decreased the signal-to-noise ratios. The differences may be due to a different matrix selection.

In contrast, sulfated peptides can show a major fragment ion in both the positive and negative ion modes for the loss of the sulfate group (Table 2). The fragment appears at the same mass as the molecular ion of the non-sulfated analog. Thus, it is difficult to determine whether or not there is a mixture of sulfated and non-sulfated peptides. FAB MS can generally indicate the presence of a sulfate group but not the amount of sulfation. Matrix additives were examined to see what effect they had on the appearance of the mass spectrum of the sulfated peptides. Preliminary results seem to indicate that the addition of tetramethyl ammonium hydroxide increases the molecular ion intensity in the negative ion mode. We have also attempted to stabilize the sulfate group by preparing the methyl ester derivative, but the sulfate group is either cleaved or unmodified.

CONCLUSION

FAB MS can differentiate between phosphorylated peptides and the corresponding non-phosphorylated analogs; and the location of phosphorylation can be determined from the fragmentation pattern. Because no fragment ion for the loss of H_2PO_3 is observed at M-80, the ratio of the molecular ions of the phosphorylated and non-phosphorylated peptides can give quantitative information. The ratio of the molecular ion intensities do not directly correspond to the molar ratios but by plotting the intensity ratio versus the molar ratio, a linear relationship is observed. A standard curve must be prepared. Sulfated peptides, however, are not so easily distinguished from their non-sulfated analogs. The molecular ion is usually seen, but a fragment ion for the loss of the sulfate is observed at the same mass as the molecular protonated ion for the non-sulfated analog. The sulfated peptides do not always give sequence information because the sulfate group is so labile. It may be possible to modify the FAB matrix to increase to molecular ion intensity relative to the M-80 ion.

CALIFORNIUM-252 PLASMA DESORPTION AND CESIUM ION LIQUID
SECONDARY ION MASS SPECTROMETRY STUDIES OF SOME NATURAL AND
RECOMBINANT PROTEINS.

B. Pramanik, A. Tsaropoulos, M. Siegel*, R. Tsao*, P. Reichert, P. Das, P. Bartner, G. Her, V. Doelling*, T.L. Nagabhushan and P.P. Trotta. Schering-Plough Research, 60 Orange Street, Bloomfield, NJ 07003 and * American Cyanamid Company, Medical Research Division, Lederle Laboratories, Pearl River, NY 10965.

Californium-252 plasma desorption time-of-flight mass spectrometry (PDMS) has demonstrated the ability to analyze peptides and small proteins, whereas magnetic sector instruments using 10 keV xenon atoms or cesium ions as the primary beam, have also been employed in the analysis of small peptides up to 10 kDa. Recently, the use of higher energy ion guns has not only improved the liquid secondary ion mass spectrometry (LSIMS) sensitivity in the analyses below 10 kDa, but also expanded the useful analytical mass range of the technique. We have compared ^{252}Cf -PDMS and 35 keV Cs^+ -LSIMS in the analysis of a number of recombinant and naturally occurring proteins in order to determine their respective strengths and limitations as well as to assess their analytical utility.

In the PDMS analysis, a protein solution in 0.1% aq. TFA was deposited onto a nitrocellulose-coated aluminum foil as a 2:1 (v/v) mixture in ethanol, rinsed with 0.1-1.0 ml of a 0.1% TFA solution and spin-dried before its insertion into the BIOION 20 plasma desorption mass spectrometer. In the LSIMS analysis the protein sample, preferably in lyophilized form, was dissolved in 2 μl of m-nitrobenzyl alcohol or a glycerol/thioglycerol mixture directly on the probe tip followed by addition of 2-3 μl of neat TFA. The sample mixture was thoroughly mixed with a pasteur pipet prior to its insertion into the source of a VG ZAB-SE double sector mass spectrometer operating at 5 kV and equipped with a cesium ion gun generating a primary beam of 5-10 μA of Cs^+ at 35 kV. Two types of scans were generated, a wide range scan and a narrow scan of 3000 Da centered on the expected molecular weight. The protein samples that have been successfully analyzed were recombinant human α -2 interferon (rh-IFN α -2) and recombinant human granulocyte-macrophage colony stimulating factor (rh-GM-CSF; Schering-Plough/Sandoz), porcine trypsin, porcine and bovine somatotropin and a cyanogen bromide fragment of GM-CSF. The PDMS and LSIMS spectra presented similarities in the shape of the quasi-molecular ion peaks and the background continua. All these spectra were characterized by the presence of singly and multiply charged protonated molecule ions as shown in Figures 1 & 2. The mass measurement accuracy for the observed ions as determined by PDMS and narrow scan LSIMS experiments was better than 0.2% and 0.4% respectively, whereas the wide scan LSIMS experiments provided lower accuracy mass measurements.

Two factors were found to be important in obtaining LSIMS spectra: the amount of salt present in the protein sample and the liquid matrix used in the analysis. The presence of salt decreased the intensity of the molecule ion in the LSIMS spectrum of porcine trypsin in either m-NBA and thioglycerol/glycerol matrix. Similar effect on the intensity of the PDMS signal can be readily minimized by washing the nitrocellulose-adsorbed protein sample to remove salt contaminants. Among the several matrices attempted, m-NBA with neat TFA provided enhanced sensitivity and longer signal lifetimes. Sensitivity studies using porcine trypsin showed that the yield of the singly charged LSIMS molecule ion increased with increasing concentration from 100 pmol and 2 nmol, where it reached a saturation point. In the PDMS analysis the singly charged ion signal was observed from the 10 pmol sample, whereas those of the multiply charged species were observed from the 1 pmol sample.

In conclusion, 35 keV Cs⁺-LSIMS has comparable or slightly lower sensitivity and mass measurement accuracy compared to the PDMS method, even though both these mass spectrometric techniques have much better mass accuracy compared to that obtained by the most commonly used methods of gel-chromatography and SDS-electrophoresis.

SOLVING DIFFICULT PEPTIDE STRUCTURAL PROBLEMS BY TANDEM MASS SPECTROMETRY

* Université de Sherbrooke, Sherbrooke, Quebec, Canada J1H 5N4.

That MS/MS with a tandem double-focusing instrument (e.g., a VG ZAB-SE 4F) yields much enhanced spectral information from peptides is by now well-established. Here we illustrate that MS/MS with high energy collisions is able, even in complex sample mixtures, to distinguish isomeric amino acids, sequence N-terminally blocked peptides, sequence through cystine bridges, handle unusual peptide modifications, and resolve complex amino acid insertion/deletion problems. Clarification of these problems would have been difficult by any other method. It should be evident that deducing chemical structures of modified peptides based solely on arithmetic differences between the expected and the observed molecular ion masses is potentially fraught with error.

SEQUENCING OF CYSTINE-BRIDGED PEPTIDES: Premature termination of peptide syntheses can, upon oxidation of cysteine thiols, result in mixtures of homogeneous and heterogeneous disulfide dimers, the exact chemical nature of which is difficult to determine. If one maintains the cystine bridges intact, however, it is possible to sequence through the disulfide bond. Fragmentation of the cystine yields a characteristic spectral pattern consisting of a very intense triplet of signals separated by one Da derived from disulfide cleavage bracketed on either side by peaks representing $\pm$ sulfur. This is illustrated in Figure 1 by the tandem mass spectrum of a simple, N-terminally blocked homodimer. Note the intensity of the disulfide cleavage ions (m/z 604 is 7 times more intense than m/z 545). In general we treat the smaller of the linked peptide sequences as a modification of the cysteine of the larger peptide and use the traditional ABCD/VWXYZ nomenclature. We then reverse the peptides and treat the larger sequence as a modified cysteine of the smaller and employ 'A'B'C'D'/V'W'X'Y'Z'. 'Y' indicates internal fragments equivalent to Y-type cleavages from a single peptide chain formed by collisional reduction of the dimer.

DISULFIDE MAPPING OF PROTEINS: Tandem MS also promises to be useful in disulfide bond mapping of proteins. This technique can be applied to situations in which the parent ion signal intensity is too weak to allow tandem mass spectrometric sequencing through a cystine bridge as described above. For example, it is still often possible to perform disulfide mapping of higher mass compounds such as insulin or disulfide-bridged peptides in enzymatic digestion mixtures of proteins, even in cases where the parent ion signal would normally be considered insufficient for tandem MS. In these cases virtually the only fragments observed correspond to cystine bridge cleavage which yields the molecular weights of the linked peptides.

DISULFIDE SULFUR DELETION: A series of synthetic somatostatin analogues containing L- and D-amino acids and a putative disulfide were found to be 32 Da mass deficient by FAB. Exact mass measurements strongly suggested deletion of a sulfur rather than amino acid substitution. The compound did not display a mass shift when treated with DTT/DTE/ NH_4OH to reduce the disulfide thought to be present. By first opening the cyclic peptide by prolonged chymotryptic digestion (24 hrs, 35% yield) and acquiring a tandem mass spectrum of the hydrolyzed peptide ($M + \text{H}_2\text{O}$)⁺, it was possible to demonstrate that the two cysteines were still bridged but that a sulfur had been split out. The tandem mass spectrum of the ring-opened peptide is rich in sequence information (Figure 2). Fragment ions not explained in the scheme correspond to internal double cleavages.

SIMULTANEOUS AMINO ACID INSERTIONS AND DELETIONS: Unexpected insertions or deletions of amino acids are a common problem in peptide synthesis. In one case, a synthetic peptide purified as a single peak by RP-HPLC, and which had the expected amino acid composition, was shown by FABMS to be a mixture of five components differing by insertions and deletions of glycine. The tandem mass spectrum of the first glycine deletion peak revealed further heterogeneity in that the glycine deletion could be demonstrated in either one of two positions. Proof of deletion in the third position would require internal double cleavages which are often weak or not observed. Apparently the number of glycine deletions balanced the number of insertions so that the amino acid composition was fortuitously correct.

ISOMERIC ASPARTIC ACIDS: One batch of recombinant tumor necrosis factor (TNF) had proven inactive. FAB mapping of the inactive protein revealed a tryptic fragment 1 Da more massive than expected (1). The deamidation site was localized to a specific asparagine residue by tandem mass spectrometry; however, the deamidation process can result in isomeric forms of aspartic acid. By comparing the tandem mass spectrum of the tryptic peptide with tandem spectra of synthetic model compounds containing α - and β - aspartic acid, it was determined that the inactive protein contained a mixture of the aspartic acid isomers in place of the asparagine. D, V, and W ion fragments enable aspartic acid isomers to be distinguished much like the leucine/isoleucine method (2).

Recent studies in this and other laboratories have established the utility of hybrid tandem MS in the characterization of peptides, while recognizing the distinct advantages of four sector instruments for certain applications. We describe here several new developments which enhance the value of hybrid tandem MS in the detection and structural analysis of peptides. All analyses were performed on a VG ZAB SEQ instrument of BEqQ configuration. Acquisition was via a VG 11-250 data system. Ionization was by fast atom bombardment with a primary atom beam of xenon (8 keV). Two means of sample introduction were used: (i) conventional FAB probe introduction using 2,2'-dithiodiethanol/thioglycerol (1/1) as the matrix; (ii) continuous flow introduction using the following solvent composition - glycerol/acetonitrile/water (1/2/7) plus 0.1% trichloroacetic acid. The solvent was delivered at 4.5 μ l/min using a Waters high pressure syringe pump under control of a microliter-adapted Waters Automatic Gradient Controller. Injections were made through a Rheodyne 7520 injector with a 0.5 μ l fixed internal loop. Silanized fused silica tubing (1m x 0.05 mm, id) was swaged into the injector and the rear of the continuous flow probe with graphitized vespel ferrules. The space between the capillary and the "bullet" shaped probe tip was sealed by wrapping a small piece of teflon tape around the capillary and screwing the tip firmly in position. Capillary placement was adjusted to be slightly recessed in the probe tip. The probe tip was heated to 70 C for all injections.

1) Structural analysis.

Low energy CAD in the quadrupole collision cell of a hybrid instrument has been shown to provide useful structural information for small peptides (with M_r to above 1000). The observed fragmentations generally correspond to cleavages of the peptide chain. CAD of peptide MH^+ ions at keV collision energies have been shown (1) to promote additional fragmentation of amino acid side chains, permitting, for example, the differentiation of leucine and isoleucine residues. When collisional activation of peptide MH^+ ions is performed in a quadrupole collision cell, $E_{lab} > 200$ eV is required for detection of these fragment types and signal intensities are poor (2). Instruments of BEqQ geometry provide the facility for both low energy CAD (in q) and high energy CAD (between B and E). In the latter case, simultaneous scanning of E and Q yields daughter ion spectra with good mass resolution.

An appropriate strategy for structural characterization of peptides using a BEqQ instrument therefore involves (a) low energy collisional activation in q with scanning of Q to provide sequence information, and (b) high energy collisional activation in the cell between B and E, with linked E/Q scanning over selected narrow mass ranges to permit the differentiation of isobaric amino acid residues. Figure 1 illustrates the second stage of this strategy applied to Substance P. The E/Q linked scan recorded following high energy CAD of MH^+ ions includes the A_{10} fragment of m/z 1171 and an ion of m/z 1129 corresponding to additional loss of 42u, characteristic of a leucine (rather than isoleucine) residue.

2) Trace analysis.

Continuous flow sample introduction for FAB MS facilitates applications to trace detection of peptides. When analyses are performed on a tandem instrument, improved selectivity of detection may be achieved using selected reaction, rather than selected ion, monitoring. Figure 2 illustrates this approach with the analysis of replicate aliquots (500 pg) of Substance P, fragment 2-11. The fragmentation of MH^+ ions (m/z 1152) to m/z 966 (Y_g) was monitored.

STUDIES ON STRUCTURES OF BRAIN CALBINDINS:
AMINO ACID SEQUENCE ANALYSIS ON THE TSQ 70

A.L. McCormack, D.F. Hunt, J. Shabanowitz, N.-Z. Zhu, and P.R. Griffin
Department of Chemistry, University of Virginia,
Charlottesville, Virginia 22901

Calcium binding proteins, calbindins, whose synthesis is regulated by vitamin-D, have a widespread distribution in vertebrate tissue. Recently, two new calbindins, CaBP-28k and CaBP-29k, have been isolated from the Purkinje cells of rat cerebellum (1). Both proteins exhibit cross-reactivity with antibodies raised against chick intestinal calbindin-D_{28k}. It has been suggested that in the nervous system CaBP-28k plays a role in cell differentiation and in calcium mediated enzyme activities; the role of CaBP-29k is unknown. Recently, a 29 kDa calcium-binding protein, calretinin, was isolated from chick retina and brain (2). However, the neuronal distribution of calretinin does not coincide with the distribution of chick brain calbindin, as calretinin is absent in cerebellar tissue. Our initial objective was to determine if the two brain calbindins were derived from a single precursor. Most recently our objectives have been to characterize the complete amino acid sequence of both proteins and to determine the extent of homology between the two proteins and chick calretinin.

Both calcium binding proteins were isolated from the Purkinje cells in rat cerebellum using gel permeation chromatography and preparative gel electrophoresis. Each protein was purified further by reverse phase HPLC. Typically, proteolytic digestion of the reduced and S-carboxymethylated protein (3-5 nmoles) was accomplished using trypsin, endo-Glu-C, or endo-Asp-N at 37°C for 8 to 24 hours. In addition, approximately one nmole of the native protein was digested by either trypsin or endo-Lys-C at 37°C for 24 hours. Peptides were fractionated by reverse phase HPLC. Peptides in the resulting fractions were characterized by tandem mass spectrometry using either a triple quadrupole or a quadrupole Fourier transform instrument.

In an effort to determine if the two calbindins were derived from the same precursor, both proteins were enzymatically digested under identical conditions with trypsin, endo-Asp-N, and endo-Glu-C. The resulting peptides from each digest were fractionated and the molecular weights were recorded. Each of the three digests produced only a few peptides which were found in both proteins, determined by similarities in molecular weight and HPLC retention time. Partial sequence analysis indicates that the two proteins are only 67% homologous, which further suggests that these two calbindins are different proteins.

Sequence data indicates that CaBP-28k is rat spot 35 protein, a Purkinje cell-specific calcium-binding protein, which has been sequenced using oligodeoxynucleotide probes (3). An endo-Lys-C digest of 800 pmoles native CaBP-28k yielded 75 percent of the sequence. In addition, metastable decomposition and photodissociation QFTMS spectra strongly suggest that the amino terminus is acetyl-alanine.

Interestingly, several peptides isolated from different digests of CaBP-29k only exhibit homology to chick calretinin, whose partial sequence has been determined from the chromosomal gene clone. This suggests that CaBP-29k may be rat calretinin or a closely related calcium binding protein. Research will continue to determine the primary structure of both cerebellar calbindins.

Shown below in Figures 1-3 are spectra that illustrate the current status of peptide sequence analysis on the TSQ-70 mass spectrometer in our laboratory. Collision experiments are conducted in the energy range of 25-40 eV on a 2/1 mixture of argon and xenon at 3 mtorr. Sample quantities are typically 1-10 pmol below m/z 1,000; 5-50 pmol below m/z 2,000 and 30-300 pmol below m/z 2600.

TOF-SIMS and FAB of Modified Peptides: A Comparison of Sensitivities

B. Hagenhoff, E. Niehuis, A. Benninghoven

Physikalisches Institut, Universität Münster

Wilhelm-Klemm-Str. 10, D-4400 Münster, FRG

C. Wünsche, H. Musche

Bayer AG Pharmaanalytik, D-5600 Wuppertal, FRG

The last years have shown the necessity of ultimate sensitivity in the analysis of peptides in protein and/or DNA analysis. The sample amount directly available or available after preseparation techniques such as high pressure liquid chromatographies is in or even below the pmol- range.

We investigated a number of modified, pharmaceutically relevant peptides in the mass range between 500 and 900 u (see figure 1) both with a high resolution TOF-SIMS built at the University of Münster ($I_p = 1$ pA, spot diameter 50 μ m, $m/\Delta m_{50\%} = 4000$ [1]) and with a Kratos MS 80 FAB instrument (acceleration voltage 4 kV, $I_p = 10$ μ A, $m/\Delta m_{10\%} = 1000$). Both instruments were operated in the same laboratory of the Bayer AG pharmaanalytical research center.

For SIMS measurements 1 μ l of diluted solutions ($10^{-3}, \dots, 10^{-7}$ mol/l) in methanol was deposited onto an area of about 40 mm² of an etched silver substrate. In the case of FAB 0.5 μ l of the corresponding solutions was mixed with 0.5 μ l m-nitrobenzyl alcohol (MNBA) as matrix.

Table 1 shows the results obtained for the different peptides.

The FAB detection limit is mainly determined by background peaks originating from the matrix material and the transmission of the double focusing magnetic spectrometer. The lowest detectable sample amount was 50 pmol, in one case 5 pmol.

The TOF-SIMS sensitivity is limited by chemical background from the solutions and the fact that the analyzed area is about 10^4 times smaller than the prepared sample area. The lowest deposited sample amount was 1 pmol, in one case 0.1 pmol, corresponding to 0.1 fmol and 0.01 fmol in the analyzed area respectively. By an improvement of the sample deposition technique it should be possible to reduce the required sample amount.

Future investigations will concentrate on this point in the case of TOF-SIMS and will include a Finnigan MAT 90 instrument for the FAB investigations.

Structural Characterization of Lens Proteins by FABMS

Jonathan Leeds, Wen Qin, and David Smith
Department of Medicinal Chemistry and Pharmacognosy
Purdue University, W. Lafayette IN 47907

Cataract, which is the most common cause of blindness throughout the world, is due to the failure of the lens to transmit light. Of the several different factors which contribute to opacification of the lens, aggregation of proteins located within the lens is believed to be the most important. Although cataract is most often treated by extraction of the lens, it is desirable to understand the causes of cataract at the molecular level so that preventive treatments may be developed. A complete understanding of cataractogenesis will be possible only when the structures and reactivities of the lens proteins have been well characterized.

Approximately 30% of the wet weight of the lens comprises a group of structural proteins often referred to as crystallins. These proteins are classified as α , β , and γ , according to their tendency to form high molecular weight aggregates. Each of these general types of crystallin consists of five to ten forms which differ in amino acid sequence. For some forms, the complete sequence is known. Other forms have been characterized primarily by their chromatographic properties or by their peptide maps. This is the best characterized of the lens proteins. All of the lens proteins contain cysteinyl residues which may participate in intermolecular disulfide crosslinking, and hence formation of covalently bonded aggregates.

The goal of this investigation is to characterize at the molecular level the structures of lens proteins so that future investigations of protein aggregation, as it relates to cataract, will be possible. This will require isolating the different forms of the lens proteins and confirming or determining their amino acid sequences. FABMS will be used to make molecular weight maps of peptides produced by proteolytic fragmentation of homogeneous lens proteins. This information will be used to confirm or correct sequences which have been predicted or determined by other methods. For those crystallins for which complete sequences have not reported, this information will be used as a measure of the homology of lens proteins.

In this preliminary investigation, highly purified forms of two of the best characterized forms of lens proteins, β Bp and γ II, have been isolated from bovine lenses. These native proteins were fragmented with trypsin and *Staphylococcus aureus* V8 protease and fractionated by reversed phase HPLC. Molecular weights of the peptides, determined by FABMS, were used to verify the sequences of these proteins. These results indicate that sequences predicted from the corresponding cDNA are correct, where as those based on conventional sequencing methods contain several errors.

To achieve the ultimate goals of this investigation, we must be able to identify as well as locate modifications to the lens proteins. Linked scan daughter ion mass spectra, as illustrated in the accompanying figure, will undoubtedly play a major role in this investigation. This spectrum, which was obtained for the 90-100 segment of β Bp, contains a nearly complete set of peaks for both the A and Y" series of fragments.

Results of this preliminary investigation of the crystallins suggest that FABMS will be very useful in identifying modifications which ultimately lead to cataractogenesis. Peptide mapping results of two of the crystallins, including linked-scan daughter ion spectra, have been used to confirm their primary structures. From these results, it is apparent that FABMS can be used to determine precisely which portions of the lens proteins participate in intermolecular crosslinkages.

Linked Scan Daughter Ion Spectrum

COLLISION-INDUCED DISSOCIATION OF MULTIPLY CHARGED PEPTIDES

T. R. Covey Sciex, Inc. 55 Glen Cameron Road, Thornhill Ontario, Canada L3T 1P2
J.J. Conboy, J.D. Henion, Equine Drug Testing, 925 Warren Dr. Cornell Univ., Ithaca,
N.Y. 14850

In order to fragment ions in MS/MS, a variety of methods have been proposed to deposit sufficient internal energy into an ion to effect decomposition. These include collision induced dissociation (CID), photodissociation, surface induced dissociation (SID), and electron induced dissociation. CID has proven to be the most popular because of the instrumental simplicity, large cross section for excitation, and ease of changing parameters such as collision gas thickness and collision energy which can effect fragmentation efficiency. One draw back is that CID efficiency has been observed to decrease with increasing mass (ca. 800 d or higher) because of a dissipation of the collision energy into many vibrational modes with a resulting small fractional increase in the internal energy of the molecule.

With Ion Evaporation ionization, intense multiply charged molecular ions are produced from peptides and proteins effectively extending the mass range by a factor of 10 - 100 fold. A Sciex API III triple quadrupole mass spectrometer with Atmospheric Pressure Ionization and an Ion Spray interface was used to produce Ion Evaporation spectra and conduct MS/MS studies of multiply charged ions.

The majority of the work on the MS/MS of peptides has concentrated on the CID of the singly charged pseudo-molecular ion. Studies were undertaken to see if CID could be performed on molecules in the 2 - 20 kdalton range on molecules with as many as 20 charges. Because of their highly charged state internal repulsive forces put these molecules into a "strained" configuration allowing for a very efficient CID process at low collision voltages. Daughter ion spectra of the $(M+2H)^{2+}$, $(M+3H)^{3+}$, and $(M+4H)^{4+}$ of bovine insulin (mw = 5732) are shown.

It has been determined that the charges are localized at the basic amino acid residue sites in a peptide (arginines, lysines, and histidines) as well as at the amino terminus. Systematic studies correlate the type of fragmentation observed with the position of the charged site in the molecule. With doubly or triply charged parent ions with the charges localized toward the amino terminus sequence information is primarily of the "A and B" type. Ions of the "D" type are also observed. Substance P was used as one of the model compounds for this study. If the charges are located at either end of the molecule the fragmentation is dominated by "Y and B" ions with valuable sequence information being observed.

Proteins treated with trypsin yield peptides that are all doubly charged because trypsin cleaves at the carboxy terminus side of arginines and lysines. On-line LC/MS separation of the tryptic fragments of hemoglobin are shown. Daughter ion spectra of the doubly charged tryptic fragments yield the desired "Y+B" fragmentation providing extensive sequence information.

Tryptic Peptides From Protein Digests are Always Doubly Charged with Charge Localized at Ends

- Exceptions:
1. Carboxy terminus peptide is likely to be singly charged because it will not have an arginine or lysine. It can therefore be identified.
 2. Fragments containing an internal histidine will have a triply charged as well as doubly charged ion offering additional information.

COLLISION-INDUCED DECOMPOSITIONS OF PEPTIDES CATIONIZED WITH ALKALINE EARTH AND ALKALI METAL IONS

Lynn M. Teesch and Jeanette Adams: Department of Chemistry, Emory University, Atlanta, GA 30322.

A few research groups recently have investigated the complexation of peptides and alkali metal ions, mainly Li^+ and Na^+ , by collisionally activating the $(\text{M}+\text{Cat})^+$ ions (1-3). The predominant fragmentation observed in the collision-induced decomposition (CID) spectra was proposed to be a rearrangement involving the cleavage of the C-terminal amino acid to produce $(\text{B}_{n-1}+\text{OH}+\text{Cat})^+$ ions (1,2).

In work presented here, CID spectra of $(\text{M}+\text{Cat})^+$ and $(\text{M}-\text{H}+\text{Cat})^+$ ions, where Cat=alkali and alkaline earth metal ions, respectively, of 13 model peptides were investigated. The parent ions were desorptively ionized by fast atom bombardment (FAB), then B/E linked scanning was used to obtain the CID spectra. Trends in relative ion abundances with changing metal ion are observed.

The $(\text{M}-\text{H}+\text{Cat})^+$ series, in which Cat=an alkaline earth metal ion, for leucine enkephalin is shown in Fig. 1 and is a representative example displaying the characteristic fragmentations. Collisional activation (CA) of

Fig. 2 CID spectra of Tyr-Gly-Gly-Phe-Leu (leu-enkephalin) cationized with alkali metal ions. The A and B series follow the nomenclature in ref. 4. The 1 ions arise from the loss of the tyrosine side chain. The 2 ions arise from the mechanism in eqn. 1, discussed below. To conserve space, (M+K)⁺ is not included.

Because fragment ions containing both the N- and C-terminal amino acids are observed in CID spectra of (M-H+Cat)⁺ ions, CIDs of these ions may be used to complement structural assignments derived from CIDs of (M+H)⁺ ions. Within the alkali-ion series of (M+Cat)⁺ ions, CID spectra show an increase in the abundance of (A_{n-1}-H+Cat)⁺ ions as the size of the metal ion increases, which suggests that the larger cations prefer a site other than the carboxylate terminus.

We also find that (M+Cat)⁺ parent ions that have an appropriate R group on the C-terminal amino acid decompose via a rearrangement reaction that involves the C-terminal carboxylate and the C-terminal R group (eqn. 1). This fragmentation is useful for delineating leucine from isoleucine and from other C-terminal amino

acids. In cases in which the C-terminal amino acid is leucine, the identifying fragment corresponds to loss of 88 u (labeled as 2 in Fig. 2). For isoleucine, the fragment ion arises from loss of 74 u; for methionine, the fragment ion arises from loss of 106 u.

We have previously reported on the feasibility of determining the pattern of bovine pituitary peptides by mass spectrometry [1]. The largest molecules observed were oxytocin-neurophysin (OT-NP) and vasopressin-neurophysin (VP-NP) with molecular weights of almost 10,000 u. We have since studied these small proteins in more detail for the following two reasons: i) The molecular weights determined for equivalent samples from duplicate chromatographic separations differed considerably. We suspected that this variation was largely due to sample heterogeneity (multiple cationization, methionine oxidation, cystine reduction, amino acid substitutions, methylations, truncations, etc.) rather than to technical difficulties of the mass measurement in this mass range. We therefore initiated this study to prove the heterogeneity of our neurophysin samples. ii) Many neuronal peptides coexist in multiple forms due to only partial completion of proteolytic and other post-translational modification reactions. As these modifications proceed, the chemical message being conveyed by the corresponding secretory neurons may change. The neurophysins are interesting model compounds to study these processes because of their microheterogeneity and because they are believed to be subject to methylation and C- and N-terminal truncations. Neurophysin variants with only single amino acid differences may be resolved and quantified with RP-HPLC, but the common practice [2] of identifying the variants by amino acid analysis, carboxypeptidase digestion, gel electrophoresis, and Edman degradation is time-consuming. We were interested in exploring the possibility of more rapidly identifying the variants by mass spectrometry.

We have resolved our crude neurophysin fraction by RP-HPLC (Fig. 1) and analyzed the fractions that correspond to single HPLC peaks by FAB-MS and by PD- and FAB-mapping. Following purification, at least some of the individual neurophysin variants can be mass measured with reasonable accuracy although multiple cationization still leads to broad molecular ion peaks. Molecular weight information may thus lead to tentative identification of particular neurophysin variants including their methylated forms. Fig. 2 shows the FAB spectrum of fraction 5 (Fig. 1), which, in combination with N-terminal sequence information from Edman degradation, identifies this variant as OT-NP(1-91). The proteins in fractions 4 and 3 have been tentatively identified as OT-NP(1-92) and OT-NP(1-93), respectively.

Tentative identifications can be confirmed by peptide mapping. The neurophysins in fractions 1 and 2 have been characterized by PD- and FAB-mapping as Val-89-VP-NP and Ile-89-VP-NP, respectively. Fig. 3 compares the expected tryptic fragments for the known bovine VP-NP and OT-NP variants. Using the crude tryptic digest, not all tryptic peptides were observed but, unless methylation patterns are to be deduced, complete maps are not necessary. Since the protein cores of the neurophysins are conserved and the amino acid variation is only in the C- and N-termini, the latter unambiguously characterize the neurophysins. Fortunately, they give rise to prominent ions in the PD- and FAB-maps (Figs. 4 & 5). The N-terminus allows differentiation between VP-NP and OT-NP ($[M+H]^+$ 934 vs. 900) and the truncated C-terminus VP-NP(87-93) allows differentiation between Val- and Ile-VP-NP ($[M+H]^+$ 761 vs. 775). The full length of the VP-NP variants was deduced from analysis of proteolytic digests with *S. aureus* V8 protease (for example, $[M+H]^+$ 887 for Val-89-VP-NP(88-95)), Fig. 5).

Multiple molecular ions due to cationization with protons and sodium and potassium ions were seen throughout the study. With FAB-MS this can only be avoided/reduced by careful choice of reagents and matrices, whereas PD-MS offers the possibility of removing the interfering ions by washing of the sample on the target. Unfortunately, however, the small peptides may also be removed during this procedure (Fig. 4) and this option therefore has to be used with caution.

In conclusion, the mass variations previously observed for the neurophysins are largely due to sample heterogeneity. Individual neurophysin variants can, after chromatographic resolution, rapidly be identified by PD- and FAB-MS in conjunction with enzymatic digestions.

RESOLUTION AND IDENTIFICATION OF DERIVATIZED ENANTIOMERS OF α -AMINO ACIDS
ON A CHIRAL DIAMIDE PHASE BY GC/MS:

Joseph Shu-Cheng Chang, and Shiaw-Rae Lin
The Fourth Department, Chung-Shan Institute of Science and Technology
Lung-Tan, Tau-Yuan, TAIWAN, R. O. C.

INTRODUCTION:

Much of the research carried out in recent years on the resolution of optical isomers has centered around systems in which the solute-solvent association necessary for chiral recognition is effected through hydrogen bonding. In particular, the highly selective diamide phase derived from L-phenylalanine, N-Lauroyl-L-Phe t-butylamide, permits the resolution of different classes of compounds. However, their most important application lies in the area of α -amino acids, both N-trifluoroacetyl (N-TFA) isopropyl esters and N-TFA t-butylamides have been resolved on L-Phe diamide phase^{1,2}. Generally, mass spectrometers provide more sensitivity and selectivity compared with other GC detectors. A extension of this resolution system of enantiomers of α -amino acids from GC to GC/MS is clearly useful. The enantiomers of derivatized α -amino acids (e.g., Ala, Val, Leu, Pro, Phe and Phg) were resolved on L-Phe phase by GC. Subsequently, the eluted enantiomers were identified by EI or CI (CH_4 , NH_3 and D_2O as reagent gases) mass spectrometry.

MECHANISM OF RESOLUTION:

Diamides can interact through hydrogen bonding in a number of ways to form structures of the pleated sheet type. The diamide molecules can, for instance, be aligned parallel or antiparallel to each other, as illustrated in Fig. 1. As in the chromatographic process the solute is always present in a very low concentration in the liquid phase, its potential for hydrogen bonding will be fully implemented by interaction with surrounding solvent molecules, resulting in intercalation.

In the separation of derivatized of α -amino acids on diamide phase, it is assumed that the interaction between pertinent solute and solvent molecules occurs through hydrogen-bonded association of the " $\text{C}_5\text{-C}_5$ " or " $\text{C}_5\text{-C}_7$ " type, as shown in Fig. 1. N-TFA- α -amino acid esters have only a C_5 conformation. N-TFA- α -amino acid t-butylamides have both C_5 and C_7 sides. The stereoselectivity observed should result from the differences in interaction between the substituents at the asymmetric centers in the diastereomeric interaction complexes.

EXPERIMENTAL:

A stainless-steel capillary column (25 m x 50 mm) coated with N-Lauroyl-L-phenylalanine t-butylamide was mounted on a Finnigan 4023 GC/MS. The temperature of the injector was 200 C; column temperature was programmed from 120 to 150 C at 7 C per minute. The helium flow-rate was 1 ml/min. The order of elution of the peaks was established for Ala, Val, Leu and Pro by operating with mixtures enriched in the L enantiomer, and for Phenylglycine (Phg) enriched in the D enantiomer. This result was extrapolated to Phe.

The pressure of reagent gas in the ion source was 0.4, 0.7, and 1.0 torr for CH_4 , NH_3 and D_2O , respectively.

RESULTS:

A mixture of α -amino acid enantiomers were injected into the GC/MS, separated using a chiral column and identified by the selected ion monitoring mode of the mass spectrometer. The D-enantiomeric derivatives eluted prior to the L-enantiomeric derivatives on L-Phe diamide phase in all cases at the operating temperatures used (Fig. 2).

The mass spectra (EI or CI) of enantiomers were almost identical with respect to fragmentation patterns and peak intensities for both derivatives of α -amino acid of N-TFA isopropyl esters and N-TFA t-butylamides. The EI-MS base peak in most cases resulted from fragmentation of the C-terminal bond adjoining the asymmetric carbon of α -amino acids with retention of the charge on the N-terminal group.

The NH_3 CI spectra of the N-TFA isopropyl esters of phenylalanine and phenylglycine are dominated by $(\text{M}+4)^+$ ions which are proposed to be $(\text{M}+\text{NH}_4\text{-CH}_2)^+$ ions (Fig. 3). Further evidence for this structure is the formation of $(\text{M}+\text{D-CH}_2)^+$ ions with D_2O CI (Fig. 4).

INTRODUCTION

C-Phycocyanin (PC) is a light-harvesting protein in the photosynthetic apparatus of cyanobacteria and red algae. The visible chromophores on PC are open-chain tetrapyrroles, phycocyanobilins, attached to cysteinyl residues through thioether bonds (1). The posttranslational attachment of phycocyanobilin to apophycocyanin may be an enzyme-catalyzed process (2). In *Synechococcus* PCC7002, insertional inactivation of one of the genes in the PC operon, *cpcE*, leads to loss of phycocyanobilin from the PC α subunit. A phenotypic revertant of a *Synechococcus* PCC7002 *cpcE*⁻ mutant produced an altered PC. The structural difference between wild type PC and that produced by this revertant (designated PCR) was determined by a combination of peptide mapping and mass spectrometry.

EXPERIMENTAL

Purified *Synechococcus* PCC7002 and *cpcE*⁻ PCs (3) were reduced and carboxymethylated with iodoacetate. Peptides were obtained by tryptic digestion followed by subdigestion of purified tryptic peptides with chymotrypsin or staphylococcal V8, as required. All peptide purification was performed by reverse phase HPLC. All samples were desalted on a reverse phase C-18 column prior to MS analysis.

Mass spectra were obtained on a VG ZAB2-EQ mass spectrometer of BEqQ geometry. FAB experiments were performed using a cesium ion gun operated at 20 kV and 1.5 emission current. For CAD experiments the parent ion was selected with 1:1000 resolution and transmitted into the collision quadrupole at 20 eV (laboratory frame-of-reference) energy. Argon was used as the collision gas at a pressure which optimized daughter ion current. Daughter ion spectra were obtained by scanning from 50-950 in 20s and acquiring 2-3 scans. The mass scale of the quadrupole was calibrated with the m/z 69 and m/z 866 from CAD of the m/z 866 ion derived from tris-(perfluoroheptyl)-S-triazine. Accurate mass measurement of the chymotryptic peptide from PCR was made by peak matching against met,lys-bradykinin (MH⁺ 1319) at 1:10,000 resolution.

RESULTS AND DISCUSSION

The revertant grew more slowly than wild type and produced a spectroscopically altered PC. Comparison of the tryptic peptide profiles of wild type and mutant PC showed that an altered peptide was present in PCR. FAB MS and sequential Edman degradation in a gas-phase sequenator identified the tryptic peptide as TFDLSPSWXVEALK (I), where X is tyrosine in the wild type PC. Sequence analysis showed X was altered in PCR. Peptides TFDLSPSWXVE (II) and DLSPSWXVEALK (III) were prepared from I by subdigestion with staphylococcal protease V8 and chymotrypsin, respectively.

FAB-MS of I determined that the mass of the peptide from PCR was 2 AMU lower than that of the corresponding PC peptide. Sequence indicative ions in the FAB spectra of I and II (Figure 1) localized the changed amino acid to residues 8-11. Low energy CAD of the Y₆⁺ ion (PSWXVE) from II (Figure 2) confirmed that the changed residue was at position 7 in peptide II, and that this residue had a nominal mass of 161 (MW-H₂O). Exact mass measurement of peptide III matched the inclusion of

S-carboxymethylcysteine in the empirical formula of the modified peptide. The revertant compensated for the absence of the *cpcE* gene product by substitution of a cysteine for a specific tyrosine in the PC α subunit.

Wilmington, Delaware 19880-0228

Cyclophilin is a soluble, highly conserved cytosolic protein present in high concentrations (0.1-0.4% of total cytosolic proteins) in many mammalian systems and nearly all organisms. It forms a tight stoichiometric complex with cyclosporin A (CsA), a cyclic 11 residue peptide that is a powerful suppressor of the immune response. CsA is used to prevent organ transplant rejection. Recent efforts to characterize peptidyl-prolyl cis-trans isomerase (PPI) showed the n-terminal sequence was identical to cyclophilin, suggesting the two proteins are identical. Therefore, it is possible that cyclophilin might not be just a high affinity binding site for CsA but also the site of the drugs primary biological effect - inhibition of the enzymatic activity of PPI.

Studies to characterize the cyclophilin binding site of cyclosporin A are underway for the express purpose of understanding this interaction and to design new immuno-suppressant drugs that are more potent and less toxic. The CSA activity of cyclosporin is sulphhydryl dependent which suggests that one of the 4 cysteines is involved in binding CsA. To determine which cysteine binds to CsA, each of the 4 cysteine residues were individually changed to serines by recombinant DNA technology. The conventional analytical techniques for identifying single point mutations in a protein like cyclophilin are quite time consuming. Fast Atom Bombardment (FAB) mass spectrometry is a fast and sensitive method for characterizing peptides and protein digests. A tryptic map was used to characterize the modified cyclophilins (Figure 1). The molecular ions (M+H)⁺ of the tryptic peptides can uniquely be assigned to discrete portions of the protein sequence (Figure 2). In the spectrum of the modified proteins, the molecular ion containing the serine change is reduced in mass by 16 Daltons (Table 1). The assignments from a FAB Map can be further confirmed by a single step of Edman Degradation where the molecular ion is reduced by the loss of the n-terminal residue. In a short period of time, the protein sequence was analyzed and the modifications to the protein sequence confirmed.

TABLE 1: Comparison of molecular ions from human cyclophilin to the modified proteins containing single residue change of cysteine to serine.

MODIFIED PHENYLISOTHIOCYANATES FOR PEPTIDE SEQUENCING BY
NEGATIVE ION CHEMICAL IONIZATION MASS SPECTROMETRY

Amit Ghosh and Robert J. Anderegg, Department of Chemistry,
University of Maine, Orono, Maine 04469.

Protein microsequencing using phenylisothiocyanate (PITC) is currently possible in the low picomole range using HPLC with UV absorbance to identify the phenylthiohydantoin (PTH) derived from the amino acid released at each cycle. For many interesting proteins that can be isolated in only small quantities, the sensitivity of detection is insufficient to permit sequencing. Recently, several techniques have been put forward for high sensitivity sequencing, centering around the direct identification of PTH-amino acids. We are investigating the use of negative ion mass spectrometry as a detection method. PITC can be modified in a number of ways to make it electron capturing. We have compared meta-trifluoromethyl phenylisothiocyanate (mCF₃PITC) and pentafluoro phenylisothiocyanate (PF₅PITC) (1,2) to the normal unsubstituted PITC to assess their suitability as Edman reagents.

One important aspect of the comparison is the speed and completeness of coupling reaction. Our results (Figure 1) show that PF₅PITC has the fastest speed and highest yield of the three in the coupling reaction with amino acids. On this basis, it was selected for further study. There is little or no by-product formation with any derivative. Almost all PF₅PTH-amino acids undergo fragmentation (2) in negative ion chemical ionization (electron capture) mass spectrometry (NICI-MS). Amino acids can be grouped into four categories based on fragmentation: (a) the largest group has a base peak at M - 28 (presumably loss of CO), (b) the second largest group has a base peak at M - 48 (presumably loss of CO and HF), (c) the third group has a base peak at M - 18 (loss of H₂O) and (d) the fourth group shows more extensive fragmentation. In spite of this fragmentation, one or more diagnostic ions are produced for each amino acid.

Using a model peptide (Phe-Gly-Gly), manual sequencing with PF₅PITC was attempted. The cycle time was 60 minutes, although this may improve with optimization. In each cycle, the expected PF₅PTH-amino acid was indicated by a diagnostic ion (Figure 2). There was no observed overlap between cycles or by-product formation. When scanning the full mass range (m/z 245 - 610), five picomoles applied to the DCI probe was easily observed. To enhance sensitivity still further, selected ion monitoring can be used (Figure 3). In this mode, 155 femtomoles of PF₅PTH-Asn was observed with a signal-to-noise ratio of over 80.

CONCLUSION:

Pentafluoro PITC is a promising reagent for peptide sequencing using NICI-MS for detection of the modified PTH-amino acids. There is no need for chromatography since the negative ions can be detected selectively and since the mass (or combination of masses) is unique to each derivative.

Pentafluoro PITC couples to amino acids faster and to greater extent than either meta-trifluoromethyl PITC or unsubstituted PITC. The excess PF₅PITC and amino acid derivatives are nonpolar and easily extracted into the organic solvents.

The major drawback of the pentafluoro PTH-amino acids is that almost all of them undergo fragmentation in NICI-MS, with a few of them having more than three major ions. This causes some loss of sensitivity, but allows the PF₅PTHs to be identified with greater confidence, since the presence of multiple ions in the proper ratio is unlikely to occur by chance. Work is continuing to demonstrate sequencing with longer peptides and to understand the mechanism of fragmentation.

LSIMS ON MULTIPLE CYSTINE-LINKED PEPTIDES FROM
RECOMBINANT HIRUDIN VARIANT 2-Lys 47 (rHV2-Lys 47) DIGESTION.

P. Lepage*, C. Roitsch*, M. Acker*, F. Bitsch* and A. Van Dorsselaer*

* Transgène S.A., 11 rue de Molsheim, 67082 Strasbourg CEDEX, FRANCE

* UA31 CNRS, 5 rue Blaise Pascal, 67084 Strasbourg CEDEX, FRANCE

Natural hirudin isolated from the salivary glands of the medicinal leech *Hirudo medicinalis* is a highly potent anti-thrombotic agent destined for pharmaceutical use in venous and arterial thrombosis. Production of recombinant hirudin variant 2-Lys 47 (rHV2-Lys 47) (65 amino acids, 3 cystine bridges) has been undertaken through recombinant DNA technology using a *Saccharomyces cerevisiae* host and a secretion vector based on the alpha-pheromone export signals (1, 2). Hirudin for pharmaceutical purpose requires periodic routine characterization on production lots. To this end, average mass measurements from Liquid Secondary Ion Mass Spectrometry (LSIMS) on different hirudin variants and improperly processed hirudin have been described (3, 4). The primary sequences of various hirudins have been previously obtained by Edman degradation of tryptic peptides after cysteine modifications (5, 6), and cystine bridge determination was performed after thermolysin digestion which generated numerous peptides. In this paper, both primary and secondary structure derived from the combination of LSIMS and Edman degradation of successive tryptic and V8 protease digestions is described.

From tryptic digestion of rHV2-Lys 47, four peaks are separated from RP-HPLC (Figure 1). Complete sequencing of rHV2-Lys 47 could be easily done with three steps of Edman degradation obtained on the tripeptide T1, and 30 steps on peptide T3 where the three sequences are read simultaneously, thus 33 steps in total.

LSIMS was performed on peptides chains linked by cystine bridges. In addition to the mono and doubly protonated molecular ions, other peaks are observed and are generated by fragmentation of disulfide bonds. They appeared at m/z values corresponding to the protonated masses of the peptide which a chemical reduction would have produced.

FIGURE 1 : RP-HPLC RUN OF rHV2-Lys 47 TRYPTIC DIGEST

Cystine bridge identification was performed after V8 protease digestion of tryptic fragment T3. By RP-HPLC three fractions containing cystines were isolated (Figure 2). LSIMS on V8 subfragments showed mono and doubly protonated molecular ions, as well as other peaks generated by disulfide bond fragmentations. Results from Edman degradation and LSIMS performed on the RP-HPLC purified peptides retain a maximum of 2 indistinguishable combinations of cystine bridges (S-S 6-14, 16-28, 22-39 or S-S 6-16, 14-28, 22-39) from the 15 theoretical arrangements possible.

FIGURE 2 RP-HPLC RUN OF V8 DIGEST OF TRYPTIC FRAGMENT-T3

In this method, the enzymatic digestions generate few peptides and only two RP-HPLC runs are required. In conclusion, the combination of tryptic and V8 protease digestion, LSIMS and Edman degradation (33 steps) performed on rHV2-Lys 47 allowed a very efficient characterization of the primary sequence and cystine bridge identification in 3 days. This simple and relatively rapid method could be used as a routine technique for quality control of a recombinant hirudin production.

CONFIRMATION OF INDOLE-3-ACETIC ACID BOUND TO ZEIN

Leslie A. Leverone¹, John L. Caruso¹ and K. Jayasimhulu²

¹Department of Biological Sciences, University of Cincinnati, Cincinnati, OH 45221-0006; ²Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, OH 45267-0056.

Indole-3-acetic acid (IAA), a plant hormone, was reported earlier by other workers to be released by alkaline hydrolysis from zein, the dominant storage protein in the corn kernel. Bioassays were used in the analysis. Since then studies have primarily addressed the metabolic fate of lower molecular weight conjugates of IAA, the primary auxin of plants. The present work uses combined gas chromatography-mass spectrometry (GC/MS) to confirm the presence of IAA in zein. Protein bodies from mature corn kernels were isolated by isopycnic centrifugation. Protein extracted from these organelles and subjected to SDS gel electrophoresis revealed major bands corresponding to 22 and 19 kD, which are in agreement with known zein monomers. Zein (lot 0833 EL) was also purchased from Aldrich Chemical Company, Inc. The commercially obtained zein and the protein bodies prepared in our laboratory were purified, as follows. Samples (200 mg) were washed in methylene chloride, filtered and the dry residue was solubilized in 50% acetone. The addition of salt gave an upper organic phase and a lower saline phase which was dialyzed against water overnight at 4°C. The protein precipitate was dried, solubilized in a small volume of 70% ethyl alcohol and subjected to alkaline hydrolysis in 1N NaOH for 1 hour at room temperature, which releases esterified IAA. Following adjustment of the mixture to pH 3 with the addition of HCl, the free IAA was extracted into methylene chloride. Dried samples were methylated with ethereal diazomethane and trifluoroacetylated with trifluoroacetic anhydride. The derivatized samples were analyzed using a Kratos MS-80 high performance mass spectrometer interfaced with a Carlo Erba Fractovap 4160 series gas chromatograph fitted with a SPB-5 capillary column (0.32 mm I.D., 20 m long, coated with 0.25 µm 5% phenyl methyl siloxane). The samples were dissolved in 5 µl of methylene chloride and were injected on-column, maintaining the column temperature at 38°C. The temperature was then raised to 200°C and maintained for 2 minutes before the eluent was introduced into the mass spectrometer. The temperature of the GC was programmed from 200°C to 260°C at 5°/minute during the time of data acquisition. Data were acquired using the selected ion monitoring (SIM) technique.

When quantification of IAA was desired, an internal standard (¹³C₆-IAA) was added after the methylene chloride rinse early in the purification procedure. Using molecular ions 291 and 285 and base peaks 232 and 226, for the analog and endogenous IAA, respectively, several SIM analyses revealed an average of 50 µg IAA/g zein, dry weight. Partial mass spectra for the internal standard and authentic IAA as well as a purified extracted sample are shown in the Figure (A: standards ¹³C₆-IAA and IAA; B: purified, hydrolyzed extract of zein to which a known amount of ¹³C₆-IAA had been added).

IAA HYDROLYSIS FROM COMMERCIAL ZEIN

CHARACTERISATION OF PHENYLGLYCIDYL ETHER NUCLEOSIDE ADDUCTS USING FAB/MS/MS.

Epoxides are of vast industrial importance because of their application in plastic and resin industry.¹ Their properties are generally believed to be induced by covalent reactions with cellular DNA. The aim of this study was the structure elucidation of phenylglycidyl ether (PGE)-adducts of 2'-deoxynucleosides with the aid of spectroscopic techniques. The PGE-adducts were synthesised by reacting PGE with Thymidine (Thy), 2'-deoxyadenosine (dAdo) and 2'-deoxycytidine (dCyd) at 37°C in methanol. The corresponding PGE-adducts were isolated by centrifugal circular thin layer chromatography (Kieselgel 60 PF 254, eluant: CH₂Cl₂/THF) and reverse phase HPLC (10RP18, eluant: 0.01M HCOONH₄/CH₃OH). The adducts were collected and analysed by U.V.- and ¹H-NMR spectroscopy. In this work we wish to present the mass spectral data.

FAB/MS, using glycerol as the matrix, yielded intense [MH]⁺ and [M-H]⁻ ions. These ions were selected in CAD/MS/MS experiments (VG70SEQ, EBQQ) using Argon as collision gas in the 3rd FFR. The following ions could be detected: [RBH₂]⁺, [RBH₂-O-OH]⁺, [RBH₂-O-OH-H₂O]⁺, [S]⁺ or [RB]⁻, [RB-O-OH]⁻, [(M-H)-C₃H₆O₃]⁻.

In the case of 2'-deoxyadenosine a prolonged reaction time (48 hrs instead of 24 hrs) led to the formation of both mono- and bis-alkylated PGE-adducts (MW=401 and 551). Both [MH]⁺=402 and [MH]⁺=552 were selected for a CAD/MS/MS experiment.

FAB/MS analysis of the 2'-deoxycytidine/PGE-adduct gave the expected protonated molecular ion [MH]⁺ at m/z=378. However it was noticed that the abundance of m/z= 379 was too high taken into account the isotope contribution of m/z=378. Slightly heating of the glycerol matrix, containing the adduct, followed by consecutive FAB/MS recordings showed

the ion at $m/z=379$ gradually to increase in intensity. Both $m/z=378$ and $m/z=379$ were selected for a CAD/MS/MS experiment giving diagnostic ions at $m/z=262$ and $m/z=263$ respectively. They were assigned to $[\text{RBH}_2]^+$ -ions. DCI(NH_3) mass spectrometry of the same sample gave ions at $m/z=379, 280, 263, 245, 169, 134$ and 116 . The aforementioned results can be explained by a PGE-dCyd to PGE-dUrd conversion. Simular results have been observed by Solomon et al.² although there it was proven that the hydrolytic deamination of 3-HP-dCyd to 3-HP-dUrd ocured during the coarse of the reaction. Our results, although preliminary, may indicate that thermal effects applied during sample preparation can also produce such a conversion. In addition ,the PGE-adducts were analysed by DCI/MS(NH_3) on a Ribermag 10-10B (Nermag S.A.)quadrupole mass spectrometer. Along with the $[\text{MH}]^+$ -ion ,fragment ions were observed at $[\text{RBH}_2]^+$, $[\text{RBH}_2-\text{OH}]^+$, $[\text{S}]^+$, $[\text{S-H}]^+$ and $[\text{S-H}]\text{NH}_4^+$. From the combined data the following structures were deduced:

Interchain Disulfide Bond Fragmentations of Dimeric Peptides.

F. Bitsch, H. Hietter and A. Van Dorsselaer.
UA 31 CNRS, 5, rue Blaise Pascal 67084 Strasbourg, FRANCE.

The assignment of disulfide bonds is one of the most important step in the structural analysis of peptides and proteins. Partial reductions, isomeric combinations of disulfide bonds often alter the biological activity of proteins containing disulfide bonds (1,2). LSIMS could play a key role in the study of peptides linked by one or more disulfide bonds which are typically obtained when a cystine containing protein is enzymatically digested (1-3) but are also naturally occurring (4). Different types of peptides are obtained by such degradations:

- single peptides with one or multiple intramolecular disulfide bonds.
- peptides with independant chains linked together by disulfide bonds.

Only a few reports are available on the second type of peptide. We have therefore synthesised a variety of homo and heterodimeric peptides to study their fragmentations under LSIMS conditions in various matrix. The molecular weight of these synthetic interchain disulfide peptides is ranging from 1 to 6 kDa (see a few examples bellow).

We report here on the main fragments observed on this type of cystine containing, double or triple chain peptides. Also source spectra were compared with the MIKES (with and without CID) and the main fragments identified and compared.

All these peptides yielded a clear molecular ion but also intense fragment peaks corresponding to the different chains. These intense fragments are generated by a cleavage at the level of the disulfide bond of the cystine which appeared therefore to be more fragile in these conditions than the peptide bonds. It is therefore possible to determine the molecular weight of each individual chains. This is particularly useful since it avoids a preliminary chemical reduction of the peptide to determine the mass of the different chains.

Such fragmentations were already reported on rather low molecular weight peptides with interchain disulfide bonds (3). We showed that this fragmentation is also preferential on large peptides up to 6 kDa. For example the peptide presented on fig. 1 yielded a clear $[MH]^+$ and two major fragments at m/z 2097.4 and 2621.6. These values correspond to the expected $[MH]^+$ for the two monomeric chains resulting from a putative reduction by the matrix. But our study showed that these two peaks were in fact generated by a source fragmentation of the molecular ion at m/z 4716.4. This preferential source fragmentation was observed for all peptides we studied up to 6 kDa.

MIKES on the molecular ions also produced major fragments corresponding to cleavages at the disulfide bond level (Fig. 2). Use of CID enhanced the S-S fragment ions by 4. In addition, two peaks at +33 and -33 mass units from the disulfide bond fragment were spontaneously formed and correspond to carbon-sulfur bond cleavage. The detailed

Figure 1. LSIMS of a dimeric peptide in thioglycerol. $[MH]^+ = 4716.4$.

mechanism of these fragmentations are under investigation, but it seems that the source fragmentation and the MS-MS fragmentation are following different patterns.

Figure 2: MIKE spectrum of molecular ion $[MH]^+$ 1384 from a homodimeric peptide.

A time dependant study in various matrix was realised for several peptides as shown on Fig. 3. The relative intensity of the fragments and the molecular ion were constant over 3 to 5 minutes (15 to 25 scans) but was varying from one matrix to another. Reduction solely induced by the matrix was therefore insignificant or slow.

Figure 3: Relative intensities of the dimeric peptide $KLAGCSD \ KLAGCSD$ ($MH^+ = 1383.7$) and of the disulfide bond fragment M1 ($MH^+ = 693.3$) vs time in thioglycerol (a) and glycerol (b).

In thioglycerol, glycerol and DTT/DTE we also observed peaks at $[M+matrix-2+H]^+$ corresponding to matrix covalently bonded to peptide. Formation mechanisms of such ions must involve reactive species formed at the surface of the matrix. An analogy could be done with the formation of reactive species formed from sulfides and disulfides under UV light, X rays or electrons (1,5).

Conclusion: When several peptide chains are linked together by disulfide bonds the mass of the individual peptide chains is usually given by the main LSIMS fragments (see example on figure 4). No chemical reduction is needed.

Figure 4: Triple chain peptide, $[MH]^+ = 1906.7$, obtained from the tryptic digest of Apamine. The peptide ($10\mu g$) was previously dissolved in AcOH 5%. Matrix: thioglycerol.

Quantification of 1,25-dihydroxyvitamin D₃ by stable isotope dilution using combined high performance liquid chromatography-thermospray mass spectrometry.

D. Watson, K. D. R. Setchell, R. Ross and I. Bjorkhem*.
Children's Hospital Medical Center, Cincinnati, Ohio 45229, U.S.A.
and Huddinge Hospital, Karolinska Institute, Stockholm, Sweden.

Introduction: Combined gas chromatography-mass spectrometry (GC-MS) has been used in the past to study aspects of vitamin D₃ metabolism (e.g., ref. 1). While these methods provide useful data, lengthy sample preparation procedures are required. Furthermore, thermal degradation of the derivatized compounds often occurs at the temperatures required for GC analysis (>200°C), complicating chromatographic profiles and compromising sensitivity.

Recently combined thermospray liquid chromatography-mass spectrometry (LC-MS) has proved to be a suitable alternative to GC-MS for analysis of many polar and thermally labile low molecular weight (<1000 Da) compounds in biological matrices (see refs. 2-4). For this reason we examined the thermospray ionization behaviour of 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃) and developed a stable isotope dilution assay based on selected ion monitoring thermospray LC-MS.

Methods:

Biological sample preparation: 25-hydroxyvitamin D₃ (10μg per tube) was incubated with 5-10mg of either guinea pig or sheep renal mitochondrial protein. The incubation medium contained 0.05M Tris/acetate buffer pH 7.4, 0.01M MgCl₂, 0.012M isocitrate and 1.6μg ml⁻¹ NN'-diphenyl-p-phenylenediamine. Incubations were performed for 15-60min under air at 37°C and were terminated by addition of acetonitrile. The internal standard (40ng of [26,26,26-³H]₃1,25(OH)₂D₃) was added at this stage. Precipitated protein was removed by centrifugation and the supernatant was applied to a Waters C₁₈ Sep-Pak cartridge which had been prewashed with 3ml methanol and 3ml water. The sample was washed with 3ml methanol/water 30/70 (v/v) and eluted with 3ml acetonitrile. Extracts were dried and reconstituted in the mobile phase described below.

Analytical method: The instrumentation used was a Waters model 600MS liquid chromatograph equipped with a 15cm x 0.46cm i.d. C₁₈ Nova-Pak column, interfaced with a Vestec model 201 Thermospray LC-MS system. A thermospray compatible mobile phase suitable for isocratic elution of 1,25(OH)₂D₃ was selected (0.1M ammonium acetate pH 6.5 in methanol/water 80/20 (v/v)). A solution of 1,25(OH)₂D₃ (2μg ml⁻¹) in the mobile phase was pumped directly into the mass spectrometer at a rate of 1ml min⁻¹ to allow selection and optimization of the most useful ionization mode. The [M+H-H₂O]⁺ fragment ions of 1,25(OH)₂D₃ and [26,26,26-³H]₃1,25(OH)₂D₃ (m/z 399 and 402) were chosen as the most suitable for use in quantitative selected ion monitoring (SIM) analyses. Standard mixtures containing 40ng of the stable-labelled internal standard and varying amounts of 1,25(OH)₂D₃ were analyzed by thermospray LC-MS using SIM and a standard curve was derived by linear regression analysis. Incubation extracts were analysed in the same way and the amount of 1,25(OH)₂D₃ formed was estimated from the standard curve.

Results: The tuning solution was used to compare the overall signal intensity generated by 1,25(OH)₂D₃ in six different operating modes (pure thermospray, filament-on and discharge-on with either positive or negative ions detected). The positive ion, filament-on mode yielded the most useful data (mass spectrum shown, Figure 1). By SIM at m/z 399 the limit of detection (S/N 2:1) was 250pg injected on-column. A standard curve across the range 0-40ng 1,25(OH)₂D₃ derived by least-squares linear regression analysis showed good linearity (r² = 0.997). The incubation extracts

generated readily measurable responses in the m/z 399 channel at an elution time corresponding to that of authentic $1,25(\text{OH})_2\text{D}_3$ (Figure 2). The quantities present, estimated from the standard curve, are listed in Table 1. Due to chemical noise the practical limit for reliable quantification in biological extracts was 3ng. In some cases earlier eluting species were also observed in the m/z 399 channel (Figure 2). The species eluting at 3.4 min had a retention time identical with that of $24,25\text{-dihydroxyvitamin D}_3$. The more hydrophilic compound (2.7 min) probably corresponds to $25,26\text{-dihydroxyvitamin D}_3$ but an authentic standard was not available for comparison.

Summary:

Combined thermospray LC-MS is a suitable alternative to GC-MS for the detection of $1,25(\text{OH})_2\text{D}_3$ in biological samples, with the advantage that minimal sample preparation is required. By selected ion monitoring of the $[\text{M}+\text{H}-\text{H}_2\text{O}]^+$ fragment ion it was possible to detect as little as 250pg of $1,25(\text{OH})_2\text{D}_3$ injected on-column. Using a stable isotopically labelled analogue as internal standard a linear and reproducible calibration curve for quantification in the range 0-40ng was established. The method was applied to the study of *in vitro* 1α -hydroxylation of $25\text{-hydroxyvitamin D}_3$ by guinea pig and sheep renal mitochondria.

Table 1. Amounts of $1,25\text{-dihydroxyvitamin D}_3$ formed by guinea pig and sheep renal mitochondria.

Incubation (time)	Experiment A	Experiment B
Guinea pig (30min)	22.0ng	28.2ng
Sheep (15min)	23.6ng	16.7ng
Sheep (60min)	17.9ng	23.0ng

THE ANALYSIS OF NONIONIC, CATIONIC, ANIONIC
AND AMPHOTERIC SURFACTANTS USING THERMOSPRAY MS/MS
AND FAB MS/MS

Md. A. Mabud, P.A. Dreifuss, W.E. Killinger and M.W. Smith
W.R. Grace & Co., Washington Research Center
7379 Route 32, Columbia, MD 21044

The analysis of surfactants has significant industrial and some environmental importance. Various spectroscopic, chromatographic and colorimetric tests which are available for the analysis of surfactants must address complexities resulting from: the diverse range of samples they appear in, the low levels of surfactants present, various classes of surfactants and the distribution of the chain lengths on both hydrophilic and hydrophobic ends.

We report here an analytical scheme for a wide range of surfactants utilizing a colorimetric screening test followed by thermospray (TSP) MS/MS or FAB MS/MS, which is specific, sensitive, and rapid since it requires little, if any, extraction and no chromatographic separation. MS/MS is used for the characterization of surfactants and to distinguish surfactants from other components in complex industrial samples.

A particular type of a surfactant is best analyzed by a specific MS technique and polarity. For quick characterization it is helpful to know the type prior to analysis. We have found the colorimetric test based on a dimidiobromide-disulphine blue mixed indicator [1] useful to screen for the type of the surfactant present. Appropriate mass spectrometric techniques can then be successfully applied for quick characterization of the surfactant.

Non-ionic surfactants produce a series of abundant pseudo-molecular ions with the thermospray interface by discharge ionization with 100% methanol as the mobile phase. Figure 1 shows a TSP mass spectrum of a complex mixture of polyethoxylated alcohols obtained by direct sample introduction (bypassing the HPLC column). The presence of a series of ions separated by 44 and 14 mass units is indicative of the varying chain lengths of the hydrophilic ethyleneoxy group ($n=2$ to 12) and the hydrophobic alkyl chain ($R=C_9-C_{11}$), respectively. Some unsaturated alkyl groups are also present. Tandem mass spectrometry (MS/MS) can be applied to select any ion from the complex mixture and obtain structural information (Figure 2).

To-date, thermospray also appears suitable for the characterization of amphoteric surfactants which provide reproducible spectra with molecular weight information. Investigation with additional amphoteric is being pursued to fully understand their behavior under thermospray conditions and their response to the colorimetric screening test.

Characterization of non-ionic surfactants by FAB was found to be less sensitive than thermospray in our hands. FAB-MS/MS on the other hand, is the preferred method for the analysis of both cationic and anionic surfactants. TSP-MS with discharge ionization was also found to be satisfactory for anionic surfactants. Cationic surfactants are prone to the loss of alkyl groups under thermospray conditions [2].

The above methods are extremely rapid, as HPLC separation of the surfactant components is not required. The presence of all the protonated molecular ions of the components with the hydrophobic and hydrophilic group distribution in one spectrum allows one to identify the components at once by knowing the identity of one of the ions in the mass spectrum.

Therospray LC/MS Interface
for
Time-of-Flight Mass Spectrometry
A.L. Yergey and F.W. Lampe
NIH, Bethesda, MD 20892 and
Penn. State Univ., University Park, PA 16802

Ion focusing in time-of-flight mass spectrometry requires the ions to be formed in a carefully defined location at a particular point in time. On the other hand, ions are formed continuously in a therospray source. These two apparently incommensurate demands can be met if the therospray ions can be manipulated into packets of ions that are defined in space and time. Rather than trying to accomplish this by manipulating the ion formation conditions, we have chosen to modify the ion source external to the therospray ion exit region and before the Ion Focus Pulse (IFP) grid.

We require that the therospray ions enter the ion focusing region only at times that are consistent with application of the IFP. This is accomplished by adding two lens elements between the therospray ion exit and the IFP. The position of and potentials on these grids are determined by ion trajectory considerations. The first, the Backing Grid (BP), is close to the therospray ion exit and is maintained at ground potential in order to define a potential plane. The second, the Therospray Retarding (RTH) grid is intermediate between the BP and IFP grids. It is normally biased, but pulsed to allow ion entry into the focus region. These two lens elements and the presence or absence of a pulse on the RTH grid define 3 regions of interest for ion trajectories into the ion focus region:

Region 1 - RTH pulse ON. Ions are accelerated toward RTH grid by a field E_1 . Ions present initially receive the full effect of the RTH pulse, while others, which pass through BP after the start of the pulse, receive proportionately less acceleration. Ions experience acceleration for a time $\alpha \tau_p$ where τ_p is the duration of the RTH pulse and α is a fraction.

Region 2 - RTH pulse OFF. E_1 is such that ions of $m/z = m^0$ and $\alpha = 1$ reached the RTH grid just as the pulse shut off. All other m^0 ions experience deceleration from the biasing of the RTH grid by field E_2 . There is a value of α_c , for which m^0 ions experience so little acceleration in Region 1, that they, and all ions with $\alpha < \alpha_c$ cannot pass the RTH grid.

Region 3 - RTH pulse OFF. m^0 ions with $\alpha > \alpha_c$ have passed beyond the RTH grid and are accelerated by the field, E_3 , resulting from the RTH grid bias. Ions of m^0 and $\alpha = 1$ just exit a 1mm wide area at the center of the ion focus region, the "sweet spot", at τ_{A^0} . Other well focussed ions, with $\alpha = \alpha_b$, will just enter the "sweet spot" as those with $\alpha = 1$ exit.

The time after the end of the RTH pulse, τ_{A^0} , for an m^0 ion with $\alpha = 1$ to transit the RTH grid and the top of the sweet spot,

determines the delay required between the RTH pulse and IFP. The analogous time for an ion with $\alpha = \alpha_b$ is τ_3 . These times are calculated from the equations given below, obtained from solution of the trajectory expressions for each of the three regions of ion motion.

The magnitudes of the fields E_1 and E_2 can be adjusted proportionately so that various values of m/z follow the trajectory calculated for m^0 . In addition, the relative values of these two fields for a particular m^0 , determine that fraction of ions, γ , which have passed the RTH grid that are in the "sweet spot" when the IFP is applied. For ions of $m/z=100$, an RTH pulse

length of 1 usec, and with the distances BP- RTH (d₁) and RTH-IFP (d₂) set at 0.16 and 0.635 cm respectively, a 5.3V RTH pulse height coupled with a 2V bias leads to $c = 0.52$, $b = 0.878$ and $a = 0.25$. That is 25% of the ions passing the RTH grid should be well focused. For this same focus efficiency at m/z 5600, an RTH pulse height of 297V with a 112V bias would be required. Good quality 1 usec pulses of this magnitude can be obtained.

Results to date are confined to thermospray solvent ions, and the effectiveness of this system has been demonstrated in principle. Work continues to obtain spectra a reasonable values of higher m/z .

$$\gamma_A^0 = \gamma_P \left(\frac{E_1}{E_3} \right) \left[\sqrt{1 + \left(\frac{E_3}{E_1} \right) \frac{2 m d_T'}{e E_1 \gamma_P^2}} - 1 \right]$$

$$d_T' = d_1 + \frac{1}{2} d_2 + 0.05$$

$$\gamma_3 = \gamma_P \left(\frac{E_1}{E_3} \right) \left[\alpha - \frac{\gamma_2}{\gamma_P} \left(\frac{E_3}{E_1} \right) \right] \left[\sqrt{1 + \frac{2 e E_3 d_2'}{m v_2^2}} - 1 \right]$$

$$d_2' = d_1 + \frac{1}{2} d_2 - 0.05$$

**USE OF DEUTERATED SOLVENTS IN THERMOSPRAY LC/MS TO DISTINGUISH
CLUSTER COMPOSITION, ADDUCT FORMATION, DIMERIZATION AND
EXCHANGEABLE PROTONS**

R. M. Goodwin, R. J. Johnson and A. P. Breaux
Lilly Research Laboratories
Indianapolis, IN. 46285

INTRODUCTION: Thermospray (TSP) spectra can be difficult to interpret, especially the spectra of complete unknowns. The "soft" nature of the the TSP ionization process yields few or no fragment ions. Both molecular ions and pseudomolecular ions are commonly observed in both positive and negative ion modes. Rearrangement ions, adduct ions, cluster ions and clusters of analytes are commonly observed. The ambiguous interpretation of these spectra is compounded by the qualitative and quantitative changes due to filament, discharge electrode and instrument parameters. This poster illustrates how a simple procedure using either a "plug" or a "sandwich" of an appropriate deuterated solvent may be employed in certain cases to determine whether an observed ion is a molecular ion, an adduct ion or a cluster ion. The technique also provides information about the number of exchangeable protons on a given molecule.

METHODS AND PROCEDURES: All TSP spectra were obtained using a Vestec TS101 TSP interface installed on a Finnigan 4500 MS/DS. Samples were introduced via the "direct loop" procedure -- i.e. no HPLC column in line and manual injection using a 50 μ l fixed loop. The isocratic mobile phase was delivered to the Vestec interface at a flow of 1ml/min. Analytes passed from the injector to a U.V. detector in order to monitor injections. Specific experimental procedures are discussed separately for each set of experiments described below or are included in figure legends.

SOLVENT CLUSTER EXPERIMENTS: The spectra shown were obtained in "loop" mode at a flow of 1.0 ml/min. and a TSP probe tip temperature of 180° C. The mobile phase was either 60/40 methanol/water or 60/40 acetonitrile/water as indicated. A "plug" of 50 μ l of deuterium oxide or D₄-methanol was introduced into the mobile phase via manual injection. The non-deuterated control experiment (figure 1) shows methanol clusters at m/z =65 and 97 in positive ion detection and at m/z= 63 and 95 in negative ion. The ions at 83 in positive and 81 in negative ion represent methanol-water complexes. The addition of a "plug" of D₂O (figure 2) results in proton exchange with the methanol clusters and methanol-water complexes. The methanol clusters in positive ion shift to 68 and 99 amu indicating the addition of 1 deuterium atom and 1 proton exchange per methanol molecule. The methanol-water complex displays the incorporation of D₂O into the complex. The negative ion data also show proton-deuterium exchange. Using D₄-methanol the hydroxy deuterium exchanged with the mobile phase, resulting in methanol clusters at m/z= 71 and 106, indicative of D₃-methanol (figure 3). Negative ion data were consistent with the positive ion proton exchanges.

ANALYTE CLUSTER EXPERIMENTS: Thermospray spectra often have ions at twice the nominal mass of a given analyte. Use of deuterated solvents can help distinguish a TSP formed dimer from a preformed dimer. Under the TSP conditions indicated, phenylglycine (MW=151) exhibits ions at m/z=152,302 and 303 in pos ion monitoring and at m/z 150 and 300 in negative ion monitoring (figure 4). When the phenylglycine is injected in a plug (figure 5) or in a "sandwich" of D₂O-made by injecting 50 μ l of D₂O immediately before and after the sample itself (figure 6), the spectra show isotope patterns indicative of deuterium exchange. In this case the isotope pattern is consistent with a thermospray phenylglycine cluster ion rather than a dimer. The number of exchangeable protons for two phenylglycine molecules is the number of proton-deuterium exchanges observed in the dimer. The sandwich technique described by Siegle (1) yields a more robust exchange than the plug technique.

OPTIMIZATION OF SENSITIVITY AND INFORMATION IN THERMOSPRAY LC/MS

W.M.A. Niessen, C.E.M. Heeremans, R.A.M. van der Hoeven, U.R. Tjaden
and J. van der Greef,
Division of Analytical Chemistry, Center for Bio-Pharmaceutical
Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

Introduction

Many applications of thermospray LC/MS in our laboratory are concerned with qualitative analysis, i.e. confirmation or identification of structures. Two aspects play an important role in solving this type of problems:

- * sensitivity: because small amounts of sample are available and people are interested in the minor components.
- * information content: obtain both molecular weight information and useful fragmentation for structure elucidation.

These aspects are discussed in this contribution using some recent examples and applications.

Experimental

All experiments were performed on a Finnigan MAT TSQ-70 mass spectrometer equipped with a Finnigan MAT thermospray interface. The ion source contains a repeller electrode opposite to the sampling cone. Two LKB 2150 HPLC pumps controlled by an LKB 2152 HPLC controller were used for solvent delivery.

Sensitivity

Several experimental parameters have been investigated with respect to their influence on sensitivity, e.g. ionization mode, solvent composition, flow-rate, vaporizer temperature, repeller potential. The most important parameter determining the sensitivity is the analyte itself. Differences in sensitivity of five orders of magnitude are observed with various compounds.

In thermospray buffer ionization best signals are mostly obtained at repeller potentials between 50 and 100 V, while in discharge-on mode intense protonated molecules are observed at low repeller potentials and fragmentation at high repeller potentials.

Information

Structural information can be obtained from thermal decomposition, repeller-induced fragmentation and by collisionally induced dissociation. Depending on the type of molecule one or more of these methods can be successful. Pitfalls may also be present. Two examples:

1. Mitomycin C gives next to the protonated molecule at $m/z=335$ a thermal hydrolysis product at $m/z=278$ (after loss of HNCO) (see figure 1 for structures)
2. Cyano-compounds analyzed can either lose HCN or give a hydrolysis product ($-\text{CN} \rightarrow -\text{OH}$, apparent loss of 9 amu) (see figure 2 for reactions and figure 3 for some spectra)

Figure 1: Structure of mitomycin C and its hydrolysis product, formed at higher vaporizer temperatures.

Figure 2: Thermal decomposition of cyano-compounds.

Figure 3: Thermospray mass spectra of cyano-compounds.

Low flow thermospray

Preliminary experiments with low-flow thermospray (0.25 ml/min of methanol) in discharge-on mode with (substituted) polycyclic aromatic hydrocarbons indicate that it is possible to obtain charge exchange type spectra under these conditions. The charge exchange behaviour is more clearly seen at higher vaporizer temperatures. For these thermally stable compounds higher vaporizer temperatures are no problem. Experiments will be continued and results will be reported in due course.

The Effect of Ion Source Configuration on the Gas-Phase Ionization and Ion-Evaporation Components of Thermospray.

McLean, M.A.* and Vestal, M.L.; Vestec Corporation, Houston TX.

* present address: Exxon Research and Engineering Co., Annandale NJ.

INTRODUCTION

To better evaluate the gas-phase ionization and ion evaporation mechanisms in thermospray, a set of five compounds were subjected to thermospray MS analysis on three different ion sources. The response for each compound was related to the efficiency of the ionization process. This information was then used to determine which ion source configuration was optimum for a particular compound class. The ion sources investigated were the conventional, or transverse, thermospray ion source, an on-axis thermospray ion source, and an ion source of counter-flow design. The five compounds used for these investigations were amonafide, imipramine, secobarbital, T-2 toxin and Direct Violet 32. These compounds were chosen because of their varying degrees of thermospray sensitivity and their different mechanisms of ionization.

EXPERIMENTAL

A Vestec model 201 dedicated LC/MS system (Houston, TX) was used for all experiments. The liquid chromatograph was an SSI (State College, PA) model pump. A Hewlett-Packard model 9100 data system (Palo Alto, CA) was used for all data collection and to control all the mass spectrometric parameters. The mobile phase used in all experiments was 0.1 M aqueous ammonium acetate. Modifications performed on the conventional thermospray ion source to obtain the on-axis and counter-flow ion sources are shown diagrammatically in Figures 1 and 2, respectively.

RESULTS AND DISCUSSION

On-Axis Ion Source: The on-axis ion source exhibited good sensitivity for those compounds which are ionized in the gas-phase. The $(MH)^+$ ions of imipramine and amonafide, and the $(M-H)^-$ ion for secobarbital, gave intermediate response compared to the transverse and counter-flow designs. A typical response curve for these compounds is given in Figure 3. For T-2 toxin, the on-axis ion source gave the highest response. No response was observed for the $(M-2Na)^{2-}$ ion of Direct Violet 32 (Figure 4). These observations are consistent with efficient gas-phase ionization generating $(MH)^+$, $(M-H)^-$ and $(MNH_4)^+$ ions.

Transverse Ion Source: The results indicate that this ion source is very efficient for detecting ions formed by gas-phase ionization. The transverse source gave the highest relative response for imipramine, amonafide and secobarbital which are ionized by proton transfer reactions (Figure 3). The transverse source also gave good results for the $(MNH_4)^+$ adduct ion of T-2 toxin. The transverse source gave a weak signal for the $(M-2Na)^{2-}$ ion of Direct Violet 32 (Figure 4). In water, and 0.005 M aqueous ammonium acetate, a higher signal was obtained.

Counter-flow Ion Source: A schematic of the counter-flow ion source is given in Figure 2. The counter-flow ion source, like the on-axis ion source, was designed to increase sensitivity for ions generated directly from the condensed phase (i.e. those that are produced by ion-evaporation). This is essentially done by increasing the residence time of the droplets inside the ion source. The increased residence time allows ions to evaporate from the charged droplets that would otherwise be swept past the ion sampling region. The longer residence time of the droplets in this region also increases the probability for ion evaporation to occur. The back flow of hot vapor also

aids in neutral evaporation from the droplet thus, increasing the charge-per-unit area on the droplet which is necessary for ion-evaporation.

The increase in ion-evaporation is reflected in the dramatic increase in response for the $(M-2Na)^{2-}$ ion of Direct Violet 32 (Figure 4). This increase is also aided by a decrease in gas-phase neutralization reactions which is directly related to the lower pressure within the counter-flow ion source. The lower ion source pressure is also responsible for a dramatic decrease in the sensitivity for compounds ionized by gas-phase ionization.

CONCLUSIONS

The conventional ion source works best for those compounds that are ionized by proton transfer reactions in the gas-phase. Very good sensitivity was obtained for compounds having high gas-phase acidities or basicities using this ion source. The model compounds used to measure gas-phase ionization efficiency were amonafide, imipramine and secobarbital.

The on-axis ion source gave best results for T-2 toxin indicating enhanced response for those compounds which have low proton affinity but ionize by gas-phase ionization to form ammonium adduct ions. It appears that gas-phase proton transfer reactions occur in the initial jet expansion region near the vaporizer exit. This region is most efficiently sampled by the transverse ion source. Adduct ion formation is a less energetic process and may require less energetic collisions which occur downstream from the initial jet expansion. In this case, the on-axis ion source would sample these ions more effectively.

The counter-flow ion source increases sensitivity for ions generated directly from the condensed phase by increasing the residence time of the thermospray droplets inside the ion source and by decreasing gas-phase neutralization reactions. Full-scan mass spectra (m/z 300-750) of Direct Violet 32 were easily obtained on two micrograms of dye injected. Selected ion monitoring results for the $(M-2Na)^{2-}$ ion of Direct Violet 32 gave signal-to-noise ratios of more than ten-to-one with two nanograms of the dye injected.

DESIGN AND PERFORMANCE OF A NEW COMBINED THERMOSPRAY-EI LC-MS SYSTEM

M. L. Vestal, D. Winn, C. H. Vestal, and J. G. Wilkes
Vestec Corporation, 9299 Kirby Drive, Houston, TX 77054

Performance data are presented on a new interface between liquid chromatography and EI mass spectrometry which efficiently transports the sample to the mass spectrometer while removing almost all of the solvent without introducing significant loss in chromatographic efficiency. A block diagram of the system is shown in Figure 1. It employs a thermospray probe to partially vaporize and nebulize the LC effluent. Vaporization is completed in the heated spray chamber, and most of the solvent vapor is removed in novel countercurrent flow gas diffusion separator. (Fig. 2) Further solvent vapor reduction and carrier removal to reach an appropriate EI ion source pressure is accomplished using a 2-stage momentum separator. Carrier flow is typically 2 L/min of He, but only 1-2 mL/min (STP) enters the ion source along with less than 1 ppm of the solvent vapor (Fig. 3), and except for the most volatile materials, about 70% of the sample. (Fig. 4) Total dispersion due to the interface is typically 1.6 sec (Fig. 5), which is somewhat less than that introduced by the on-line UV detector. Response is independent of LC flow up to at least 1.5 mL/min (Fig. 6), and dependence of solvent composition is minimal. (Fig. 7)

All heating is controlled from a standard thermospray vaporizer controller and heater power is automatically adjusted for flow and composition changes without operator intervention. Library searchable EI spectra are routinely obtained with less than 100 ng of sample injected on column, for samples within the volatility range of the technique, and SIM detection limits are usually in the subnanogram range. Instrument sensitivity is comparable to GC-MS, but detection limits may be somewhat poorer in some cases due to interference from solvent impurities and because of reduced sample mass flow rate caused by lower chromatographic efficiency of LC vs. capillary GC. The interface is compatible with all LC separations (except the MS does not tolerate nonvolatile buffers) and all EI mass spectrometers, including benchtops.

APPLICATION OF THERMOSPRAY HPLC/MS TO ORGANIC SYNTHESSES

Lily Yang, Keystone Environmental Resources, Inc., Houston, TX 77063

Thermospray HPLC/MS has been widely applied to environmental science, pharmaceuticals, biochemistry and drug analyses since 1981. Dr. M. L. Vestal et al. first introduced the technique.

This paper presents the application of Thermospray HPLC/MS to organic syntheses. Because of the unique characteristics and the practical calibration method developed⁽¹⁾, Thermospray HPLC/MS can be used to identify and confirm the final product in a synthetic mixture. Figure 1 shows an example of the confirmation. Protonated molecular ion at m/z 264 provides significant evidence of the formation of the compound expected by the organic chemist.

Thermospray HPLC/MS has been successfully applied to the organic synthesis of histidine from prebiotic precursors. Intermediates such as Imidazole-4-acetaldehyde, Imidazole-4-ethanol, and Imidazole-4-glycol were first identified by Thermospray HPLC/MS⁽²⁾. The analytical results encouraged the continuation of the synthetic process, although the histine was not found in these synthetic mixtures. When the final product was identified in a very small yield (Figure 2), the Thermospray HPLC/MS once again directed the synthetic route. Based on two years efforts, the final product, histidine, was successfully obtained and confirmed (Figure 3). The formation of histine from prebiotic precursors was further confirmed with HPLC/MS/MS⁽³⁾.

These results point out the importance of HPLC/MS in organic syntheses.

This work began at the chemistry department of the University of Houston, was finished at Vestec Corporation, and was summarized at Keystone Environmental Resources, Inc.

The use of immobilized forms of enzymes offers a number of advantages including: a) potentially higher enzyme stability than soluble forms, b) controlled reaction kinetics, and c) fewer reaction by-products. To realize the many advantages attending the use of immobilized enzyme combined with HPLC/thermospray MS, the immobilized enzyme must exhibit high activity and stability. Optimal conditions as well as accepted operating range of conditions for a variety of peptidases including trypsin, chymotrypsin, V-8 protease, thermolysin, and carboxypeptidase, A, B, and Y were determined. Immobilized enzyme activity is dependent on pH, temperature, solvents and buffers used for the hydrolysis. Extremes in any one condition can irreversibly destroy the bioreactor activity. Hydrolysis at conditions far from optimal can lead to no hydrolysis or partial hydrolysis of a peptide, providing limited useful information on the peptide.

The effect of pH on the activities of the immobilized enzymes indicate that the endopeptidases have an optimum pH between 7.5 and 8.0, carboxypeptidase A from pH 7.0-7.5 and carboxypeptidase Y from pH 5.5-6.5. Furthermore, when the pH was adjusted 1-2 units from the optimal range for a period of 1-4 hours, 90% of the activity could be regenerated when conditions were returned to optimum, indicating enzyme stability. However, exposure to pHs above 10 and below 4 often resulted in an irreversible loss in enzyme activity.

The temperature of the immobilized enzyme bioreactors affects the enzyme activity according to the activation energy of the reaction, the effects on mass transfer, and the effects on enzyme structure. Column temperatures of 40-50°C could increase activity by a factor of 2 to 3 compared to the activity measured at 20°C.

Enzymatic activity is strongly dependent on the choice and percentage of organic solvent in an aqueous solution. To achieve suitable resolution and elution, organic modifiers must be added to an aqueous solution for reversed-phase chromatography. Isopropanol, acetonitrile, and tetrahydrofuran (25% v/v in H₂O) solutions do not appreciably affect the activities. Use of ethanol or methanol shows nearly a factor of 2 loss in activity for trypsin and carboxypeptidase B. Acetone exhibited the greatest denaturing power resulting in nearly complete loss of activity. The 0-30% organic range appears to be suitable for bioreactor operation. Often low percentages of organic component (2-15%) can result in higher enzyme activity, perhaps due to increased structural flexibility of the enzyme when low percentages of organic are present. Solutions containing 15-30% organic phase resulted in losses of enzyme activity (typically less than 50% loss of activity). At organic percentages greater than 30% the enzyme activity further decreased, presumably due to structural changes in the enzyme.

Usually the best enzymatic activity was found using aqueous solvents with tris or phosphate buffers. However, these buffers must be substituted with volatile buffers for suitable thermospray MS operation. Buffers including ammonium acetate, ammonium formate and ammonium hydroxide all exhibit similar enzyme activity compared to tris. Additional experiments indicate ammonium acetate concentrations between 0.1M to 1M resulted in the highest immobilized enzyme activity. Buffer concentrations at 0.01 M or lower resulted in a factor of 2 or more loss in enzyme activity as well as reduced thermospray MS sensitivity.

The combination of immobilized peptidase bioreactors HPLC/thermospray MS can provide an unequivocal, rapid method for identification of disulfide bond position in proteins.

Such analytical methodology would greatly facilitate studies of disulfide bond formation pathways in the folding mechanisms of proteins. Selection of the proper endopeptidase in the case of most fully reduced peptides or proteins will yield peptide fragments containing only one cysteine. This is usually true for thermolysin or combinations of chymotrypsin, trypsin or V-8 protease generated peptides from vasopressin, BPTI and somatostatin. Comparison of the molecular masses of peptides obtained from the native peptide to those from the reduced peptide will thus identify the disulfide bond position in peptides of known primary structure. For example, the tryptic hydrolysis of native somatostatin resulted in a thermospray spectrum showing ions at m/z 741 and 935 (Figure 1A). The latter ion can be attributed to the disulfide bond linkage of the tryptic fragments T_1 and T_3 . The reduction of the disulfide bond and subsequent thermospray MS analysis showed ions at m/z 378, 741, and 558 for tryptic fragments T_1 - T_3 (Figure 1B). The absence of the ions at m/z 935 and the presence of ions at m/z 378 and 558 indicated the location of the disulfide bond. While somatostatin is a trivial example, this procedure was used to determine the disulfide bond location in BPTI.

This work was supported by the National Institute of Drug Abuse, Grant No. 5 R01 DA 04202-02.

Introduction

During the past few years there has been a growing concern about residues of antibiotics and other pharmaceutical substances in agricultural products such as milk and meat. This concern has led to the search for more rapid and simple methods for the determination of such drug residues. The current work examines the utility of supercritical fluids for the extraction (SFE) and chromatography (SFC) of tetracycline antibiotics. Cephalirin, another antibiotic of interest which was not successfully chromatographed using supercritical fluids, was analyzed by HPLC and HPLC/MS to determine its metabolites and its presence in bovine milk.

Experimental

SFE of tetracyclines were performed using 12% methanol in CO₂. A 0.2 mL stainless steel extraction cell held at 40°C was loaded with the tetracycline samples and dynamically extracted with 8 mL of supercritical fluid at 5500 psi. A crimped 0.001 mm stainless steel tube or a 25 mm i.d. fused silica tube was used to maintain supercritical conditions. The outlet was placed in methanol to dissolve the extracted components as the supercritical fluid was expanded. The methanol was evaporated and the sample was redissolved in 0.5 mL of methanol prior to analysis by SFC or MS. SFC separations were performed on a 30% biphenyl column using pure CO₂ with flame ionization detection (FID). Mass spectra of the tetracyclines were obtained on a particlebeam interface on an HP-5988A quadrupole MS. The interface was operated at a desolvation temperature of 40°C, source temperature of 250°C under EI conditions (70 eV).

The experimental conditions for the analysis of cephalirin were as follows: Extraction of cephalirin from milk was accomplished by using ultrafiltration with a 10,000 dalton cutoff filter. A 0.5 mL milk sample was diluted with an equal volume of acetonitrile:methanol:water (2:1:2), mixed and centrifuged at 3000 G for 30 minutes. The ultrafiltrate sample was used directly for HPLC or HPLC/MS analysis. The HPLC analysis was performed using a microbore phenyl spheri-5 cartridge (22 cm x 2.1 mm) with a 20% acetonitrile, 5% methanol solution containing 0.005 M dodecanesulfate and 0.5% H₃PO₄. The mobile phase flow rate was 0.4 mL/min. An ultraviolet photodiode array detector (200 nm - 360 nm) was used to monitor the separation. HPLC/MS was performed on a Finnigan MAT 4800 with a thermospray interface. The HPLC conditions were changed to 6.5% isopropanol in 0.03 M ammonium acetate solution with 0.5% acetic acid. The separation was performed on a phenyl spheri-5 (22 cm x 4.6 mm) cartridge at 1.3 mL/min. The thermospray interface was operated under ion evaporation conditions with a vaporizer temperature of 135°C and a source temperature of 270°C.

Results and Discussion

Analysis of tetracyclines:

Tetracycline could be extracted using 12% methanol in CO₂. Extraction recoveries greater than 75% were achieved for solution standards. Tetracycline showed poor recoveries (less than 10%) when using pure CO₂, probably indicating poor solubility in supercritical CO₂. However, SFC separation of tetracycline could be accomplished using pure CO₂ on a 30% biphenyl column. Tetracycline, oxytetracycline and chlorotetracycline

have retention times of 20.9, 20.6, and 21.2 minutes respectively, making their simultaneous detection difficult. Separation of tetracycline using pure CO₂ enabled the use of FID for their detection, permitting determinations down to 0.1 ng. The identity of tetracyclines were confirmed by particlebeam HPLC/MS. Particlebeam interface permitted acquisition of EI spectra which showed [M]⁺ ions as well as numerous fragment ions, permitting compound confirmation.

Analysis of cephalixin:

Ultrafiltration provided a quick and easy method to extract cephalixin from milk. The mean recovery of cephalixin from spiked milk within 50-1000 ppb range was 85%. The ultrafiltrate could be directly analyzed by HPLC/UV down to 10 ppb (0.5 ng) with minimal interference from the milk matrix. The retention time for cephalixin was 6 minutes. The best UV sensitivity for cephalixin was obtained at 291 nm, the UV max for the antibiotic. The UV chromatogram also showed a peak at a retention time of 4 minutes which exhibited a similar UV spectrum as cephalixin. This possible metabolite of cephalixin was identified by thermospray HPLC/MS.

Thermospray HPLC/MS proved specific for cephalixin and permitted the tentative identification of the metabolite as desacetyl-cephalixin. The thermospray spectrum of cephalixin (mw 423) exhibited an [M+H]⁺ ion at m/z 424 and fragment ion at m/z 382, 364, 338, 317, 304, 268, 252, 209, and 168. The first three fragments were losses of CO₂ and H₂O while the ions at m/z 209 and 168 are protonated fragment ions from the opening of the ring cleavage of the cephalixin ring. Desacetyl-cephalixin (mw 381) exhibited an [M+H]⁺ ion and the same fragment ion (below m/z 380) as cephalixin.

Desacetyl-cephalixin was detected in-vivo and in-vitro in bovine milk and in serum. The in-vivo ratio between cephalixin to desacetyl-cephalixin correlated closely with in-vitro incubation of bovine milk and serum. However, the metabolite was not formed in pasteurized milk, probably due to the destruction of an esterase responsible for the metabolism of cephalixin.

The quantity of cephalixin and desacetylcephalixin could be determined by HPLC/UV and confirmed by thermospray HPLC/MS in bovine milk. The quantity of each component found in bovine milk various times after intramammary administration is presented below:

Time after administration (hrs)	Cephalixin (ppm)	desacetyl-cephalixin (ppm)
16	17.0	16.5
24	1.3	1.8
40	0.02	ND
48	0.01	ND
64	<0.01	ND
72	<0.01	ND
96	<0.01	ND

ND=not determined due to matrix interference.

Only the 16 hr and 24 hr samples were confirmed by thermospray HPLC/MS. Clearly, cephalixin can be found in milk 48 hours after its administration.

ANALYSIS OF CATIONIC HEAVY METAL ALKYLATES BY THERMOSPRAY LC/MS

M. Linscheid

ISAS Institut für Spektrochemie
Bunsen-Kirchhoff-Str.11
D-4600 Dortmund 1
West Germany

The analysis of metals in environmental and biological samples becomes increasingly important. Due to the growing knowledge about the metabolic pathways, it is not longer sufficient to determine the amount of a metal in a biological fluid or tissue. More important are the informations about their transport mechanisms in organisms; this means in such a context the analysis of element-organic species.

The main problem appears to be the separation from the matrix, since a wide variety of different complexes may be formed (cationic, anionic, coordinative a.s.o.). Therefore, a mass spectrometer is the ideal detector for such a separation and LCMS on-line instrumentation is most promising.

Fig. 1

Our objective is evaluation of the scope and the limitations of Thermospray-LCMS for the analysis of element-organic species.

The compounds of this study have been chosen with respect to toxicology, importance in technical products and their abundance in the environment. The trimethyllead cation is one of the most toxic lead derivatives formed by demethylation from the gasoline additive tetramethyllead; its analysis in biological fluids is difficult and we have used thermospray successfully in a cooperative study already [1]. The organo-tin compounds are used as fungicides (triphenyltin acetate = "Fentin-acetate") and stabilizers for plastics, polyurethan foams and paints in large amounts and some of them or their environmental breakdown products are known as highly toxic.

Fig. 2

We have used our self constructed Thermospray-LCMS [2][3] system

comprising a single focusing MAT CH5, a probe with replaceable 50 micron nozzle and a home made LC/MS ion source. For the chromatography, a syringe ISCO LC-2600 precision pump was employed and a RP-column (LiChroCart 125-4, Merck, Darmstadt). The solvent was NH_4OAc buffer (0.1M) in 20% Methanol/80% H_2O or 80% Methanol/20% H_2O for the organotin compounds adjusted with acetic acid to pH 4.5. The typical flow was 1.1 ml/min.

For the full spectra, a MAT 90 equipped with the Thermospray ion source was used. The samples were introduced without a column and the solvent was 100% Methanol with 0.1M NH_4OAc ; the flow was set to 1.5 ml.

Discussion

It becomes evident that the detection of mono-cationic organolead and organotin compounds is possible with high sensitivity and specificity, although adduct-ions with ammonia and methanol are formed. There is little fragmentation; results from MS/MS experiments indicate a rather complex fragmentation pattern (loss of H_2 , CH_2 , CH_4 a.s.o). For the dicationic species the most abundant ion is the adduct with the acetate anion; no further clusters of remarkable intensity are recorded. The trichloro monobutyltin compound was not detected. In the future, the isotopic pattern may serve as a chemometric detector for the species in more complex matrices.

In conclusion we have shown that thermospray LC/MS is a very powerful technique for the analysis of metal organic species. The first experiments indicate that the detection and quantitation of organolead and organotin compounds is possible with linear responses down to the low ng level absolute. The identification of such compounds with the help of their isotopic pattern allows the analysis of complex mixtures of biological samples. With modified LCMS systems in the near future the detection limit will approach the picogram range.

Acknowledgements

We are grateful to P. Dobberstein, Finnigan MAT, Bremen, for measurement of the full spectra on a Finnigan MAT 90 mass spectrometer. Financial support from the BMFT, Bonn, and the MWF, Düsseldorf, is gratefully acknowledged.

HPLC-MS ANALYSIS OF COCONUT AMINE SALTS OF ORGANIC PHOSPHORIC ACIDS

Lauren M. Yelle and Paul E. Farrow,
Arthur D. Little, Inc., Cambridge, MA 02140

Coconut amine salts are fatty amine salts which have wide applications as surfactants and biocides. They typically contain an alkyl homologous series (x) on the amine portion of the molecule as shown below.

In some cases it is desirable to determine the identity of the species present in products comprised of these particular salts. We have utilized plasmaspray LC-MS to identify the components in a product containing coconut amine salts of organic phosphoric acids.

Experimental Conditions

Equipment

HPLC: Waters Nova-Pak C₁₈ Column (3.9 mm x 15 cm)
Waters 600-MS Multisolvant Delivery System
Mass Spectrometer: VG-70 SEQ with VG Thermospray/Plasmaspray
LC-MS Interface

Chromatographic Conditions

85% Methanol/15% 0.1M Ammonium Acetate in Water
Isocratic 1 mL/minute

Mass Spectrometry Conditions

Mass Range Scanned: 800-120 amu
Scan Speed: 1.0 sec/decade; 0.3 sec interscan delay
Ion Source Temperature: 200°C
LC-MS Interface Probe Tip Temperature: 300°C

Solutions of the following were prepared at 10mg/ml concentrations and analyzed (10uL) by plasmaspray LC-MS under the conditions described.

1. di-ethyl hexyl phosphonic acid (DEPA)
2. mono-ethyl hexyl phosphonic acid (MEPA)
3. coconut amine neutralized salt of DEPA
4. coconut amine neutralized salt of MEPA
5. Product containing mixtures of #1-4

The coconut amine neutralized salts contain a homologous series with the carbon chain length ranging from C_8 through C_{18} . Analysis by LC-MS of the product mixture resulted in separation and identification of approximately 10 species. The mass spectra could distinguish between these components by virtue of their carbon chain length. Shown below is an example of a typical plasmaspray mass spectrum for these compounds. Also shown is the LC-MS chromatographic profile for one of these products.

By full scanning, the method was adequately sensitive to detect approximately 50 ng per component. Since these products occur as mixtures (no standards are available) but contain no chromophores, LC-MS was needed to identify the species present. Selected ion monitoring would obviously have improved on the sensitivity, of the method but was not necessary for this work.

Analysis of Environmentally Significant Compounds by Thermospray EI LC-MS Winn, D.H., Vestal, M.L., Vestec Corporation, 9299 Kirby, Houston, TX 77096

There have been numerous methods developed for both GC and GC-MS for a number of environmentally significant compounds. However, a greater number of these compounds are amenable to analysis by HPLC than GC. The lack of an HPLC detector that can definitively identify compounds in a mixture has been lacking up till the advent of a reliable interface for EI LC-MS. With Thermospray EI LC-MS it is possible to combine the versatility of HPLC and the confirmational capabilities of a mass spectrometer.

Data from the adaptation of EPA method 610 for the analysis of polynuclear aromatic Hydrocarbons, (PAH) by Thermospray EI are presented. The data presented shows that it is possible for routine quantitation of target compounds as well as confirmation of its presence.

Figure 1 shows a chromatogram of a mixture containing 25 ng of chrysene. It is possible to extract an individual ion chromatogram and spectrum to show the compound's presence. Further comparison can be to a user generated library spectrum, Figure 2, or from a standard reference library, Figure 3.

Figure 1.

Figure 2.

Figure 3.

Just as target compounds can be identified and confirmed, with Thermospray EI it is possible to identify total unknowns in a mixture, Figure 4.

Figure 4.

NIST Mass Spectrum of Dimethyl Phenanthrene

NIST Mass Spectrum of Trimethyl Phenanthrene

From this work, it will be shown that Thermospray EI is a dependable means and reliable means for the analysis of not only PAH mixtures as well as many other environmentally significant compounds.

Peptide Mapping Using Thermospray LC-MS/MS

Michiko Kanai and Patrick J. Rudewicz; Finnigan MAT, Inc.
2-7-1 Hirakawa-cho, Chiyoda-ku, Tokyo 102, Japan

Peptide mapping is often used in the biotechnology industry to confirm that the structures of proteins produced by recombinant DNA technology are identical to reference proteins and to ensure that there are no inter-lot variations of protein structure. The method involves cleavage of a protein into smaller peptide fragments using an enzyme or chemical reagent. Confirmation of samples is based on correspondence of the number of peaks and their retention times; hence, a highly accurate and reproducible HPLC system is essential. Because peptide maps generally contain 30 to 100 peaks, problems arise with instrument-specific differences in gradient elution, especially when shallow gradients are required. Nonretained and overlapping peaks can also make the analysis difficult.

Thermospray (TSP) LC/MS is ideally suited to alleviate these chromatographic problems and to generally increase the information available in the HPLC analysis of peptide mixtures. Previous studies, however, have been limited to full scan spectra to m/z 2000 (1,2). With the extended mass range available on current triple stage quadrupole instruments, full scan spectra can be recorded to m/z 4000. Furthermore, MS/MS spectra can be recorded on lower mass fragments. In this paper, an evaluation of this technique in the analysis of a tryptic digest of β -lactoglobulin A is described.

Experimental

These experiments were done on a Finnigan MAT triple stage quadrupole mass spectrometer and a Finnigan MAT TSP LC/MS ion source. The peptide mixture (10 nmol, purchased from Applied Biosystems) was separated on a 250 x 4.6-mm Aquapore RP-300 column (Applied Biosystems). The peptides were eluted at a rate of 1.2 ml min⁻¹ over 30 min with a linear elution gradient of 0% to 100% of buffer B. Buffer A was 0.1% TFA; buffer B was 70% acetonitrile in 0.1% TFA. The TSP conditions were: ion source block, 190°C; vaporizer, 85°C; and aerosol, 160°C. MS/MS spectra were recorded using 0.8 mTorr of Argon with a collision energy of -35 eV.

Results and Discussion

These experiments indicate that TSP LC/MS has a number of advantages over other MS methods for peptide mixture analysis. First, TSP LC/MS is compatible with the chromatographic systems most often used by the peptide chemists: gradient elution with TFA buffers and flow rates of 1 to 2 ml min⁻¹. Figure 1 shows the UV trace at 214 nm and the TSP total ion current. Spectra were obtained for all but two of the expected tryptic fragments, including two peptide fragments with molecular weights in the 2000 to 3000 u range. The spectra consist of abundant singly protonated and doubly protonated molecular ions with little fragmentation. Figure 2 is a TSP LC/MS spectrum of tryptic fragment T4, a 20-amino acid residue peptide. The peak at m/z 2313.8 corresponds more closely to the largest peak in the isotopic cluster and not the average molecular weight of 2314.7 u. A reduction of quadrupole resolution would result in a centroid of the entire molecular ion cluster (average molecular weight determination), as well as increased sensitivity. A TSP spectrum of the two tryptic fragments T5 and T18 connected by a disulfide bond was also obtained. The spectrum contains both a doubly protonated molecular ion of m/z 1390 and a singly protonated molecular ion of m/z 2780.

TSP LC-MS/MS spectra are recorded for smaller molecular weight tryptic fragments. Figure 3 is a collisionally activated dissociation (CAD) spectrum of tryptic fragment T2, with a MH^+ equal to m/z 673. The sequence ions shown in Figure 3 correspond mostly to Y and B type ions. Above mass 900 u, it becomes increasingly difficult to record MS/MS spectra of tryptic fragments during the time frame of a chromatographic peak. For example, for tryptic fragment T10 ($MH^+ = 1065$), no significant fragmentation of the molecular ion is achieved under these CAD conditions. An increase of the center-of-mass energy by using Xenon instead of Argon as a collision gas facilitates fragmentation of these higher mass ions.

A FACILE METHOD FOR THE PREPARATION AND LC/MS CHARACTERIZATION OF BENZYLOXYCARBONYL METHYL ESTERS DERIVATIVES OF REDUCED GLUTATHIONE, CYSTEINE AND CORRESPONDING XENOBIOTIC-THIOETHER CONJUGATES

Mohamed S. Rashed, Rasmy E. Talaat, Paul G. Pearson, Thomas A. Baillie; Department of Medicinal Chemistry, and Mass Spectrometry Facility, School of Pharmacy, Univ. of Washington, Seattle, WA 98195.

Introduction

Formation of glutathione-S-conjugates is an important mechanism for the detoxification of many xenobiotics. The xenobiotic-thioether conjugates may be excreted as such in bile or further metabolized to cysteine (CYSH) and mercapturic acid conjugates and excreted in urine. Recently, we utilized an approach of derivatizing xenobiotic-glutathione conjugates to their benzyloxycarbonyl methyl ester derivatives (CBZM). This approach facilitates the isolation of these compounds from biological matrices and assist in their subsequent purification prior to mass spectrometric analysis. The derivatives are then analyzed by FAB/MS/MS. The collision induced dissociation (CID) daughter ion spectra recorded showed several diagnostic fragment ions that are specific for these types of derivatized glutathione conjugates.¹ In the present study, we report a simple method for the preparation of synthetic standards of CBZM derivatives for the xenobiotic-thioether conjugates to aid in mass spectral confirmation of biologically formed metabolites. We have also investigated the use of thermospray liquid chromatography/mass spectrometry (TSP LC/MS) for analysis of the CBZM derivatives of xenobiotic-glutathione conjugates, cysteine conjugates and the methyl ester derivatives of mercapturic acid conjugates.

Experimental

Synthesis:

1. The bis-benzyloxycarbonyl methyl ester derivatives of GSSG or cystine were prepared by adding a 6 molar excess of benzylchloroformate to a vigorously stirred solution of either compound in sodium carbonate buffer (pH 9.0). Excess chloroformate was extracted out with methylene chloride. The solution was acidified, the derivative extracted out with ethyl acetate and treated with excess anhydrous methanolic HCl at room temperature for 10 h to yield the methyl esters.
2. Reduction of the bis-derivatives to the CBZM thiol was carried out in refluxing acetonitrile using one equivalent of dithiothreitol (DTT) as reducing agent. DTT and DTT-oxidized were removed by evaporation of acetonitrile by addition of water. The derivatives recovered by filtration.
3. The methyl ester derivative of N-acetylcysteine and N-[2H₃-acetyl]cysteine were prepared from the methyl ester derivative of cystine followed by acetylation with a mixture of pyridine/acetic anhydride or [2H₆]acetic anhydride (4:1) for 10 min at room temperature. Excess reagents were removed by rotary evaporation.
4. The CBZM derivatives of xenobiotic-thioether adduct were prepared by gradual addition of the synthetic xenobiotic electrophile in acetonitrile to a solution of the CBZM thiol in acetonitrile. Triethylamine was used as a catalyst in case of reaction with styrene oxide.

LC/MS:

Thermospray (TSP) LC/MS spectra were generated using a Vestec 201 instrument (Vestec Corp., Houston, TX) with a directly heated probe vaporizer. TSP probe control and tip temperatures were 115 and 174°C, respectively, and were adjusted to maintain a jet temperature of 204°C. The source block was normally held at 265-285°C. The HPLC system consisted of an LKB 2150 pump and LKB 2152 controller unit (LKB, Bromma, Sweden). Separations were achieved using an Ultrasphere C18 column (15 cm x 4.6 mm, i.d.; 5µm particle size) with a mobile phase consisting of 40% acetonitrile in aqueous 0.1 M ammonium acetate (flow rate 1.2 ml/min). Analyses were carried out in the "filament on" mode (filament current 350-400 µA).

Results and Discussion

In addition to the advantages described above for the derivatization strategy, the synthetic procedure described for obtaining the CBZM thiols provided several advantages: 1. The disulfides are commercially available in pure form and therefore provided an ideal method for protecting the thiol group. 2. The derivatization proceeded smoothly and rapidly in quantitative yield. 3. Using DTT as the reducing agent provided a reactant that is water soluble and therefore together with its oxidized form can be easily removed after the reaction. 4. The presence of oxidized DTT at the end of the reaction keeps the thiol in the reduced form and can be removed at any time before reacting the thiols with the xenobiotic electrophile. 5. The reaction with xenobiotic electrophiles is a rapid one step reaction although in some cases has to be catalyzed.

Our evaluation for TSP LC/MS for analysis of these types of compounds indicated that the spectra obtained provided somewhat similar information to that obtained by collision induced dissociation (CID) in FAB/MS/MS. However, for the CBZM-glutathione type compounds the spectra obtained showed either a weak [M+H]⁺ ion (Fig. 1) or no [M+H]⁺ ion at all, as in the case of methylisocyanate glutathione conjugate. Still, the spectra show diagnostic ions that would be taken as indicator for the presence of a glutathione conjugate.

The CBZM-cysteine conjugates (Fig. 2) and the methyl ester derivative of the mercapturic conjugates behaved favorably in TSP and gave several diagnostic ions that indicated the presence of either species. The spectra also showed both the protonated as well as the ammoniated molecular ions. The derivatization procedure described allows for screening for the presence of both type of compounds in the same biological sample without

need for any HPLC purification following the derivatization. The preparation of deuterated analogs of such compounds allows for their use as internal standards for quantifying these conjugates by selected ion monitoring. This work was supported by grants from NATO and the National Institutes of Health (DK30699).

STRUCTURE DETERMINATION OF IMPURITIES IN A SYNTHESIS
OF A PROTECTED DIAZABICYCLOHEPTANE BY LC/MS

Kenneth J. Rosnack, Justin G. Stroh, and Michael J. Cohen
Analytical Research Department, Pfizer Central Research, Groton, CT 06340

LC/MS is a useful method for rapidly identifying unknown compounds in reaction mixtures. Diazabicycloheptanes are useful in many organic syntheses. In the present case, it was desired to prepare the diazabicycloheptane as shown in scheme 1. It was of particular importance to make the N-methyl product as shown in scheme 1 without making any of the des-methyl analog as the des-methyl analog would react in later synthetic steps to produce unwanted side-products. Plasmaspay LC/MS was employed to determine the presence of impurities in the reaction product. Elemental compositions of the compounds present in this mixture were confirmed by high resolution EI and high resolution FAB.

The total ion chromatogram of the diazabicycloheptane mixture is shown in Figure 1. Five reaction products and a small amount of dioctylphthalate were identified. Compound 1, which was the impurity sought for, was identified as the des-methyl impurity. Compound 2 was the desired product. Compound 3 was generated from reaction of an impurity in a previous synthetic step with RedAl. The origin of compound 4 is not known. However, it is possible that 4 may have arisen from reaction of compound 1 with an impurity in a previous synthetic step. Compound 5 was derived from reaction of benzyl amine with the CBZ derivative shown in Scheme 1. This compound is unreactive with RedAl.

The elemental composition of compounds 1, 2, and 5 were obtained by scanning high resolution EI of the reaction mixture. The elemental composition of compound 4 was determined by high resolution FAB of the reaction mixture. Compound 3 did not yield a molecular ion by EI. Although an ion at $m/z = 239$ was observed in the low resolution FAB mass spectrum, it was too weak to obtain high resolution data on. The isotopic distribution of the molecular ion observed in the plasmaspay mass spectrum of this compound suggested that the compound contained a chlorine atom. Searching the scanning high resolution data for this isotopic distribution yielded an ion at $m/z = 118$. Based on the molecular ion data and the high resolution data of the ion at 118 amu, we are proposing the structure of compound 3.

Conclusion

LC/MS was used as a rapid method for identifying five compounds in a synthetic reaction mixture. None of the compounds identified were preparatively separated prior to analysis, which greatly reduced the analysis time. Once molecular ions were established by LC/MS, their elemental compositions were determined by high resolution (again on the mixture). Using this procedure allowed us to determine the structure of four compounds in the mixture and propose the structure of a fifth. An undesired compound (compound 1) was determined to be present which indicated that this reaction should not be used to prepare fully protected diazabicycloheptanes.

SCHEME 1

INVESTIGATION OF PRAVADOLINE METABOLITES BY THERMOSPRAY MASS SPECTROMETRY

Judith A. Johnson, George J. Gonyea and James F. Baker

Department of Drug Metabolism and Pharmacokinetics

Sterling Research Group, Rensselaer, NY 12144

Pravadoline maleate is an orally active non-opioid analgesic.

Radiolabeled studies in mice, rats, dogs, monkeys and humans have shown that the compound is well absorbed from the gastrointestinal tract, is cleared almost entirely by metabolism and is subject to moderate levels of pre-systemic metabolism in most species. The objective of these studies was to determine the metabolic profile of pravadoline in a number of species and to structurally characterize the metabolites.

A Varian 5500 HPLC was interfaced with a Ramona radioactivity monitor and a Finnigan 4500 mass spectrometer equipped with a Finnigan TSP interface. Optimum operating parameters included 0.05 M ammonium acetate/acetonitrile gradients, a 1.5 ml/min flow rate and jet and vaporizer temperatures of 230°C and 120°C, respectively. Qualitative metabolic profiles of urine, bile and/or deproteinized plasma samples from a variety of species were obtained by direct injection onto the TSP-LC/MS system. Representative data, a radiogram of a 0-24 hr human urine specimen and the corresponding reconstructed TSP ion chromatogram are shown below. In most cases, metabolites were also isolated and purified by gradient reverse phase HPLC. Structural assignments were confirmed through comparison of their electron impact mass spectra and relative retention times with those of synthetic metabolites.

The results demonstrate the utility of TSP-LC/MS for rapid, direct analysis of drugs and their metabolites in biological fluids. With gradient conditions, metabolites of varying polarity can be analyzed in a single run. Interfacing a high pressure radioactivity monitor with the system eliminates the need for HPLC effluent splitting. The sensitivity of TSP ionization (Filament off) is highly dependent on the analyte. Although TSP spectra are useful for molecular weight determinations, limited fragmentation may preclude unambiguous identification; this can be supplemented by EI or MS/MS analysis.

RADIOGRAM OF 0-24 hr HUMAN URINE

RECONSTRUCTED ION MASS CHROMATOGRAM

METABOLISM AND CARCINOGENICITY OF HAIR DYES:
A TSP LC/MS STUDY

C.E. Parker and K.B. Tomer, LMB, NIEHS, RTP, NC 27709
and
F.W. Kari, S.M. Driscoll, and K.M. Rudo, TRTP, NIEHS, RTP, NC 27709

H.C. Blue 1 and H.C. Blue 2 are nitrophenylenediamine dyes that have been used in the hair color industry. These two closely-related permanent hair coloring agents are representative of a large class of dyes which fall into two groups based on their biological activity. H.C. Blue 1 induces significantly greater hepatocarcinogenicity than does H.C. Blue 2, producing cancer in 96% of the female mice to which it was fed, while Blue 2 is not carcinogenic even at 3 times the dose used for the Blue 1 studies (1).

In order to explain these carcinogenicity differences, which appear to relate to differences in metabolism (2), an LC/MS study was initiated to identify the urinary metabolites. Blue 1 forms many more metabolic products than does Blue 2. Thus far, TSP LC/MS of Blue 1 metabolites has provided evidence for an acetylated analog and a demethylated product. Demethylated Blue 1 was the only one of the metabolites which was present in sufficient quantity to be detected by TSP in gradient analyses of whole urine. For the other metabolites, fractions had to be collected and concentrated.

A metabolite in which the NO₂ group has been reduced to the amine has also been identified. In similar systems, amines have been implicated in pathways leading to carcinogenicity, often via N-acetylation (3). In addition, three conjugates of Blue 1 have also been detected: one is a glucuronide conjugate, one appears to be a conjugate of the parent Blue 1, and one is a conjugate of demethylated Blue 1.

The identification of the demethylated Blue 1, the acetylated Blue 1, and the nitroreduced Blue 1 metabolites has been confirmed by synthesis and comparison of TSP spectra. The identity of the glucuronide conjugate has been confirmed enzymatically.

In contrast, the non-carcinogenic Blue 2 is not extensively metabolized to demethylated, nitroreduced, or acetylated forms. Instead, Blue 2 is metabolized to one major product which may be a conjugate, whose structure is still under investigation.

HIGH SENSITIVITY AND STRUCTURAL ANALYSIS OF DYES
BY THERMOSPRAY, PARTICLE BEAM IONIZATION AND
CAD TECHNIQUES*

J. Yinon[#], L.D. Betowski, and T.L. Jones,
U.S. Environmental Protection Agency, P.O. Box 93478

INTRODUCTION

Dyestuffs are of major environmental interest because of their widespread use as colorants. Synthetic intermediates, byproducts, and degradation products of these dyes could be potential health hazards due to their toxicity or carcinogenicity or both. In addition, dyes form about 10 percent of those new or imported compounds that are reviewed under the U.S. Environmental Protection Agency's (U.S.EPA's) Premanufacturing Notice (PMN) program.

Thermospray high performance liquid chromatography/mass spectrometry (TSP-LC/MS) has been found to be a suitable technique for the analysis of nonvolatile dyes.^{1,2} One of the drawbacks of TSP-LC/MS is that one obtains mainly protonated molecules and adduct ions, and this information may not be sufficient for structural elucidation of dyes of unknown structure. While tandem mass spectrometry (MS/MS) has been used to deconvolute fully the structural information contained in the TSP mass spectra of dyes³, it would be of great utility to analyze dyes with a single quadrupole LC/MS system and obtain structural information.

The purpose of this present work is to refine further the LC/MS technique for the detection and analyses of dyes in environmental samples. The new methodology should have the following characteristics and capabilities: high sensitivity, molecular weight determination, and structural information.

EXPERIMENTAL

A Finnigan TSQTM45 was used with three different configurations of LC/MS instrumentation. For the first two types of experiments a Vestec thermospray LC/MS interface and ion source were used. A modification to the commercial ion source block was made by adding a wire-repeller connected to an external power supply. The wire-repeller was flush with the base of the ion source block and operated at 200 - 250 V for the sensitivity-enhancement experiments. For repeller-induced collision activated dissociation (CAD) experiments, the repeller was inserted 4 mm into the ion chamber and was operated at 400 V.

An Extrel Corporation ThermaBeamTM particle beam (PB) LC/MS interface was attached to the triple quadrupole mass spectrometer in the other mode of operation. A machined adaptor made mainly of Vespel and partly of brass was used to fit the ThermaBeamTM interface to the mass spectrometer. This adaptor was heated from 200 - 250°C.

RESULTS AND DISCUSSION

The limits of detection of some commercial dyes are reported in Table 1. The detection limits for the dyes with the wire-repeller under thermospray ionization are compared to the limits under particle beam introduction on our

*NOTICE: Although the research described in this article has been supported by the United States Environmental Protection Agency, it has not been subjected to Agency review and, therefore, does not necessarily reflect the views of the Agency, and no official endorsement should be inferred. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

system. Also, included in this table are six of the dyes that were previously obtained under thermospray ionization with an ion source without a repeller. The configuration with the wire-repeller shows the greatest sensitivity. Enhancement factors of between 10 and 400 are observed over thermospray ionization without a repeller. The limits of detection for the wire-repeller mode are better than the particle beam results by factors of 20 to 16,000.

Three different types of spectral information were compared for use in structural interpretation. Tandem mass spectrometry was used to generate daughter ion CAD spectra from the thermospray ionization of dyes; particle beam electron impact spectra were generated from the same dyes; and repeller-induced CAD spectra were obtained in the thermospray ion source. The repeller-induced CAD spectra show fragmentation characteristic of both CAD MS/MS spectra and the particle beam EI spectra.

Tandem mass spectrometry in conjunction with the particle beam introduction of Basic Green 4 was able to confirm the existence of doubly-charged ions.

THERMOSPRAY-LC/MS POSITIVE AND NEGATIVE
IONIZATION MODES OF CHLORINATED HERBICIDES

T.L.Jones, L.D.Betowski and J. Yinon*,
U.S. Environmental Protection Agency, P.O.Box 93478
Las Vegas, Nevada 89193-3478**

INTRODUCTION

The goal of this study was to find a way to detect the chlorinated herbicides (free acid form) and their esters by thermospray-liquid chromatography/mass spectrometry (TSP-LC/MS). The potential of TSP-LC/MS to analyze for chlorinated phenoxyacetic acids at the ppb level had previously been shown by Voyksner using the "filament on" mode with negative-ion detection. During the course of this investigation various ionization modes were examined to find the mode which would produce not only the greatest sensitivity but also structural information. The positive (wire-repeller enhanced) and negative (discharge on) ionization modes, daughter ion collision activated dissociation (CAD), and wire-repeller induced CAD in the positive ion single quadrupole mode were examined. The application of a wire-repeller in the thermospray source has greatly improved the limits of detection for the thermospray positive-ion mode.

EXPERIMENTAL

A Finnigan MAT TSQTM45 was interfaced to a Spectra-Physics SP8700XR gradient pump and an ISCO LC-5000 syringe pump for (postcolumn flow) via a Vestec Thermospray system. A wire-repeller was inserted into the ion source opposite the ion exit orifice. Normally, the repeller was operated at 225 V in the positive ion mode and 0 V in the negative ion mode. Negative ion spectra were acquired with the discharge on and filament off. Single quadrupole collision activated dissociation spectra were obtained when this repeller was operated at 400 V and inserted 4 mm into the ion chamber. Separation of analytes was achieved using a flow of 0.4 mL/min through a 15 cm x 2.1 mm Supelcosil 5- μ m LC-18 analytical column (Supelco, Bellefonte, PA) with a linear gradient elution program of 100% water to 100% methanol in 10 minutes with a 15 minute final hold.

The CAD experiments were conducted at a collision energy of 20 eV with argon at a pressure of approximately 1 mTorr.

RESULTS AND DISCUSSION

The herbicides investigated in this study are listed in Table 1 along with their molecular weights, positive and negative mode quantitation ion, and their limits of detection (LOD). They are all chlorinated phenoxy acids except dalapon, which is a chlorinated aliphatic acid, and dinoseb, which is a nitrated phenol. The positive ion mode gave the ammonium adduct ion ($M+NH_4$)⁺ as the base peak in all cases; for two compounds, 2,4-DB and dinoseb, the ($M+H$)⁺ ion is present. No ions were detected for dalapon.

Little structural information is obtained from the positive ion spectra; therefore, three options to the single quadrupole positive ion mode were tested: (1) the negative ion "discharge on" mode; (2) daughter ion CAD (MS/MS)

Table I - CHLORINATED HERBICIDES MOLECULAR WEIGHTS AND THEIR LIMITS OF DETECTION IN THE POSITIVE AND NEGATIVE ION MODES

COMPOUNDS	M.W.	POSITIVE MODE	LOD (NG)	NEGATIVE MODE	LOD (NG)
		QUANTITATION ION		QUANTITATION ION	
DALAPON	142	ND	-	141(M-1) ⁻	11 ± 4
DICAMBA	220	238(M+NH ₄) ⁺	13 ± 5	184(M-HCl) ⁻	3.0 ± 1
2,4-D	220	238(M+NH ₄) ⁺	2.9 ± 1	219(M-1) ⁻	48 ± 25
MCPA	200	218(M+NH ₄) ⁺	116 ± 8	199(M-1) ⁻	28 ± 5
DICHLORPROP	234	252(M+NH ₄) ⁺	2.7 ± 1	235(M-1) ⁻	8.4 ± 3
MCPP	214	232(M+NH ₄) ⁺	5.0 ± 2	213(M-1) ⁻	12 ± 4
2,4,5-T	254	272(M+NH ₄) ⁺	169 ± 8	218(M-HCl) ⁻	6.5 ± 5
SILVEX	268	286(M+NH ₄) ⁺	162 ± 1	269(M+1) ⁻	43 ± 30
DINOSEB	240	228(M+NH ₄ -NO) ⁺	24 ± 12	240(M) ⁻	19 ± 6
2,4-DB	248	266(M+NH ₄) ⁺	3.4 ± 2	247(M-1) ⁻	114 ± 38

spectra of the (M+NH₄)⁺ ions; and (3) wire-repeller induced CAD spectra in the positive ion single quadrupole mode. The results from our work in the negative ion (discharge on) mode gave a fairly intense (M-H)⁻ ion, along with significant fragmentation in most cases. Losses of Cl and (CH₂)_xCOOH from the (M-H)⁻ ion form the majority of the fragment ions. An interesting ion observed in our work and not in Voyksner's experiments is the (M+H)⁻ ion. The ion is clearly observed at m/z 269 for 2,4,5-TP (Silvex, Figure 1) after subtracting the ³⁷Cl isotopic contribution from the (M-H)⁻ ion. Yinon had previously reported this ion, (M+H)⁻, in the isobutane negative chemical ionization spectra of two nitrated explosives. This ion is apparently formed from the ion-molecule reactions with M⁺ or (M-H)⁻.

Characteristic spectral patterns were generated in the MS/MS mode of operation of the triple quadrupole mass spectrometer for these chlorinated herbicides. Peaks resulting from the loss of OH (or NH₂), Cl, and (CH₂)_xCOOH·NH₄ from the ammoniated species comprise the majority of the ions in the spectrum.

Attempts to increase further the sensitivity in the thermospray positive ion mode, with the wire-repeller, were made by increasing the voltage. The wire-repeller was also moved further into the thermospray stream and closer to the sample cone orifice. Instead of increasing the sensitivity this resulted in additional fragmentation ions. Figure 2 shows the single quadrupole CAD spectra of 2,4-DB generated with the wire-repeller at 400 V. The resultant spectra was similar to those obtained by electron impact. The EI spectra of 2,4-DB, from the NBS library, and the wire-repeller CAD spectra both show a major ion at m/z 162, the resultant loss of (CH₂)₃COOH from the main structure. Also both spectra display a m/z 98, which is possibly from the opening of the ring with a chlorine left attached, C₅H₃Cl.

and ²Guizhou Chemical Industry Institute, Guiyang, China

INTRODUCTION

Nereistoxin (4-N,N-dimethylamino-1,2-dithiolane) a naturally occurring neurotoxin isolated from the marine segmented worm *Lumbriconereis heteropoda* (1) has been found to inhibit neuromuscular transmission in some insects (2). Nereistoxin and compounds analogous to nereistoxin, such as Evisect (5-N,N-dimethylamino-1,2,3-trithiane), and Duo-Sewan (7-N,N-dimethylamino-1,2,3,4,5-pentathiocane) (3,4) are a series of polythiacycloalkanes that are useful as insecticides (5). Because of the low UV absorptivity of these compounds, analytical methodologies using high performance liquid chromatography (HPLC) for their analysis and characterization have been limited. Thermospray (TS) is a mass spectrometric (MS) ionization technique that is amenable for coupled HPLC-MS analysis (6,7). In this report we describe the direct HPLC-TSMS analysis of an insecticide sample from China containing these polythiacycloalkanes.

EXPERIMENTAL

Chemicals

A crude sample of formulated pesticide containing a series of Nereistoxin analogs was synthesized by Guo *et al.* (4) of Guizhou Chemical Industry Institute, Guiyang, China.

HPLC-TSMS system

Chromatography was achieved using a conventional Cyano-propyl bonded-phase analytical column (Beckman Instruments, Inc./Altex Scientific Operations). The mobile phase was aqueous buffer/acetonitrile (80/20, v/v). The aqueous buffer was 0.1 M ammonium acetate and was adjusted to pH 5 with acetic acid. The mobile phase was pumped at 1.0 mL/min by a model LC-5000 syringe pump (Isco). The dissolved pesticide sample was injected in the system with a model 7125 septumless injector (Rheodyne) equipped with a 20 μ L loop.

Mass spectral analysis was performed with a model R1010C quadrupole mass spectrometer equipped with a thermospray source (Delsi-Nermag) and thermospray interface (Vestec). Typically, the control temperature was 132°C, and the tip temperature was 192°C. The TS source was operated in the discharge-off and filament-off modes. Mass spectra obtained over the mass range m/z 100 to m/z 550 at a scan rate of 2 s per scan were recorded and processed with a Finnigan/Inco 2300 data system.

RESULTS AND DISCUSSION

HPLC-TSMS, using the conditions described above, was used to analyze a crude pesticide sample which contained a series of polythiacycloalkanes. The sample was dissolved in aqueous solution and its

components resolved using reversed-phase HPLC and detected by on-line TSMS operated in the positive ion mode. The results of this analysis were a set of four resolved HPLC peaks (Figure 1). The TS mass spectrum of the major HPLC peak seen at 4.8 min is shown in Figure 2. This mass spectrum shows essentially only the base peak at m/z 150 which corresponds to the $[M+H]^+$ ion for Nereistoxin. The second major peak (RT=5.2 min.) seen in Figure 1 corresponded to Evisect which has an elemental composition of $C_5H_{11}NS_3$ and a molecular weight of 181. The TS mass spectrum for this compound (Figure 3) included the $[M+H]^+$ ion as the base peak. Two minor HPLC peaks are seen at 5.5 and 6.1 minutes. TS mass spectra of these minor components showed m/z ions at 214 and 246, respectively, indicating an increase of 32 and 64 in molecular weights compared to Evisect. The latter corresponds to the $[M+H]^+$ ion for Duo-Sewan which contains two additional sulfur atoms, relative to Evisect. The compound seen eluting at RT=5.5 min was not identified.

CONCLUSIONS

These data demonstrate HPLC-TSMS to be a useful tool for the analysis and characterization of pesticides that contain nereistoxin or its structural analogs which are typically difficult to analyze using conventional HPLC detectors. The methodology may therefore be applicable for the determination of polythiacycloalkane-type insecticides and their metabolites or degradation products in biological samples

GC/MS and LC/MS in the Analysis of NPPD ("Spy Dust")
J. Bursey, R. Moseman, Radian Corp., and C. Parker, K. Tomer,
LMB, NIEHS, and C. Jameson, DTRT, NIEHS, Research Triangle Park,
North Carolina 27709

NPPD (5-(4-Nitrophenyl)-2,4-pentadien-1-ol, Figure 1) has reportedly been used by the Soviet Union as a "spy dust" for tracking of U.S. embassy personnel in the USSR. In field use, "spy dust" would be sprayed or deposited on surfaces that embassy personnel frequently touch, applied in amounts so small that the material was essentially invisible. The "spy dust" would then be transferred by touch, allowing for the embassy employee to be tracked and thus monitor his/her activities.

The analytical method developed for NPPD¹ is based on a standard spot test technique which relies on a color reaction to detect aromatic and alpha, beta-unsaturated aldehydes. In a methanol solvent, naphthoresorcinol is used as the color reagent with HCl to catalyze the color reaction. A pink-to-red-violet color is produced proportional to increasing concentrations of NPPD. In the field, detection procedures consist of wiping the surface to be tested with a cotton swab moistened with methanol and developing the color reaction in a test tube. As little as 150 ng NPPD/100 cm² will yield a color reaction visible to the eye. At 506 nm with a spectrophotometer, the sensitivity can be increased to less than 20 ng/cm².

For a particularly critical field sample, confirmation of the identification provided by the color test was sought. The initial technique used for the confirmation of identification was capillary GC/MS, using a 30m DB-1 fused silica capillary column (0.32 mm, 1 μ film thickness). At levels of 100 ng injected on the column, a reasonably well-shaped chromatographic peak was observed (Figure 2) and a mass spectrum characteristic of NPPD was obtained (Figure 3). However, at levels near the concentration level of interest, the molecular ion at mass 203 was not observed and the base peak of the mass spectrum (mass 128) was very difficult to distinguish from other residues present in the sample. Calibration of the instrument over this concentration range for quantitative analysis could not be performed with acceptable reproducibility. On-column injection was attempted, with and without the use of chemical ionization techniques, but a characteristic (M+1)⁺ ion was not obtained and the reproducibility did not improve significantly. The identification could not be confirmed and accurate quantitative analysis could not be performed.

Because of the critical nature of the wipe sample in question, the use of LC/MS as a technique for the confirmation of the compound identification was explored. The mass spectrometer used was a VG 12-250 quadrupole mass spectrometer fitted with a Vestec model 201 thermospray source for LC/MS analysis. The LC/MS analysis was performed in methanol:water. A clear extracted ion current profile (Figure 3) was observed at low concentrations and a molecular anion at mass 203 was the major peak of the mass spectrum (Figure 4). Using this technique, the confirmation of NPPD in wipe samples can be confirmed at 20 ng/cm².

SYNTHESIS AND CONJUGATION OF A NEW CARBOHYDRATE DERIVATIVE
WITH FEMTOMOLE NCI-MS SENSITIVITY

J.P. Caesar, D.M. Sheeley, R.S. Johnson & V.N. Reinhold
Harvard University School of Public Health, Boston, MA 02115

The detectability of oligosaccharides by HPLC has benefited from their conjugation with photoaffinity groups by reducing-end glycosylation (pyridinylamine) (5) or reductive amination (aminobenzyl ethylester) (1). These reagents have also found some use in structural studies employing FAB-MS, but MS sensitivity for carbohydrate samples remains a problem.

SFC-MS brings new opportunities for the enhancement of oligosaccharide detectability through selective derivatization and negative-ion chemical ionization (NCI). Improved sensitivity using NCI has been demonstrated with the pentafluorobenzyl (PFB) derivative of prostaglandin analogs (2). The same derivatives have been used to study cyclooxygenase products (3) and greater than 100-fold increases in sensitivity (compared to EI) were reported for lipoxigenase products (4).

We have prepared a new reagent that combines the sensitivity observed with the PFB derivative to the capability for reducing-end conjugation utilized in the preparation of the PA and ABEE derivatives. This is the pentafluorobenzyl ester of p-aminobenzoic acid (PFBAB). This product was purified by HPLC and characterized by mass spectrometry. We have conjugated the reagent to numerous N-linked glycans, mono-, di-, and oligosaccharides by both glycosylation and reductive amination. Although the glycosylation of the PFBAB derivative to carbohydrates results in anomeric products, it has interesting advantages over the reduced analog (5). Most important of these is the retention of the PFBAB label under conditions of periodate oxidation (6).

Results and Discussion

PFBAB was synthesized by condensation of p-aminobenzoic acid (PABA) with pentafluorobenzyl bromide (PFB-Br), Scheme 1. The subsequent conjugation of this product was investigated using glycosylation and reductive amination approaches. Carbohydrate conjugation was evaluated under aqueous and nonaqueous conditions using numerous samples. A more quantitative study was carried out with maltoheptose, fucose, and N-Acetylglucosamine. Nonaqueous conditions gave yields approximating 90% for maltoheptaose and 80% for GlcNAc with reaction times of 1/2 hour. These results are preliminary and further work to maximize glycosylation conditions are underway. SFC-MS sensitivity studies were conducted with known amounts of PFBAB-derivatized fucose under NCI conditions by sample dilution. Full scan spectra were obtained (800 amu) for each injection at a rate of 10 s/d. The spectrum in Figure 1 represents a dilution to 55 fmol and the selected ion plot for the (M-PFB)⁻ ion is shown in Figure 2.

SFC-MS in combination with NCI and PFBAB-derivatized carbohydrate samples appears most promising. Further signal enhancing techniques, such as isotope carrier, array detection, and single-ion monitoring suggests further improvements in sensitivity may be possible.

Institut für Physikalische und Theoretische Chemie, TU München
Lichtenbergstr. 4, D-8046 Garching, FRG.

The advantages of MultiPhoton-Ionization (MUPI) in comparison with conventional ionization-techniques in mass spectrometry has been shown in recent years [1]. In addition to Laser-Desorption (LD) chromatographic methods have been coupled to MUPI-MS volatilizing thermally labile and involatile molecules [2]. This methods allows to create mass spectra over long time periods by using extraction-techniques. We think that by using the high sensitivity of MUPI the detection of molecules after chromatography could also be drastically increased. The Golay equation for open tubular columns furthermore shows that the same separation efficiencies, in the same analysis time, can be achieved with GC, SFC and LC, provided the diameter of the column is reduced along with the corresponding mobil phase diffusion coefficients. Smaller column dimensions obviously have a detrimental effect on sample capacity. In analytical instruments this problem can be overcome by making use of more sensitive detectors. In more practical terms, the above also means that new mass spectrometers with greatly enhanced sensitivity are required to perform SFC-MS and especially LC-MS [3] with the same separation efficiency we routinely have in capillary GC-MS. The increase in sensitivity should preferably not be achieved with ionization techniques that lead to mass spectra with greatly diminished information content when compared to EI-spectra. It is our opinion that time-of-flight mass spectrometry with laser induced multiphoton-ionization could fulfill these requirements. The high potential sensitivity of this type of mass spectrometer has not yet been realized due to the small area of overlap (in space and time) with the pulsed ionizing laser beam [4]. Our approach to this problem is to continuously accumulate sample molecules from a chromatographic column onto a substrate and to pulse-desorb the sample by a CO₂ laser at a frequency of 2.5 Hertz. The desorbed "packet" of sample molecules is transferred to the ionization volume by the gas jet to coincide adsorption substrate that is transparent to the desorbing laser radiation, we aim to achieve both spatial and "time" focusing of the sample for maximum overlap with the pulsed ionizing beam.

The prototype of the Bruker TOF 1 mass spectrometer was coupled to a Carlo Erba VEGA Series 2 gas chromatograph equipped with a Rheodyn injection valve model no. 7410 (1µl loop). SFC grade CO₂ was delivered by a Brown-Lee SFC pump. A schematic diagram of the designed continuous SFC-MS-Inlet-System is shown in Figure 1.

The Mach disk of the supersonic beam of CO₂, which emerges from the ca. 1µm diameter orifice at the end of the fused silica transfer line, seems to lie very close to the jet tip. This prevents the sample from moving through the skimmer and into the ionizing region in a dense, well defined beam. When the AgCl cylinder is placed around this beam the amount of sample reaching the ionizing beam doubles. Samples completely lost from the beam is evidently accumulated on the inner wall of the cylinder with subsequent pulsed desorption by the CO₂ laser. This results in an additional 5-fold increase in the pyrene concentration during the desorption peak. With pyrene as our test compound, first results indicate that a 10-20 -fold signal enhancement can be obtained with the simple concentrator/pulse desorption-interface without any prior optimization. Without that interface we detected a amount of 3 ng fluorene by a signal to noise ratio of 6:1.

Figure 1: Continuous SFC-MS-Inlet-System using an integral restrictor heated by resistance wire at the very end of the tip.

**SUPERCritical FLUID CHROMATOGRAPHY/CHEMICAL IONIZATION
MASS SPECTROMETRY IN A THERMOSPRAY SOURCE**

S.M. Musser and P.S. Callery

Department of Medicinal Chemistry
University of Maryland, Baltimore, MD 21201.

Supercritical fluid chromatography (SFC) represents a new method for introducing nonvolatile, thermally labile and high mass molecules into a mass spectrometer. Interfacing SFC with mass spectrometry poses many of the same problems encountered with liquid chromatography/mass spectrometry, the most critical of which are the high vapor loads and cooling effects of the evaporating liquids. Since the thermospray source was designed to overcome these problems it is an ideal starting point for developing an SFC/MS interface. The purpose of this study was to design an interface that would be simple to build and operate, then evaluate the performance of the interface with several anticancer drugs that represented a wide range of polarities. Anticancer drugs were chosen for this study because they represent a group of drugs which are thermally unstable and generally nonvolatile, making them model compounds for describing the conditions that are necessary for drug analysis by SFC/MS.

A supercritical fluid chromatograph (Suprex Corp.), consisting of a syringe pump, column oven and controller was used to maintain SFC conditions. Carbon dioxide was used for the supercritical fluid was modified with an organic solvent via a high pressure injection valve (Valco). Sample introduction was through a Valco high pressure electronically actuated valve with a 1 μ l injection volume. SFC conditions were maintained until reaching the ion source by a 50 cm long piece of 0.25 mm id fused silica capillary with an integral restrictor. The flow of exiting gas from the restrictor was 200 ml/min when SFC conditions were 400 atm with an oven temperature of 80 °C. Under these conditions the source pressure was 0.5-0.6 torr.

A highly modified Finnigan 1015 mass spectrometer was used for all experiments. Briefly it consisted of a differentially pumped vacuum housing with oil diffusion pumping, quadrupole electronics upgraded by Extrel and a Technivent data system. A Vestec thermospray source and controller were used for all experiments. The source temperature was kept at 200 °C and the probe temperatures were 120 °C and 80 °C for the tip and control, respectively. An original thermospray probe was modified (fig. 1) such that it would fit into the thermospray source and operate with all thermospray electrical connections. The principal modification was to replace the original metal capillary with two larger inner diameter metal capillaries that would permit fused silica capillaries to be inserted.

The SFC/MS interface described in this experiment uses a thermospray ion source and modified thermospray probe to provide a simple and convenient method for interfacing SFC with mass spectrometry. We have demonstrated that chemical ionization conditions are observed and that the optimum conditions are dependent on the source pressure, with a maximum occurring at approximately 1.0 torr. Chemical ionization mass spectra were recorded for thiotepa, cyclophosphamide, diaziquone (fig.2, A) and mitomycin C (fig.2, B). While CI mass spectra were obtained for all the anticancer drugs in our study, more efficient chromatography could be achieved by adding a gradient of organic modifier to the mobile phase. The lower limit of detection was determined to be 50 ng of the test compound diaziquone, which produced a signal to noise ratio of 5:1 during full scan (135-500 amu) operation. Finally, use of the discharge electrode for ionization in place of filament ionization increases the overall sensitivity by a factor of 10, without causing increased fragmentation.

Bowman Gray Technical Center,
Winston-Salem, NC 27102.

Supercritical fluid chromatography/Mass spectrometry (SFC/MS) has become an important analytical technique for separation and identification of mixtures. Sample introduction with the fluid phase presents high pressure in the mass spectrometer. Therefore the chemical ionization (CI) mode is usually chosen. However, CI mass spectra give mainly molecular weight information which makes it difficult to interpret unknown mass spectra. EI mass spectra are of particular interest to those who need appropriate structural information for the identification of unknown compounds.

An SFC/MS system has been constructed through additions and appropriate modifications to a Hewlett-Packard (HP) 5985B GC/MS instrument. Supercritical fluid conditions are effected by transport of liquid carbon dioxide mobile phase through a Lee Scientific pump, Model 501, to the injector and then into a 10-m 50-um ID SB-biphenyl fused silica capillary column. The exit of the column was connected to a 50-um ID frit restrictor (Lee Scientific). Two approaches to a successful coupling of the resultant effluent to the MS system in order to yield EI mass spectra have been demonstrated. In one configuration, a Scientific Glass Engineering (SGE) open-split GC/MS interface is used to eliminate excess mobile phase. Inside the heated interface is a heated frit restrictor connected to a deactivated, uncoated, 110-um ID fused silica capillary column (also heated) which functions as a transfer line into the ion source of the mass spectrometer. An alternate configuration designed to accommodate the introduction of higher molecular weight components omits the open-split interface and locates the frit restrictor inside the ion source. A specially fabricated, stainless steel rod, heated by the ion source heater, has a conical opening into which the restrictor tip is positioned and also heated. In both configurations, a Balzer turbomolecular pump, Model 510, is used for the ion source.

The sample preparation consisted of dissolving the sample in an appropriate solvent for injection. Carbon dioxide was used to sweep the sample onto the GC capillary column in the oven. The mass spectrometer was operated in the EI mode at 70 eV energy. The source temperature was maintained at 200-300°C. An HP 1000 computer system with RTE-A data system was interfaced to the mass spectrometer. Selected compounds and samples were examined with the SFC/MS system. EI mass spectra were satisfactorily produced without ion-molecule contributions or carbon dioxide clusters. The resulting spectra can thus be searched against a conventional mass spectral library for the identification of supercritical fluid-separated components.

HIGH PRESSURE LIQUID NH_3 INJECTION OF POLAR MOLECULES INTO A MASS
SPECTROMETER WITH RESONANT TWO-PHOTON IONIZATION DETECTION

Ho Ming Pang and David M. Lubman, Department of Chemistry,
The University of Michigan, Ann Arbor, MI 48109.

High pressure (> 200 atm) liquid NH_3 has been investigated as a means of volatilizing polar nonvolatile molecules for injection into a TOF mass spectrometer. The NH_3 is rapidly heated to supercritical conditions ($\sim 140^\circ\text{C}$) before expansion so that a gaseous supersonic jet results and detection is performed by resonant two-photon ionization (R2PI) at 266 nm in a TOFMS. There are several key features of this technique. Liquid NH_3 can be used to dissolve polar nonvolatile molecules at room temperature and provided the residence time in the high temperature region is short (< 1 sec), then decomposition can be minimized. Using liquid NH_3 injection with R2PI detection, relatively soft ionization mass spectra have been obtained for highly polar nucleosides such as adenosine and guanosine where strong M^+ and BH^+ ion peaks were observed with little additional fragmentation. Soft ionization mass spectra have also been obtained for steroids such as estrone and estradiol and also for di- and tripeptides. By increasing the laser power, characteristic fragmentation is observed where the dipeptides leu-tyr and tyr-leu can be distinguished for example. A second key advantage of this method is the enhanced selectivity of laser ionization in supersonic jets. Although a high density jet and chamber pressure ($\sim 5 \times 10^{-5}$ torr) result from high pressure NH_3 injection, the NH_3 solvent remains completely transparent and is not ionized by the laser radiation. This allows the ability to produce either soft ionization or extensive fragmentation without physical separation of the analyte from the NH_3 solvent. In addition, based upon the supersonic expansion method cold wavelength spectroscopy of tryptamine and several dipeptides as a function of laser wavelength has been obtained for unique spectral identification in a mass spectrometer.

Figures 1a and b show R2PI mass spectra of the dipeptide isomers Leu-Tyr and Tyr-Leu injected into the TOFMS using high pressure liquid NH_3 (150 atm). The pulsed nozzle was held at 150°C in order to produce a supercritical fluid expansion with subsequent R2PI at 266 nm. In these experiments, the power was raised to 5×10^6 W/cm² to increase the observed signal. In Figure 1, the molecular ion is observed as well as several fragments distinctly characteristic of each isomer. These fragments are characteristic of MPI and are induced by the increased laser power required to enhance the signal because the solubility of these compounds in liquid NH_3 may be the limiting factor here. The fragments are not those characteristic of thermal decomposition, which might be otherwise produced due to the high temperature in the valve. The short residence time in the valve allows injection under supercritical fluid conditions without significant decomposition. The result is that R2PI/MPI of small peptides can be studied for identification and structural analysis by liquid NH_3 injection without significant interference of the solvent. The NH_4^+ peak observed in the mass spectrum is due to charge-exchange in the TOFMS acceleration region.

SFC-MS OF HIGH MOLECULAR WEIGHT GLYCOCONJUGATES

D. M. Sheeley and V. N. Reinhold
Harvard University School of Public Health
Boston, MA 02115

Structural characterization of compounds from biological tissues often presents problems in availability and difficulty in purification. Thus, there is always great interest in methods with improved specificity and sensitivity. SFC is a technique which presents great potential for the separation of complex biological mixtures, as well as important advantages for structural characterization by mass spectrometry interfacing. In view of this potential, we have applied SFC-MS to the compelling problem of structural analysis of oligosaccharides (1). Recent work in the characterization of these molecules has made use of a wide array of analytical techniques, including HPLC with varying column supports and phases, sample derivatization, multi-column separations, and a variety of sensitive detectors, including mass spectrometry. This report describes an SFC-MS study of a series of high mannose oligosaccharides, (obtained from glycoproteins by Endo H treatment), and from animal urine samples, (mannosidosis). These mixtures were used as a paradigm for development of an SFC separation scheme applicable to more complex glycans.

Experimental

SFC was performed on a model 501B supercritical fluid chromatograph (Lee Scientific, Inc.) equipped with a flame ionization detector, and a pneumatically actuated submicroliter (0.2 μ l) injection valve (Valco Instrument Co. Inc.). Pump cylinder and injection valve temperatures were held at 10 $^{\circ}$ C. Capillary columns had inner and outer diameters of 50 and 375 microns respectively, and were coated with a film thickness of 0.25 μ m (Lee Scientific, Inc.). Mobile phase pressure and flow were maintained by fabrication of the integral restrictor described by Guthrie and Schwartz. Chemical ionization MS was performed on a VG ZAB-SE high resolution mass spectrometer, (VG Instruments), operating at 8 kV. The ion source was modified for dedicated CI operation by blocking of all inlet ports, and use of a narrower exit slit. The SFC-MS interface has been described previously (1).

Results

The chromatographic efficiencies of a series of derivatives, encompassing silyl and methyl ethers, and acetyl and polyfluorinated esters, have been evaluated, utilizing a variety of column stationary phases, including 5% phenyl, 30% biphenyl, and 50% cyanopropyl/methyl polysiloxanes. The silylated derivative provides good chromatographic resolution according to chain size, but does not enable separation of structural isomers. Overall resolution is slightly poorer with the permethylated derivative, but structural isomers show improved resolution. Chromatograms of the permethylated and silylated derivatives chromatographed on the biphenyl and 5% phenyl columns show similar resolution. Neither the silylated or permethylated derivative resolves well on the cyanopropyl column. However, this stationary phase resolves peracetylated oligomers very well, and is improved considerably by the addition of the pentafluorobenzyl ester of p-amino benzoic acid (PFBAB) to the chain's reducing end. This label is used to generate enhanced sensitivity by SFC-NCIMS (2) and a total ionization plot for a glycan mixture, (Man_nGN, n=5-8), is presented in Figure 1. An insert in Figure 1 shows the selected ion profile obtained when plotting the ion representing (Man)₇GNAC. Figure 2a shows the total ion plot obtained from an identical glycan mixture, (without a reducing-end tag), following sample trimethylsilylation. Selected ion plots for each of the four components is indicated in Figure 2b. Figure 3 presents representative mass spectra for the three major components.

SUPERCRITICAL FLUID CHROMATOGRAPHY/MASS SPECTROMETRY FOR
CHARACTERIZATION OF COMMERCIAL SURFACTANT MIXTURES

Henry T. Kalinoski and Leonard O. Hargiss, Unilever Research, U.S.,
Inc., 45 River Road, Edgewater, N.J. 07020

The development of a probe-mounted capillary direct interface for supercritical fluid chromatography/mass spectrometry (SFC/MS) (1) has extended the utility of SFC for the analysis of commercial nonionic surfactant mixtures. Nearly 800 million pounds of these materials are consumed annually in the United States, seventy-five percent of this in household detergent products. Use of positive and negative ion chemical ionization provides identification and characterization information following efficient capillary SFC separation. Characterization of nonionic surfactant mixtures is enhanced by limiting fragmentation of higher molecular weight species. Contrary to other results (2,3), positive and negative ion mass spectra obtained using this SFC/MS system are influenced by the presence of the chromatographic mobile phase in the ion source. These changes in the mass spectra resulting from the mobile phase complicate the study of the SFC/MS interface and limit application of SFC/MS for evaluation of surfactant mixtures. Chemical ionization conditions in the HP5985 ion source have been studied with selected alkoxylated surfactant mixtures and varied sample introduction methods. Positive and negative ion chemical ionization were performed with and without carbon dioxide or nitrous oxide present. Conditions can be selected to permit production of only molecular species ions, allowing evaluation of interface conditions, sample transfer and system transmission.

Preliminary studies of the probe-mounted capillary direct SFC/MS interface to an HP5985 GC/MS demonstrated capillary SFC/MS could be conducted using conditions developed for SFC/flame ionization detection, with no compromise to MS operating parameters and only a minor loss in chromatographic efficiency. The design permitted rapid changeover from GC/MS or probe/MS to SFC/MS, allowing the SFC/MS interface to be compared to other methods of sample introduction (1). The design also permitted supercritical direct fluid injection, for samples not requiring preseparation. Samples of alkoxylated pyrazoles provided a well-studied mixture (4) for evaluation of chromatographic and interface performance. Although readily separated using supercritical carbon dioxide, detection of mixture components by chemical ionization mass spectrometry following SFC discriminated against higher molecular weight species. One contribution to the apparent discrimination was the single quadrupole analyzer with a stated mass range of 1000 daltons. Increased fragmentation of higher molecular weight materials further complicated system evaluation. Increased fragmentation was also found for higher molecular weight alcohol ethoxylate nonionic surfactants.

Homogeneous samples of normal alcohol ethoxylates were available and used to probe the interface and ionization complications. Positive ion chemical ionization mass spectra produced using methane, isobutane and ammonia were characterized by increased fragmentation when appreciable levels of the common supercritical fluids carbon dioxide and nitrous oxide were present in the ion source. Protonated molecules or ammonium adduct ions remained the base peaks

in the spectra and there was no appreciable rise in the molecular ion (M^+) signal, so it was not clear if the increased fragmentation resulted from charge exchange with the mobile phase gas. Negative ion CI spectra also displayed increased fragmentation and adduct ion formation when SFC mobile phases were present. The exception was chloride-attachment NICI using difluorodichloromethane (FREON-12) as the reagent gas (5). The ion produced for the alcohol ethoxylates was the $(M+Cl)^-$ ion with no fragment ions produced, even with a twofold excess of carbon dioxide present in the ion source.

Capillary supercritical fluid chromatography interfaced with chemical ionization mass spectrometry provides high efficiency separations for characterization of nonionic alcohol ethoxylate surfactants. Contrary to reports for other samples and SFC/MS systems, the presence of carbon dioxide or nitrous oxide in the CI source of the HP5985 system configured for SFC/MS significantly influences the appearance of positive and negative ion mass spectra. When supercritical fluid chromatography or direct fluid injection is employed for characterization of alkoxyated surfactants, the role of the mobile phase during ionization must be considered. Freon-12 as the reagent gas for chloride attachment negative ion chemical ionization appears least influenced by the presence of carbon dioxide and may be the preferred system for obtaining molecular weight and distribution information on commercial alkoxyated nonionic surfactants.

SUPERCritical DIRECT FLUID INJECTION AMMONIA CIMS

ION SPRAY LC/API-MS OF MORPHINANS

A.B.L.Lanting, B.F.H.Drenth, J.Bosman, and A.P.Bruins
University of Groningen, Centre for Pharmacy
Ant.Deusinglaan 2, 9713 AW Groningen, The Netherlands

Morphinan derivatives are potent drugs, chemically related to opium alkaloids. They usually exist as pairs of enantiomers, that show a remarkable stereospecific action in the body. The pure d-enantiomers dextrophan and dextromethorphan are converted into their N-methyl derivatives, and are used in pharmacokinetic and metabolism studies in Groningen.

Separations are done by HPLC on C-6 and C-1 stationary phases, the eluents being mixtures of methanol and an aqueous ammonium acetate/acetic acid buffer solution (pH 3.5). Confirmation of the identity of the parent drugs and their N-methyl derivatives takes place by on line LC-UV-MS. In the present study it is essential that thermal demethylation, as reported in thermospray LC/MS of quaternary ammonium compounds (1), is avoided to exclude the ambiguity about the presence and the position of methyl groups. Both the ion spray LC/MS interface (2) and the atmospheric pressure ion source of the NERMAG R 3010 triple quadrupole mass spectrometer (3) operate at room temperature, and thus avoid thermal degradation altogether. The effluent from the UV detector is fed through a splitter, which allows 1-10% of the effluent into the ionspray LC/MS interface. Figure 1 shows the UV and TIC trace of a mixture of 1 and 2 and their N-methyl derivatives. The amounts injected into the LC were app. 300 ng per component. The mass spectra show a complete absence of thermal degradation and fragmentation (Figures 2 and 3, nozzle 70 V). Fragmentation in the free jet expansion region between the API source and the quadrupole mass filter enables us to differentiate between isobaric ions (Figures 2 and 3, nozzle 150 V) In the course of experiments with ^{14}C labelled N-methyl derivatives a degradation product was formed during storage. An unlabelled sample did not suffer from the apparent radiation damage, unless exposed to UV light for a prolonged period. LC/MS has shown that the degradation reaction is a radiation induced oxidation process.

COMPARISON OF THERMOSPRAY AND CONTINUOUS FLOW
FAB LC/MS METHODS FOR THE ANALYSIS OF
ACYL-CoA COMPOUNDS

Daniel L. Norwood, C.A. Bus, and David S. Millington
Division of Pediatric Genetics and Metabolism
Duke University Medical Center
Box 3028, Durham, NC 27710

Acyl-CoA compounds are important intermediates in the catabolism of various biomolecules, including fats and branched-chain amino acids. Defects in the mitochondrial oxidation of either of these two molecular types can be manifested as Reye's Syndrome or Sudden Infant Death Syndrome (SIDS). It should be possible, given appropriate analytical techniques and methods, to assay specific enzyme activities in the mitochondrial system by determining the appearance or disappearance of acyl-CoA substrates and products. This paper describes a comparative study of thermospray and continuous flow FAB LC/MS methods for the analysis of short and medium-chain (C1 - C8) acyl-CoA compounds.

Methods For continuous flow (CF) FAB, two different instrumental configurations were utilized with a standard pulse-damped HPLC solvent delivery system (Waters 600-MS). The first incorporated an analytical column (Waters Nova Pak C18; 3.9 x 150 mm) with post column flow splitting, and the second a microbore column (Keystone Scientific Hypersil BDS; 1.0 x 250 mm) with pre- and post column flow splitting. With both configurations a dual solvent gradient was employed (A: 0.2 M ammonium acetate/1.75% acetonitrile/2% glycerol; B: acetonitrile) with a two step linear ramp from 100% A to 90% A in 10 minutes, then to 50% A in 20 minutes. The MS system consisted of a VG Trio-3 triple quadrupole instrument which incorporated a VG Dynamic-FAB probe (VG Masslab). Thermospray analyses were accomplished with the same chromatographic system (analytical column; no glycerol) and a standard VG probe.

Results Figure 1 presents the results of the microbore column (Fig. 1A) and analytical column (Fig. 1B) CF-FAB LC/MS analyses of eight short and medium-chain acyl-CoA compounds. These chromatograms represent extracted ion current profiles of the protonated molecular ion (MH^+) of each acyl-CoA. Note that separation efficiency is good with both systems and that chromatographic integrity was maintained throughout the rather severe solvent gradient. Addition of glycerol to mobile phase A appeared to have no effect on the chromatography of either system. CF-FAB spectra of all acyl-CoA compounds analyzed contained molecular weight information in the form of MH^+ , along with structurally significant fragment ions. Sensitivities appropriate to the analysis of biological extracts were obtained (see Figure 2, for example). Thermospray spectra (Figure 3, for example) contained no molecular weight information and numerous fragment ions which were difficult to ascribe to unimolecular processes.

The CF-FAB LC/MS techniques are deemed most appropriate for the analysis of acyl-CoA compounds.

EFFICIENT INTRODUCTION OF HPLC FRACTIONS INTO A HIGH PERFORMANCE MASS SPECTROMETER A. Cappiello, P. Palma, I.A. Papayannopoulos, K. Biemann, Dept. of Chemistry, Mass. Institute of Technology, Cambridge MA 02139
G. Crescentini, F. Bruner, Ist. di Scienze Chimiche, Universita' di Urbino, 61029 Urbino, Italy

In the determination of the primary structure of proteins by tandem MS, the manipulation of the digest, the transfer of HPLC fractions, etc. is a crucial step that can lead to sample losses and contamination.

In order to minimize sample consumption and for high separation efficiency, dry-packed capillary column (250 μ m ID) and micro gradient system are used. The column is connected to a JEOL HX 110/110 tandem mass spectrometer via a FRIT-FAB interface[®] (JEOL, Tokyo, Japan) which is directly compatible with the low mobile phase flow rate (2-4 μ l/min) of the capillary column, thus eliminating the need for wasteful effluent splitting.

(1) FAB spectra for molecular ion information are obtained by continuously scanning MS-1 over the mass range encompassing the peptides expected.

(2) Alternatively, an off-line multiple loop system is used to trap the peaks eluted from the column and to later introduce them via the FRIT-FAB interface. Some sample band broadening results which is an advantage in MS/MS operations. This approach provides control over the time scale of the experiment because the sample is introduced into the ion source more slowly and at the discretion of the operator, thus facilitating MS/MS operations.

EXPERIMENTAL- Chromatographic equipment: An Applied Biosystems 130A liquid chromatograph was modified in order to reduce the dead volume and to achieve a constant flow rate with linear and reproducible gradients.

A home made capillary column (250 μ m ID x 50 cm), packed with Spherisorb C₈ 5 μ m 300 A pore size was used for the separation of peptide mixtures. The column was directly connected through a fused silica capillary tubing 50 μ m ID to a home made 62 nL micro cell of the UV detector. A fused silica capillary tubing (50 μ m ID) connects the flow cell to the loop system.

Loop system: The loop system consists of a low dispersion injection valve where the loop ports are connected with an electrically actuated multiposition trapping flowpath valve (loop valve) made to hold 8 separate loops (Fig. 1). A 16 loop valve can be added, extending the trapping capacity to 23 loops (one is used as connection line). The loops are made from 0.01" ID teflon tubing, 20 μ L internal volume.

This system can be used both as fraction collector and as sample dispenser. Fractions can either be directly introduced into the ion source via the Frit FAB interface or trapped in consecutive loops by switching the injection valve. The content of each loop is then introduced into the ion source at the convenience of the operator. Samples can also be stored in the loops by injecting them through the syringe port placed in the injection valve and subsequently "pushed" into the ion source by pure mobile phase and sent to the MS.

Two sector operation: Conventional FAB spectra are obtained by scanning MS-1 while the effluent of the column flows directly in the MS ion source.

Four sector operation: In order to obtain MS/MS spectra two different approaches were followed:

a) **ON-LINE.** 50 pmol of the tryptic digest of human hemoglobin α chain were separated in the column (Fig. 2) and directly introduced into the MS via the FRIT-FAB interface. As soon as the precursor ions were detected on the MS-1 detector, the CID spectra were recorded with a microchannel array detector.

b) **LOOP TRAPPING.** In order to avoid a rapid change in sample during CID spectra acquisition, the off-line loop system was employed. The separated peaks of a tryptic digest of 300 pmol of human hemoglobin α chain were collected in six consecutive loops and subsequently injected into the tandem mass spectrometer via the FRIT-FAB interface. A chromatographic peak 40 sec wide (baseline) after being trapped in the loop broadens and lasts in the ion source for about 3 min (half height of the peak envelope). A CID spectrum recorded in this manner is shown in Fig. 3.

CONCLUSION- During a chromatographic analysis two different situations can be encountered:

a) Well separated peaks. In this case the ON-LINE approach is preferable because the time elapsing between peaks suffices for setting MS-1 and MS-2 for the next precursor ion. The sensitivity is high due to the high concentration of the sample during the short eluting time. On the other hand, narrow peaks require rapid scans in order to obtain flatter sample signal.

b) Overlapping peaks. Incomplete separation does not permit ON-LINE recording of CID spectra of more than one component. Loop trapping broadens the chromatographic band and extends the lifetime of the sample in the ion source to allow the recording of consecutive CID spectra. However, spreading out the signal decreases its sensitivity but also allows longer integration times. A very important feature of this way of operation is the decoupling of the separation process and the recording of the mass spectral data which can be carried out at leisure and in any order of priority.

CONDITIONS FOR MICROBORE LIQUID CHROMATOGRAPHY OF PEPTIDES FOR CONTINUOUS-FLOW FAB

Bikash C. Pramanik and Clive A. Slaughter; Howard Hughes Medical Institute, Dallas, Texas 75235.
Theodore A. Dourdeville; Waters Chromatography Division of Millipore, Milford, Massachusetts 01757.

Complex mixtures of peptides are routinely encountered in the course of sequence analysis of proteins and during peptide synthesis. Such peptide mixtures are usually resolved by reverse-phase HPLC and the structures of the components elucidated by amino acid sequence and compositional analysis. We have been exploring the use of on-line liquid chromatography/mass spectrometry to supplement the information available from these traditional approaches.

In initial experiments, a reverse-phase separation method, developed on a conventional HPLC system, was adapted for use with thermospray mass spectrometry. A tryptic digest of β -lactoglobulin A was used as a standard peptide mixture. A 3.9mm X 30cm Delta Pak C18 column (Waters, Milford, MA) was employed and elution performed in 0.02% trifluoroacetic acid at 0.45ml/min with a gradient of 0-70% acetonitrile over 1hr. 0.2M ammonium acetate was added post-column at 0.55ml/min to promote ionization. Protonated molecular ions were observed for 9 of the 16 components expected. All 9 were identifiable at the 0.5 nmol level with signal-to-noise ratios of 10:1 or better, and the mass spectra could be interpreted in the light of the peptide structures at the 2.5 nmol level. However, it was recognized that substantial improvements in sensitivity of detection would probably be difficult with thermospray.

The method was therefore adapted for use with continuous-flow (dynamic) FAB. This required reducing the flow rate to the low μ l/min range. A capillary (microbore) column (320 μ m I.D. X 30cm) was custom packed with the same stationary phase (LC Packings, Zurich), and the same linear solvent velocity was maintained by adjusting the flow rate to 3 μ l/min in order to minimize changes in retention time. Flow was metered by a pair of syringe pumps or by splitting the stream from an M600-MS reciprocating pump (Waters, Milford, MA). An on-line uv detector with a capillary flow cell was employed, and post-column addition of a glycerol-bearing FAB matrix was performed using a concentric transport-tube arrangement with mixing occurring at the FAB probe tip.

Fig. 1 (A) uv absorption and (B) mass summary chromatograms from LC/FAB/MS analysis of a tryptic digest of 200 pmol β -lactoglobulin A. The mass values indicated are those of the protonated molecular ions for the following peptides: - 331, 139 $\rightarrow$ 141; 409, 136 $\rightarrow$ 138; 573, 71 $\rightarrow$ 75; 916, 84 $\rightarrow$ 91; 673, 9 $\rightarrow$ 14; 1246, 125 $\rightarrow$ 135; 934, 1 $\rightarrow$ 8; 1066, 92 $\rightarrow$ 100; 1659, 149 $\rightarrow$ end; 2312, 41 $\rightarrow$ 60.

All analyses were carried out with digests of 200 pmol of protein, and the protonated molecular ions of 11 of the 16 expected proteins were identified (Fig. 1).

FAB produced less fragmentation than thermospray but the FAB spectra were complicated by the background contributed by the glycerol matrix (Fig. 2).

Fig. 2. Comparison of on-column mass spectra acquired by FAB and thermospray, at the 200 pmol and 2.5 nmol level respectively.

Because of the variability of the background contributed by glycerol to the total ion current, the eluting components could not be located reliably by inspection of the total ion current chromatograms, but were identified instead by their uv absorption.

The LC/FAB/MS method was applied to the analysis of digests of insulin B chain by the complex, multisubunit protease, macropain. Of the 15 peptides identified previously by amino acid sequencing, the expected protonated molecular ions of all but those of the three highest mass were identified in a digest of 1.6 nmol of substrate. The results assisted in the identification of 14 sites at which the substrate is cleaved by the enzyme.

ABSORBENT EVAPORATOR FOR CONTINUOUS FLOW LIQUID SIMS

M. Shih, T.-C. L. Wang and S. P. Markey
National Institute of Mental Health, Bethesda, Maryland 20892

Continuous flow (CF) - liquid SIMS (LSIMS) or fast atom bombardment (FAB) has become a rapidly developing field in analytical mass spectrometry (1-6). In comparison to static liquid SIMS, this technique provides lower chemical noise. A wide range of solvents, such as methanol, acetonitrile, hexane, and water, may be used. Samples can be introduced into a spectrometer at a shorter duty cycle by eliminating the procedure of withdrawing a probe from the ion source for sample loading and the subsequent re-optimizing operation needed for the probe re-insertion. Since each sample is eluted in a discrete manner, background subtraction and peak ratio calculations can be applied as in chromatographic techniques for quantification (7,8).

In the operation of a CF-LSIMS system where the liquid is delivered through capillary tubing to the LSIMS target surface to form a thin film, one of the handicaps for continuous stable operation is the accumulation of liquid around the probe tip region. This causes such adverse effects as peak broadening from stagnancy of liquid flow, film instability from the freezing of mobile phase in the capillary, and instability of ion source pressure due to dripping and bubbling of mobile phase. We have minimized these effects by installing an absorbent evaporator with extended evaporation surface at a distance from the probe tip. The evaporator is provided with a heat conduction pathway, bypassing the probe tip region, from a large heat sink. Without complicated engineering to control both mass and heat transfer, we are able to operate the continuous flow system near a state of mass transfer dynamic equilibrium without problematic accumulation of liquid for more than eight hours of continuous operation.

A prototype Finnigan (Finnigan Mat, San Jose, Ca) Bioprobe system on a TSQ-70 mass spectrometer and static LSIMS probe tip were used. An unfocused cesium ion gun was from Phrasor (Duarte, Ca). The probe stop in the source block assembly was removed to accommodate the evaporator. The homemade probe was machined from a solid rod of stainless steel. The evaporator was made out of Whatman cellulose extraction thimbles (Whatman International Ltd, Clifton, New Jersey) and force-fitted onto the probe shaft as shown in Figure 1. The thimble shaped evaporator was of 10 mm i.d. x 28 mm length. A pulse-dampened Gilson Model 302 HPLC pump was used to deliver a 20% glycerol/H₂O solution to a 0.5 μ L loop injector and through a 75 μ m i.d. x 90 cm fused silica tubing to reach the probe tip in the ion source. The mobile phase flow rate was about 8 μ L/min. The ion source temperature was 50-55 $^{\circ}$ C. The probe was heated at the probe handle to maintain the temperature of the probe shaft at the entry port of the mass spectrometer at about 40 $^{\circ}$ C. Repetitive injections of 10 ng potassium salt of 3-methoxy-4-sulfatoxyphenylethyleneglycol in 0.5 μ L mobile phase show that the continuous flow system can be operated continuously for up to about nine hours with little deterioration of performance (Figure 2).

Figure 1. Evaporator and probe assembly

Figure 2. Repetitive injections of 10 ng potassium salt of 3-methoxy-4-sulfatoxyphenylethyleneglycol, Timing started at the beginning of mobile phase flow

There are two engineering principles which this system incorporates. First, the transferring of the mobile phase away from the probe tip region reduces the thermal load on this region. Second, the use of an extended absorbent evaporation surface in contact with a large heat sink increases the rate of mobile phase evaporation at reduced temperature, and improves the overall liquid fluidity. These principles should be adaptable to other CF-LSIMS or FAB mass transfer systems. We anticipate that with adequate amounts of absorbent and evaporation surface, this device will enhance the tolerance of the flow system to various mass transfer and heat transfer control parameter changes. Thus, it should be useful for a wide range of mobile phase compositions and mobile phase flow rates in CF-LSIMS systems.

Analysis of Nucleoside-PAH DNA Adducts by CID FAB-MS and
Continuous Flow FAB-MS

Roland S. Annan and Paul Vouros, Department of Chemistry
Roger W. Giese, Department of Medicinal Chemistry
Northeastern University, Boston, Ma., 02115

The covalent adducts formed when polycyclic aromatic hydrocarbon (PAH) metabolites react with DNA are well suited for analysis by desorption MS techniques. The FAB spectra of these compounds contain $[M+H]^+$ and $[M-Sugar+2H]^+$ ions. Unfortunately, the sensitivity of these compounds to FAB is generally poor. The deoxyribose sugar present in the nucleoside and nucleotide form imparts a large degree of hydrophilicity to the molecule, resulting in a low desorption efficiency, and reduced sensitivity. This fact in combination with the small amounts of adducts recoverable from DNA or cell cultures imposes a serious limitation on the detection and characterization of DNA adducts. The goal of this research was to advance the sensitivity of FAB for the analysis of nucleoside adducts, and to increase the structural information available from the FAB experiment. Two general types of PAHs which have demonstrated carcinogenic activity, aromatic amines and Bay region PAHs, were studied.

The use of TMS derivatives was found to greatly increase the sensitivity of these compounds to FAB. Very high quality spectra could be obtained on as little as 50ng of the aromatic amines. The molecular species is predominantly the TMS_2 derivative were both TMS groups are on the deoxyribose sugar. Thus cleavage of the carbohydrate linkage results in the same mass ion as the underivatized compounds. The enhancement in sensitivity was especially great for the dihydro diol epoxide PAH adducts. Unfortunately the $[M-Sugar+2H]^+$ (AH_2) ions were still too weak to be observed.

Examination of the metastable decay of the PAH adducts showed that the $[M+H]^+$ ions decomposed to yield AH_2 primarily. Ions due to the loss of NH_2 from guanine were also common. Because the AH_2 ions were of high intensity relative to the parent the sensitivity of this transition was evaluated. Detection of 22ng of N-acetyl-N-(deoxyguanosin-8yl)-2-amino fluorene (AAF-GUAN) was possible at S/N=5. Preparation of the TMS derivative of AAF-GUAN resulted in greater than a 10 fold increase in sensitivity. The decomposition of the $[TMS_2+H]^+$ to yield the same AH_2 ion as the underivatized compound (m/z 373) could easily be detected at 4ng (S/N=15). The metastable decay of the AH_2 ions results in a few ions of very low intensity.

High energy collisional activation, with a He target gas, was found to be very useful for inducing fragmentation of the AH_2 ions. Several ions representative of the PAH were present in high abundance, as were ions resulting from cleavage of the guanine base. Figures 1 and 2 show the CID spectra of the AH_2 ions of positional 2-aminophenanthrene-guanine adducts. Visually the spectra are very different. The primary ions stem from expulsion of a cyanamide fragment which contains the phenanthrene structure. In Figure 2 (N^2 adduct) this ion is at m/z 233 rather than m/z 218 ($C8$ adduct), because the amino group of the phenanthrene moiety is not involved in the cyanamide bond. The spectra in Figures 1 and 2 were taken from the TMS derivatives using 200 ng for each.

The use of the continuous flow FAB probe resulted in high quality full scan spectra, of underivatized adducts being generated on as little as 50ng. Figure 3 shows that 10ng of AAF-GUAN can easily be detected by observing the metastable decay of the m/z 489 ($M+H$) to 373 (AH_2). Figure 3 is a B/E scan covering 600 u. Much greater sensitivity could be achieved by scanning a smaller mass range or by using reaction monitoring.

This work was supported by a grant from the Health Effects Institute.

CONTINUOUS-FLOW FAST ATOM BOMBARDMENT LC/MS IN BIOANALYSIS

P. Kokkonen^{1,2}, W.M.A. Niessen², U.R. Tjaden² and J. van der Greef^{1,2}

1. TNO CIVO-Institutes, P.O. Box 360, 3700 AJ Zeist, The Netherlands
2. Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

Within the rapidly growing research field of interfacing high performance liquid chromatography and mass spectrometry (LC/MS) continuous-flow fast atom bombardment (CF-FAB) receives a growing interest. There are essentially two reasons for this, i.e. the improved performance of CF-FAB as compared to conventional FAB and the possibility to use a "soft" ionization method in LC/MS.

However, the major part of the reports is based on evaluation of the method in flow injection mode and only a minor part is concerned with LC/MS applications. The most important reason for this is the fact that the flow-rate in CF-FAB is limited to a maximum of about 10 $\mu\text{l}/\text{min}$. As a consequence it is necessary to split after the chromatographic separation typically 1:200, which increases the concentration detection limits by a factor of about 200. Miniaturization of the HPLC system to microbore instrumentation reduces the split ratio but does not improve the concentration limits, except for cases in which the sample size is limiting, because the injection volume in miniaturized systems must be decreased correspondingly.

For quantitative analysis on-line miniaturization applying "Phase System Switching" (PSS) is an attractive alternative as we have demonstrated for the moving belt interface and the thermospray interface. The basis for PSS is a coupled column system consisting of an analytical column followed by a trapping column. After trapping the analyte on the second column and a washing step which can be used to remove non-volatile buffers from the mobile phase used in the separation, desorption is achieved with the optimum mobile phase and the optimum flow-rate for the interface used. The latter aspect enables chromatography using conventional columns and the detection at low flow-rates without the need for splitting. The experimental setup and the results for dextromethorphan are given in Figure 1 and 2.

Continuous Flow FAB-MS for Rapid Structural
Comparison of Analogous Therapeutic Proteins.

K. Mock, J. Firth, S. Evans, J. Cottrell
Finnigan MAT Ltd., Hemel Hempstead, UK.

Continuous Flow Fast Atom Bombardment (CF-FAB) [1] has been successfully used as an interface technique for Liquid Chromatography Mass Spectrometry (LC-MS). One of the most important growth areas in LC-MS is peptide mapping. In this work enzymatic digests of recombinant IL-2 were mapped using a MAT90 double focusing mass spectrometer and CF-FAB interface, (Finnigan MAT GmbH., Bremen, FRG).

Recombinant human IL-2 expressed in E. Coli was reduced and pyridylethylated (to give S-8-4-pyridylethylcysteine). The sample was desalted by reverse phase HPLC using a Brownlee RP-C18 cartridge, 5µm, 3cm x 2.1 mm internal diameter, equilibrated in 0.1% trifluoroacetic acid/water. The eluent was lyophilised, and the protein (1.6 nmol) dissolved in 0.1 M ammonium bicarbonate, pH 7.8. 800 pmol was digested with trypsin at a ratio of 1/50 w/w at 37°C for 6 hours. The remainder was digested with protease V8 at a ratio of 1/20 w/w.

Chromatography was performed with a Model 130A separations system (Applied Biosystems, Warrington, Cheshire, UK), and a Rheodyne 7410 injector equipped with a 5µl loop. Gradient elutions were performed at 8µl min⁻¹ on a packed fused silica micro-LC column, FUC-330, 5µm, C18, 320µm I.D. x 30 cm (LC Packings, Amsterdam, The Netherlands). Solvent A was 0:10:90:0.1 and solvent B 60:5:35:0.1 acetonitrile / glycerol / water / trifluoroacetic acid respectively.

Figure 1 shows examples of selected mass chromatograms for tryptic fragments obtained from a single injection of 10 pmol. Many other intense peaks were also observed, but rejected on the grounds that they did not elute as sharp chromatographic bands. In total, fragments corresponding to 97% of the sequence were observed, (Figure 2), although the signals for several important fragments were very weak and may not have been recognised as significant had we been studying a true unknown. The spectrum in Figure 3 illustrates the high signal to chemical background ratio characteristic of CF-FAB. The peaks at 562u, 690u, and 910u correspond to tryptic fragments.

These results are in good agreement with those obtained earlier using thermospray ionisation [2]. The principal advantage of using CF-FAB over thermospray is the reduction in sample consumption (10pmol versus 7nmol).

Only in favourable circumstances can complete sequence verification be obtained from FAB mapping of a single enzymatic digest. For this reason, a V8 digest of IL-2 was also analysed which provided complementary data, particularly in the vicinity of residues 55-76 where the tryptic fragment was very weak (Figure 2).

CF-FAB AND MICRODIALYSIS FOR ANALYSIS BLOOD LEVELS OF DRUGS
IN LIVE ANIMALS: MULTIPLE DOSAGE PHARMACOKINETICS

Shen-Nan Lin, Su Chang and Richard M. Caprioli

The Analytical Chemistry Center and
Department of Biochemistry and Molecular Biology
The University of Texas Medical School at Houston
Houston, Texas 77225

In this study, we have assessed the ability of the microdialysis and on-line continuous-flow fast atom bombardment (CF-FAB) mass spectrometry (1) to provide reliable *in vivo* pharmacokinetic data over prolonged periods of time for the evaluation of multiple-dose antibiotic therapy.

A Finnigan MAT TSQ-70 equipped with a CF-FAB probe (Bioprobe) was used with a Carnegie Medicin microdialysis device. Briefly, the microdialysis device was inserted inside a 22 gauge needle cannula surgically placed in the carotid vein of a male rabbit. A Harvard microliter syringe pump was used to produce a flow of about 4 μ l/min of carrier solution through the microdialysis probe. The carrier solution consisted of 95% water and 5% glycerol. The output from this device was passed through a RP8 microbore HPLC column. The compounds trapped on the HPLC column were then back-flushed off by an elution fluid composed of 5:40:0.1:55 glycerol:acetonitrile:TFA:water at 5 μ l/min. The flow was directed via the CF-FAB interface into the mass spectrometer. Thus, the pharmacokinetic data was obtained through a series of flow injection analyses 10 min sampling time followed by a 10 min elution and analysis time, with a total cycle time of 20 min.

Initial studies were designed to identify analytical problems likely to be encountered in the use of the instrumentations for analyses of commonly-used antibiotics (2). For antibiotics such as penicillin G, which is easily microdialyzable and sensitive to the CF-FAB mass spectrometric analysis, we were able to use a 20 μ l sample loop on-line, without the use of a preconcentration column, to follow with easy the time course of the drug in the blood of a rat after a bolus of 15 mg/0.3 ml was injected intramuscularly (see Figure 1). Although piperacillin can also be measured sensitively by the CF-FAB mass spectrometry, the compound does not pass through the microdialysis membrane very efficiently. The recovery efficiency of the microdialysis device for this compound is approximately 4%, a factor of 4 times less than that of penicillin G. In order to follow the *in vivo* blood concentration, it became necessary to include a 2mm id x 2cm RP8 LC column on-line as a concentrating apparatus to ensure that there was sufficient amount of drug to measure with good accuracy.

This analytical procedure was used to follow the multiple-dose pharmacokinetics of piperacillin in live rabbits (see Figure 2). The first three IV doses were given via the ear vein at 25 min intervals, resulting in high blood piperacillin concentration. The blood level decreases rapidly. The next two doses were given at 70 min intervals. The blood concentration did not spike as before but the overall pattern of accumulative concentration changes from the time course curve is typical of multiple dosage pharmacokinetics.

Aminoglycoside antibiotics are a series of new potent but very toxic compounds. Our early studies with these compounds reveal analytical problems somewhat different to those cited above. The detection sensitivity for tobramycin by CF-FAB mass spectrometry, for example, is very much dependent on the composition of the mobile phase used to carry the compound to the ion source. The data show a 10-fold decrease in detection sensitivity for tobramycin when the compound is dissolved in a 5% glycerol and 95% water solution instead of in a 5% glycerol, 40% acetonitrile, 0.1% TFA and 55% water mixture. Thus, it appears that for these compounds, a different experimental protocol will be required to achieve maximum sensitivity.

In conclusion, for antibiotics to be effective in combating infectious microorganisms, the antibiotic should reach the target site in therapeutic concentrations. However, precise information on tissue and body fluid levels are not readily available, either because a suitable analytical method is lacking or because available methods are too time-consuming for *in vivo* measurements. Microdialysis combined with mass spectrometry offers some new approaches to such measurements. We have described some initial work in this area and have pointed to some problems for measurement of antibiotic concentrations *in vivo*. However, the fact that we are able to apply the technique to follow several antibiotics at therapeutic levels in the blood over prolonged periods of time shows that the technique is effective in such applications. The measurement and evaluation of these data are critically important for ensuring safe and beneficial administration of antibiotics and for the maintenance of therapeutical tissue and blood levels.

ANALYSIS OF URINARY ACYLCARNITINES BY DYNAMIC FIB - MS/MS

M.R. CLENCH, S. WILSON, O. WEIR

VG TRITECH LIMITED, MANCHESTER, M23 9RE, UK

G.A. MILLS, V. WALKER

CLINICAL BIOCHEMISTRY, UNIV. OF SOUTHAMPTON, SOUTHAMPTON, SO9 4XY

L - Carnitine (3 - hydroxybutyrobetaine) is essential for the transport and metabolism of fatty acids. Its main function is to carry long chain acids across mitochondrial membranes for β - oxidation. An abnormal urinary excretion of L - carnitine and its acyl derivatives occurs in children with various inherited metabolic disorders (1). The excretion profile is generally disease specific. Acylcarnitines are not directly amenable to GC-MS. Millington and co workers (1,2) have analysed these compounds using static FAB-MS and FAB-MS/MS (daughter ion scanning) both neat and purified urine samples were analysed directly or after methylation to improve sensitivity.

Methods Urine samples were collected from patients with and without metabolic defects, on drug treatment and after L - carnitine administration. 200 μ l of unpurified urine was lyophilized and analysed directly or after methylation. (MeOH HCl, 50°C for 30 minutes). Dynamic FIB was carried out using a cesium gun under the operating conditions: mobile phase 70% H₂O, 20% MeOH, 10% glycerol; flowrate 6 μ l/min; sample volume 0.5 μ l; gun voltage 15kV Normal spectra were measured on a VG TRIBRID instrument, parent ion scans of m/z = 85 (non-methylated) and m/z = 99 (methylated) were carried out using collision cell 2 (MIKES cell); air admitted to 50% beam attenuation of m/z = 277.

Results and Discussion FIB mass spectra of both non-methylated and methylated acylcarnitines were dominated by pseudomolecular (M+H)⁺ ions (fig 1). Parent ion scans using the relevant characteristic daughter ions at m/z = 85 or 99 (2) gave molecular ions with excellent resolution. Such scans are only obtainable using an instrument of this geometry. Figure 2 shows the parent ion spectrum of a standard mixture of methylated C₄, C₅, C₆ and C₈ carnitines esters at m/z = 246, 260, 274 and 302 respectively. The resolution achievable makes the Spectra easy to assign.

Figure 3 shows the parent ion scans (m/z = 99) of a methylated urine sample from a neonate with diagnosed medium chain acyl-dehydrogenase deficiency (MCAD) following an L-carnitine load. The grossly elevated excretion of octanoyl-carnitine (m/z = 302 together with hexanoyl (m/z = 274) and octenoyl carnitine (m/z = 300) is characteristic of the condition. For comparison a normalised parent ion scan of urine from a normal neonate is shown in Figure 4. Other chemical studied by this technique included methylmalonic and propionic aciduria and valproate therapy.

Conclusions Dynamic and static FIB - MS/MS using high energy collisions and parent ion scans on a multi sector instrument enables the specific and rapid identification of acylcarnitines in complex mixtures.

Continuous flow FAB (CF-FAB) using microbore [1] and submicrobore [2] HPLC systems have been proven successful in the analysis of peptide mixtures and tryptic digests of proteins. This special interface also allows flow injection of aqueous samples into an effluent containing a low concentration of matrix (5% glycerol in H₂O). One of the distinct advantages of this technique over static FAB probe analysis is its improved sensitivity in the detection of peptides having different surface activities [3]. This phenomenon is thought to arise from the reluctance of hydrophilic peptides to migrate to the liquid interface. However the dynamic nature of the liquid surface under CF-FAB apparently minimizes this suppression effect and is of considerable advantage in the analysis of enzymic digests.

Most of the LC/CF-FAB interfaces reported thus far introduce the FAB matrix either in the mobile phase [1,2] or by addition via a post-column arrangement [4]. The main limitation of such system is that the addition of the matrix into the LC effluent not only changes the polarity and viscosity of the mobile phase but can also cause severe chromatographic peak-broadening. These inconveniences can be avoided by adding the FAB matrix independently to the FAB probe tip. Such an interface has been reported recently for conventional and tandem mass spectral analyses [5]. Briefly this arrangement consists of 2 coaxial capillaries, the inner one being used to deliver the LC effluent while the outer capillary is used to introduce the FAB matrix at the end of the probe tip. Figure 1 shows two LC/MS analyses of a simple peptide mixture using a 0.32 mm i.d. column, and compares the use of glycerol in the mobile phase with the coaxial arrangement. It is observed that under a similar gradient operation (flow rate, mobile phase composition of organic solvent) the incorporation of glycerol in the LC effluent increases significantly the diffusion of analytes in the column. Consequently individual peaks become broader and elute during a time period approximately two times longer than in the coaxial arrangement. A direct advantage of the narrower peak shape in coaxial CF-FAB is that a higher flux of analyte reaches the probe tip at a given time therefore allowing better sensitivity. This is illustrated in Figure 2 for the analysis of glucagon tryptic digest which contains approximately 100 pmols of each peptide. It is noteworthy that fragment 19-29 at m/z 1352 is clearly observed in the CF-FAB experiment although its signal was suppressed using static probe FAB analysis. This behavior is consistent with that reported for hydrophilic peptides [3,6].

In addition to the advantage described above, the coaxial CF-FAB interface permits operation with a gradient system containing up to 100% acetonitrile. This is not possible with glycerol in the mobile phase due to its limited solubility (approx. 5% glycerol in 60 % acetonitrile). Another application of this interface is illustrated in Figure 2 for the analysis of bovine growth hormone releasing factor 1-29. For purposes of clarity the selected ion traces are presented only for m/z: 843, 971, 1002 and 1130 corresponding to fragments 13-20, 12-20 and/or 13-21, 22-29 and 21-29 respectively. Because of the presence of arginyl-lysyl residues at position 11-12 and 20-21, the formation of m/z: 971 can arise from both 12-20 and 13-21 fragments. Due to the enzymic cleavage preferences and kinetics of this tryptic digestion it is observed that fragments 1-12 and 22-29 are not abundant. On the other hand this suggests that m/z: 971 would originate from the 12-20 fragment. This possibility was confirmed by recording MS/MS spectra of m/z: 971, using both an hybrid and 4 sector tandem mass spectrometers. The observed daughter ion masses were matched with those predicted from known peptide fragmentation schemes to validate the potential sequence candidate.

Better chromatographic resolution and sensitivity could be obtained using a 2 m micro packed column of 50 µm i.d. However the analysis time using this latter column was substantially longer (approximately 3 hours for the analysis of bovine growth hormone releasing factor compared to 30 mins with the 320 µm i.d. column).

**MICROBORE AND CAPILLARY HPLC ANALYSIS OF GLYCOPEPTIDE
ANTIBIOTICS USING CONTINUOUS FLOW FAB LC-MS**

John E. Coutant, Teng-Man Chen, and Bradley L. Ackermann
Merrell Dow Research Institute
Cincinnati, OH 45215

The use of continuous flow fast atom bombardment (CF-FAB) as an interface for liquid chromatography-mass spectrometry (LC-MS), especially in peptide analysis, has generated great interest in this technique. The constraints of this interface, including low flow rates (2-5 $\mu\text{L}/\text{min}$) and need for a non-volatile FAB matrix such as glycerol, have presented problems in the routine application of this technique. To date, most investigators have used effluent splitting along with isocratic systems containing glycerol in the mobile phase to sidestep these problems.

This work describes the adaptation of gradient high performance liquid chromatography (HPLC) systems using microbore (1mm) or capillary (320 μm) columns with post-column addition of matrix. The microbore column was a commercial column (1 mm x 250 mm Spheri-5 RP-18, ABI). The capillary column was slurry packed with 5 μ Spherisorb ODS using 320 μm i.d. fused silica to give a 250 mm long column. Teicoplanin was chosen as a model system because of the severe demands placed both on the chromatographic separation and the FAB mass spectrometry to obtain good results in the analysis of glycopeptide antibiotics.

For both systems gradients were formed by a conventional gradient HPLC system (Waters 600-MS) and the total flow was split before the injector (Rheodyne 7413 - 0.5 μL) by use of a dynamic balance column (4.6 mm x 250 mm Spherisorb ODS, 5 μ). In the case of the microbore LC system, the resulting flow was 75 $\mu\text{L}/\text{min}$ through the column. Matrix was added post-column and the combined effluent was split to allow 3 $\mu\text{L}/\text{min}$ (3%) to go to the mass spectrometer. For the capillary system, the resulting flow through the column was 2 $\mu\text{L}/\text{min}$, matrix was added post-column, and the entire amount was analyzed by MS. The capillary system is shown in Figure 1. For both LC systems good mass spectra of the main components were obtained (A2-1 through A2-5). The increased sensitivity of the capillary system allowed spectra to be obtained on components present at picomole concentrations. The UV chromatogram and TIC trace from a gradient separation of teicoplanin is shown in Figure 2. The mass spectrum of the major teicoplanin component (A2-2) is shown in Figure 3.

The increased sensitivity of the capillary system is primarily due to the fact that all material injected onto the LC column reaches the mass spectrometer. In addition the chromatographic resolution of the capillary system appears somewhat better than the microbore system due to the deletion of the extra column effects of a post-column splitter section in the interface. These advantages outweigh the problems involved in fabricating the packed capillary LC columns to make this the preferred system for CF-FAB. The use of gradients minimize the effect of large volume injections (0.5-1.0 μL) to make this a useful system for trace analysis with scanning detection limits in the low picomole range.

**MICROCOLUMN LC/CONTINUOUS FLOW FAB MS
APPLICATIONS TO AGRICULTURAL CHEMICALS RESEARCH**

Robert W. Reiser
E. I. du Pont de Nemours & Co.
Agricultural Products Department
Experimental Station
Wilmington, DE 19880-0402

Packed fused silica micro LC columns were interfaced with a magnetic mass spectrometer (Finnigan 8230) using a Continuous Flow FAB (CFF) probe designed and constructed in our laboratory to be interchangeable with a commercial moving belt interface. This gives us the capability to perform LC/MS-EI, CI and FAB, a powerful combination for the identification of unknowns (1,2,3). The low flow rates used with micro LC columns (1-2 μ L/min.) allow direct interfacing (no effluent splitting) of reversed phase LC columns using both the moving belt and CFF probe, which is very important in sample limited analyses. We routinely obtain good quality EI, CI or FAB mass spectra on injection of a 0.1 microgram sample into the micro LC.

The CFF target is heated by radiation from the ion source, and with a source temperature of 200°C the target temperature is 45-50°C. The FAB spectra obtained on thermally labile compounds under these conditions were identical to those obtained with the conventional FAB probe with the ion source at room temperature. We obtained a 10-fold increase in sensitivity with the CFF probe over that obtained with the conventional FAB probe, likely due to increased sample concentration in the glycerol matrix since a much thinner film of glycerol is obtained with the CFF probe. Addition of 10% glycerol to the mobile phase caused no problems with the chromatography. The glycerol ions are readily subtracted out of the sample spectra, allowing observation of low mass fragment ions which are very helpful for structure determination.

LC/MS-FAB has allowed us to obtain molecular weights of polar, thermally labile compounds that do not yield molecular ions using EI, CI or thermospray ionization. Figure 1 shows an LC/MS-FAB chromatogram obtained on a mixture of chlorsulfuron, a sulfonylurea herbicide, and two wheat metabolites, obtained by plotting a summation of the three protonated molecular ions. Figure 2 shows the background subtracted FAB mass spectrum obtained on the glucoside metabolite. This polar metabolite is extremely thermally labile, and does not give a molecular ion by EI, CI or thermospray ionization.

LC/MS-FAB has proven to be very useful for agricultural chemicals research. FAB mass spectra have provided unequivocal molecular weights and structurally useful fragment ions of polar, thermally labile metabolites and product impurities which are extremely helpful in their identification. These identifications are needed for environmental studies and product chemistry studies conducted on our products prior to and after market introduction.

Monsanto Company/Environmental Sciences Center
and
Mark A. Zinkl
Hewlett-Packard Company, St. Louis, Mo.

Background. Recent developments in HPLC/MS interfaces have resulted in a commercially available particle beam interface which can be used with existing mass spectrometer systems. The present paper describes preliminary results showing the analysis of non-gas chromatographable analytes which was conducted on an HPLC/MS with such an interface. The goal of these studies was to determine the usefulness of this approach for the analysis of compounds which normally require derivatization or other multistep processes to obtain highly specific analysis results using a mass spectrometric detector system. No attempt was made to maximize sensitivity or improve HPLC chromatography.

Analysis Methods. The present study was conducted on an HP-1090 HPLC which was interfaced to the HP-5988 mass spectrometer system. Most studies involved 10 μ L direct injections of standard solutions in methanol, with no liquid chromatographic separation.

Selected standards were also analyzed using 20 μ L injected volumes and were separated using gradient elution from 50% acetonitrile/water to 100% acetonitrile. Analyte concentrations for most studies were approximately 1 μ g/ μ L. Comparative GC/MS analyses were conducted using a 30 meter DB-5 fused silica column interfaced to an HP-5985 (with 1 μ L injected volumes and 37.5 ng/ μ L concentrations).

Direct Liquid Injections. The total ion chromatograms and mass spectra of individual analytes using the HPLC/MS with particle beam interface indicated that the particle beam interface could be used to successfully analyze a number of non-gas chromatographable compounds. Table 1 summarizes the compounds and their properties used to evaluate this interface. When these components (at a concentration of 1 μ g/ μ L for each compound) were injected directly into the particle beam/mass spectrometer system, reserpine, 5,12-naphthacene dione, streptozotocin, and malonitrile dimer were detected with a total ion signal/

Table 1. Properties of Particle Beam Test Mixture Components

<u>Compound</u>	<u>Molecular Weight</u> (amu)	<u>Boiling Point</u> (°C)	<u>Melting Point</u> (°C)	<u>GC-able?</u>
Reserpine	608	----	26	no
5,12-Naphthacene dione	258	----	322	no
Trypan Blue	960	----	>300	no
Safrrole/iso-Safrrole	162	230	11	yes
Benzoic Acid	122	249	122	yes
2-Picoline	93	128	-67	yes
Streptozotocin	265	----	121	no
Malonitrile Dimer	132	(possibly decomposes)		monomer-yes
Resorcinol	110	176 ¹⁸	111	yes

noise ratio of 10 or greater. Benzoic acid, resorcinol and trypan blue produced responses with signal/noise ratios on the order of 10, and all other compounds could only be detected from their extracted ion profiles. Figure 1 shows total ion chromatograms from these direct liquid injections.

HPLC/MS Analyses. The sensitivity of this instrumentation was also evaluated using a 75 ng/ μ L test mixture of the test components shown in Table 1. Only

reserpine, 5,12-naphthacene dione, and streptozotocin could be detected from total ion chromatographic data, although several analytes could be detected using the extracted ion profiles of their most intense mass spectral peaks. All standards contained phthalate esters which are thought to be artifacts from the HPLC instrumentation.

Comparison with GC/MS Analysis Method. A number of standard compounds could be detected us-

Figure 1. Total Ion Chromatogram of DLI Analyses of a Particle Beam Test Mixture.

Figure 2. Comparison of DL/PB/MS Spectrum with EI Library Spectrum for Benzoic Acid

ing HPLC/MS and GC/MS techniques. However, poorer sensitivities were measured for the very volatile compounds, using HPLC/MS instrumentation. For moderately volatile compounds, the HPLC/MS method was from one to two orders of magnitude less sensitive than the GC/MS method, when the analyte could be detected in both systems. For very low volatility compounds, only the HPLC/MS instrumentation produced mass spectra.

Comparison with Electron Impact Libraries

Standard solutions of approximately 1 $\mu\text{g}/\mu\text{L}$ 2-picoline, safole and iso-safole, benzoic acid, and 5,12-naphthacene dione gave complete mass spectra which agreed with the EPA/NIH mass spectral library. Figure 2 compares a spectrum of benzoic acid obtained from the particle beam interface with a standard reference spectrum of benzoic acid.

Conclusions

The particle beam interface may prove very useful for the extension of analysis methods to non-gas chromatographable compounds. Its limitations include: 1) the requirement to use no or only volatile buffers, and 2) sensitivity on the order of 10 to 100 times less than normal GC/MS analyses.

LC/MS OF PROTEINS AND LARGE PEPTIDES, Jack Henion, T.R. Covey, W. Muck, and E. Huang, Drug Testing and Toxicology, Cornell University Ithaca, NY 14850.

INTRODUCTION

There is considerable interest in the separation and characterization of biopolymers today. Most biochemists resort to classical separation methods including gel electrophoresis, column chromatography, or other low resolution separation methods. Following this they use a variety of degradation reactions of established chemistries to characterize the "pieces" from the original biopolymer. When all these pieces are available, the challenge remains to put all this information together to determine the original structure.

HPLC separation of enzymatic digests with UV detection to produce a "map" has significantly eased the task of characterizing a tryptic digest, for example. In spite of the help provided by this analytical contribution to biochemical characterization, the technique requires knowing the retention time of each chromatographic peak with reference to analytical standards.

If HPLC with high molecular weight mass spectrometric detection(LC/MS) was used for the characterization of such samples the biochemist could have the separation and molecular weight determination of any unknown mixture with one analytical run of approximately 20-30 minutes! Molecular weights far beyond the mass range of the mass spectrometer may be determined by the multiply-charged ions produced by the ion spray(pneumatically-assisted electrospray) LC/MS interface(1). We have analyzed a variety of enzymatic digests and unknown samples to demonstrate this capability.

EXPERIMENTAL

The system used for this work consisted of a Brownlee Labs Micro Pump for delivering gradient micro HPLC flow rates(10-40uL/min) through 1mm x 100mm 3 micron C8 reversed-phase packed columns to the ion spray LC/MS interface. The eluent typically was composed of methanol or acetonitrile mixed via a gradient of aqueous ammonium acetate or trifluoro acetic acid buffers(3-20mM). Ions generated at atmospheric pressure by the application of 3kV to the sprayer were sampled into a conical orifice of a Sciex TAGA 6000E tandem triple quadrupole mass spectrometer. The same ion spray LC/MS interface could be coupled to a capillary zone electrophoresis(CZE) column also. These liquid inlet systems provide modern, high efficiency separations for facile characterization by atmospheric pressure ionization mass spectrometry.

RESULTS AND DISCUSSION

Enzymatic digests of several proteins including hemoglobin, myoglobin, human growth hormone, and bovine serum albumin(BSA) were analyzed. The Figure below shows a representative ion spray LC/MS TIC for a 250 pmole injection of tryptic digest of met-human growth hormone. The molecular weights of all the peptides in the digests including undigested BSA, for example, which has a molecular weight approaching 68,000 daltons were determined by on-line LC/MS. In the LC/MS/MS mode structurally significant sequence information could also be obtained.

ANALYSIS OF ENZYMATICALLY DIGESTED PROTEINS BY ON-LINE CAPILLARY HPLC/FABMS

James H. Bourell, William J. Henzel, and John T. Stults

Genentech, Inc., 460 Point San Bruno Blvd., So San Francisco, CA, 94080

A JEOL mass spectrometer (MS) with a Frit-FAB probe has been linked to a packed capillary LC and utilized to obtain molecular ions for peptides of enzymatically digested proteins. The system provides the ability to completely mass analyze complicated peptide mixtures in the time frame of an LC separation. A tryptic digest of recombinant human Growth Hormone (rhGH) and an Asp-N endoprotease digest of Protein Carboxy Methyltransferase (PCMT) are used to evaluate LCMS performance. The low flow rates required for the packed capillary (5 μ L/min) permit the total column effluent to be introduced to the spectrometer. As a result, high sensitivity for molecular ions is demonstrated under mass spectral scanning conditions.

Our Frit-FAB LCMS system is shown schematically in figure 1. An Applied Biosystems, Inc. (ABI) microgradient HPLC system is equipped with a 0.32 x 15 cm packed capillary C-18 column (3 μ m packing, LC Packings, Switzerland) and an ABI Model 783 UV detector with an in-line capillary flow cell. A preinjector split (a Valco tee with one port connected to the appropriate length of 50 μ m ID capillary tubing to give an approximate 20:1 split) is used to generate a low flow rate thru the column and still maintain an efficient gradient delivery from the LC pump. The JEOL Frit-FAB probe is shown in more detail in figure 2. Capillary tubing exiting the LC is passed thru an insulated support and pressed up against a 0.25mm thick stainless steel frit. Liquid from the LC passes thru the frit and spreads across the surface exposed to the Xenon beam. Flow rates for all samples are 5 to 9 μ L per min. Water/glycerol/TFA 99:1:0.1 (Solvent A) and acetonitrile/glycerol/TFA 99:1:0.1 (Solvent B) is used in a gradient program of 2 to 60 percent B in 65 minutes with a hold time of 10 minutes for all LC runs. The small path length of the capillary flow cell combined with the concentrating effect of the column allow the UV detector to operate at 195nm wavelength. This gives an approximate five-fold increase in sensitivity over 214 nm.

Mass spectrometry was performed with a JEOL HX110/HX110 tandem mass spectrometer operated in the two sector mode. Samples were run at a resolution of 3000 and an accelerating voltage of 10kV. The Xe-FAB gun voltage was 6kV. Chromatographic runs were acquired at rate of 6 to 10 seconds per scan with a mass range of 600 to 4000 u.

The UV trace of a peptide mixture generated by 25 picomoles of an rhGH tryptic digest is shown in Figure 3. The peak separation is comparable to large column (4.6 mm) HPLC separations (1). The corresponding total ion current (TIC) trace (figure 4) shows little loss in peak separation caused by the MS or capillary transfer line. All of the tryptic peptides having masses within the scan range could be identified from the 25 picomole rhGH sample. Masses up to approximately 2500u molecular weight can be reliably detected at the 25 picomole level. The 0.5 picomole total injection amount spectra of the T1 rhGH tryptic, shown in figure 5, is indicative of Frit-FAB signal at the subpicomole level.

A NEW INSTRUMENT FOR THE ANALYSIS OF HIGH MOLECULAR WEIGHT BIOMOLECULES
S.A. Jarvis, R.H. Bateman and B.N. Green, VG Analytical Ltd., Wythenshawe,
Manchester, M23 9LE, UK.

We have developed an instrument for the analysis of high molecular weight biomolecules, incorporating an atmospheric pressure electrospray source and a VG 3000Da mass range spectrometer. Series of highly multiply charged ions are produced from which the molecular weights are deduced using simple algorithms. Data is usually acquired with the data system operating as a multichannel analyser (MCA), with 20 Channels/Da. Several scans are summed to give the final spectrum, giving total data acquisition times of between 1 and 10 minutes, depending on the ion current. Calibration is carried out by a separate introduction of a reference compound that gives a series of peaks in the required mass range (eg. myoglobin). Samples are usually introduced in a methanol/water solution at a typical flow rate of 5 μ l/min. Total sample consumption varies from a few picomoles to a few nanomoles, depending on the molecular weight of the sample.

Applications

1. Beta Lactoglobulins A and B. Figure 1 shows the peaks corresponding to the (M+14H)⁺ ion of beta lactoglobulin. The example shows the clear separation between the A and B variants of molecular weights 18363.3Da and 18277.2Da. Moreover, the resolution of ions containing 0,1 and 2 sodium atoms infers the potential to separate two proteins at this mass differing by only 22Da in molecular weight.

2. Molecular Weight Determination of Isopenicillin N Synthetase (IPNS). IPNS is a 338 amino acid enzyme containing one iron atom. A sample, produced by recombinant DNA technology, was suspected to have the N terminal methionine processed off ie, missing. Three analyses were made on 20 μ l aliquots of a 360 pmole/ μ l solution. Part of the spectrum from the third analysis, showing peaks corresponding to the molecule with between 30 and 47 charges, is shown in Figure 2. The results for the three analyses are summarised in the following table, and show a remarkable reproducibility from analysis to analysis of about 2Da.

Analysis No.	Measured MW	Std. Dev.
1	38364.1	$\pm$ 10.5
2	38364.2	$\pm$ 5.0
3	38362.0	$\pm$ 6.8
Mean	38363.4	
Std. Dev.	$\pm$ 1.2	

The measured molecular weight (38363.4) is consistent with the expected molecular weight of IPNS minus a methionine (38357.8), confirming that the N terminal methionine is indeed missing and the iron atom is present.

3. Bovine Albumin (Molecular Weight = 66kDa). Figure 3 shows a spectrum of bovine albumin taken over a mass range of 1400 to 1720Da. All the peaks show similar fine structure consistent with the samples containing several components or possibly the formation of adducts. Peaks are resolved which differ in mass by about 1 part in 500. Furthermore, mass measurements on the eight lowest mass peaks from 3 different albumins gave very reproducible values as summarised in the following table.

	Measured MW	Std. Dev.
Bovine Albumin	66444.1	$\pm$ 4.2
Porcine Albumin	66873.5	$\pm$ 6.7
Human Albumin	66456.4	$\pm$ 11.6

The measured value for human albumin is 19.5Da (0.03%) higher than the literature molecular weight (66436.9).

DESIGN AND PERFORMANCE OF A NEW MAGNETIC SECTOR MASS SPECTROMETER WITH DIMIDIATE GEOMETRY

Michel J. Bertrand, P. A. Bott¹⁾, C. J. Porter¹⁾, and R. H. Bateman¹⁾
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada H3C 3J7

¹⁾VG Analytical Ltd., Wythenshawe, Manchester M23 9LE, UK

Traditionally, double focussing sector mass spectrometers are either of forward (EB) or reverse (BE) geometry. Forward geometry instruments are usually characterized by large dispersion/magnification ratios (Dm/m) with relatively short path lengths, resulting in compact instruments with high sensitivity at high resolution. Under normal operating conditions, metastable peaks are present in the mass spectrum, and mass analyzed ion kinetic energy spectroscopy (MIKES) is not available. However, a forward geometry instrument allows linked B/E scans to be performed in order to monitor reactions occurring in the first field free (FF1) region of the mass spectrometer. In linked scans, at constant B/E, artefact peaks originating from the decomposition of higher mass species in FF1 can be observed¹. Reverse geometry instruments can also have large dispersion/magnification ratios but this is usually achieved at the expense of a longer path length resulting in larger instruments. Under normal operating conditions of a reverse geometry mass spectrometer, metastable peaks are rejected from the spectrum. However, a reverse geometry allows mass analyzed ion kinetic energy spectroscopy (MIKES) experiments to be easily conducted and linked B/E scans can also be performed. In both of these scan modes, artefact peaks are observed and they are caused by higher² and lower³ mass species undergoing decomposition in the first and second field free regions (FF1, FF2) respectively.

In order to combine the desirable characteristics of both forward and reverse geometries into a single instrument, a new double focussing magnetic sector mass spectrometer with dimidiolate geometry has been developed. The instrument consists of a magnetic sector ($r_m=381\text{mm}$) and a split electric sector arranged in an E1BE2 configuration as shown in figure 1. This geometry confers to the mass spectrometer the advantages of both conventional geometries and the preponderant character (forward or reverse) of the ion optics can be chosen by using an appropriate combination of asymmetrical dimensions for both parts (E1 and E2) of the split electric sector. The characteristics of forward geometry that can be found in the instrument described in figure 1, are revealed by its relatively small dimensions (width=1.5m) and its high dispersion/magnification ratio ($Dm/m = 819 \text{ mm}$) resulting in a compact geometry with high sensitivity at high resolution. Figure 2 shows a region of the mass spectrum of dibenzosuberone $C_{15}H_{12}O$ and as can be seen, the fragments $^{13}C_1C_{13}H_{11}$ and $C_{14}H_{12}$ are well separated at a mass resolution in excess of 80,000. Advantages related to reverse geometry instruments are also found in the instrument shown on figure 1. Metastable peaks are rejected from the normal mass spectra and (MIKES) experiments can be easily conducted with this dimidiolate geometry by scanning the second electric sector which is located after the collision cell in the third field free region (FF3). As with forward and reverse geometry mass spectrometers, the instrument of dimidiolate geometry offers B/E linked scanning facilities (E1/B, B/E2, E1/B/E2). However, in MIKES as in link scanning experiments most of the artefact peaks that are usually observed on conventional instruments are rejected.

In order to evaluate the ability of the instrument of dimidiolate geometry to eliminate most artefact peaks observed in MIKES or link scanning experiments compared with mass spectrometers of both reverse and forward geometries, several chemical systems known to produce artefact peaks have been studied^{1,2,3}. In the three systems that were chosen, the first has been reported to generate artefact peaks in linked scans at constant B/E conducted on forward geometry spectrometers¹ due to the decomposition of higher mass species in FF1. The second represents a classical example of artefact peaks in MIKES experiments² caused by the decomposition of higher mass species in FF1. The third has been reported to create artefact peak in linked scans at constant B/E on reverse geometry spectrometers³ due to lower mass species decomposing in FF2. The results obtained for the linked scans at constant B/E of the molecular ion of eicosane at m/z 282 on a ZAB-MS of reverse geometry and on an Autospec of dimidiolate geometry are compared on figure 3. The spectrum obtained on the reverse geometry spectrometer (figure 3a) shows the presence of intense artefact peaks at m/z 189 and 178 arising from the transmission of lower mass ions that decompose in FF2 immediately prior to the electric sector. The artefact peak at m/z 189 is due to the transmission by the magnetic sector of m/z 127 which decomposes to form m/z 85 in FF2. The results of the same experiment conducted on the instrument of dimidiolate geometry (E1/B/E2) are shown in figure 3b. As can be observed, the spectrum is free of the artefact peaks since the ions formed in FF3 have energies too low for

transmission by E2. The other systems studied have yielded similar results indicating the ability of instrument of dimidiatic geometry to eliminate artefact peaks from linked scans or MIKES spectra.

A HIGH SENSITIVITY/HIGH RESOLUTION TANDEM MASS SPECTROMETER FOR HIGH MASS BIOMOLECULES

D. H. Russell
Department of Chemistry
Texas A & M University
College Station, Texas 77843

Tandem mass spectrometry is a versatile method for studies of the chemical and physical properties of gas phase ions, and the method is useful for structural characterization of complex organic molecules, *e.g.*, the primary structure of peptides, nucleotides, oligosaccharides, and *etc.* Although there are clear indications that tandem mass spectrometry can be used for the analysis of complex molecules, especially peptides and small proteins, the development of tandem mass spectrometry for structural characterization of biomolecules is hampered by sensitivity and mass resolution of the second mass analyzer. Two factors which limit the sensitivity of MS-II are: (i) independent of the ionization method, the "molecular ion" yield decreases as the sample molecular weight increases, and (ii) the efficiency for dissociating the mass selected ion decreases as the size of the molecule increases. Consequently, improvements in tandem mass spectrometry can be made by increasing the ion source performance and/or by improving the performance of MS-II. One approach to improving the performance of MS-II has been to couple together two high resolution sector instruments.¹ The biggest drawback to this approach is the cost of two high performance sector instruments and the added complexity of tuning of the instruments. Such instruments are designed primarily for collision-induced dissociation to provide the structural information; a process with low efficiency ($1/10^6$ or less for ions above m/z 1000) and the collisional activation process gives rise to energy loss and increases the translational energy spread of the ion beam---both factors degrade the performance of MS-II. I feel other alternatives can be designed which can yield higher performance than the four-sector instruments and the cost of these alternatives are less. To demonstrate the feasibility of the approach I designed a hybrid high resolution (EB) magnetic sector/reflectron time-of-flight (TOF) instrument with capabilities for high sensitivity and high resolution tandem mass spectrometry experiments (see Figure 1). The instrument utilizes pulsed Cs^+ ion liquid SIMS ionization (sensitivity increased by 30-300 over CW liquid SIMS),² laser photodissociation using a pulsed excimer laser system (photodissociation efficiency increased by 10^3 - 10^4 over CW photodissociation), and time-of-flight detection of both the photofragment ion and neutral. In addition, because of the high peak laser power photodissociation can be performed by either single or multiphoton processes.

Although pulsed experiments are not a natural combination with scanning magnetic sector instruments, the first mass analyzer (MS-I) for tandem mass spectrometry is usually operated in the static mode, *i.e.*, MS-I is tuned to mass select the $[\text{M}+\text{H}]^+$ ion of the analyte, and the MS-MS spectrum is obtained by scanning MS-II. Thus, pulsed ionization and pulsed laser photodissociation can be used if MS-II is a time-array detector (TOF) or an ion trap. The EB-TOF instrument is designed around a Kratos MS-50 instrument, thus MS-I is a high sensitivity/high resolution analyzer. The instrument has been modified for pulsed liquid SIMS ionization. The TOF analyzer is a home-built gridless-reflectron system which uses off-the-shelf LeCroy electronics and an IBM-AT computer system. In the MS-MS mode, ions are produced by a short duration Cs^+ ion pulse (4-10 ns), the ions are accelerated and focussed using a high sensitivity SIMS source, and the ions are then mass analyzed by the EB instrument. Prior to photoexcitation, the mass-selected ions are decelerated (from 8 keV to ca. 10 eV to 4 keV; the drift velocity of the ions can be varied continuously over this energy range) and following photodissociation the ions drift through a field-free region (drift times range from ca. 900 ns to several microseconds) and are then re-accelerated to 6-10 keV for TOF mass analysis. Following photodissociation of the mass selected ions, the photofragment ions can be deflected off-axis and the photofragment neutrals can be ionized (multiphoton ionization) by a delayed laser pulse; efficiencies for MPI of the photofragment neutrals approach unity. The TOF mass analyzer has high collection efficiency (approaching unity) and high resolution (upto ca. 10,000). We anticipate that the EB-TOF instrument will be capable of detecting less than 100 femtomole levels of peptides of molecular weights greater than 5000.

Tandem MS-TOF Instrument

A TANDEM QUADRUPOLE MASS SPECTROMETER OF NOVEL GEOMETRY OPTIMIZED FOR INTELLIGENT DATA ACQUISITION

M.A. MCDOWALL, V. GOULD, G. LAPPIN, D.C. SMITH and D. SWAIN. VG MassLab Ltd., Altrincham, UK.

Triple quadrupole mass spectrometers have become one of the most widely used instrument types for tandem mass spectrometry (MS-MS) due to their low cost, high level of automation and above all their ease of use. We have designed a tandem quadrupole mass spectrometer of novel geometry optimised for intelligent data acquisition that incorporates (Fig.1) an intermediate ion detection device that is situated off-axis, between MS1 (the first mass filter) and the collision cell. A second detector is fitted in the conventional position, after MS2.

Figure 1. Schematic diagram of the dual detector geometry of the VG QUATTRO tandem quadrupole mass spectrometer.

The intermediate detector permits conventional MS spectra to be recorded whilst maintaining the collision cell conditions at an optimum for MS-MS analyses. Switching (under microprocessor control) between MS and MS-MS scanning is achievable in less than 50 ms and is enabled by electrostatically focussing the ion beam emerging from MS1 either into the intermediate detector (for MS spectra) or into the entrance aperture of the collision cell (for MS-MS spectra).

"Intelligent" or "expert" systems that utilize rule-driven control software to operate tandem instruments provide unprecedented scope for automated analysis. Our dual detector geometry is designed to expedite the implementation of data dependent decisions made by such rule-driven control software.

An overview of the digital architecture is shown (Fig.2). The core of the system is an unbounded local area network (or array) of 32-bit RISC architecture transputers. The operating system within the transputer array (OCCAM) is designed to facilitate high speed (20 MIPS) concurrent processing. The unbounded design of the array structure together with the concurrency of OCCAM allows the possibility of expanding the array to provide enhanced processing power.

The transputer array performs all aspects of real-time instrument control. Specific transputers within the array may be used to carry out targeted tasks for example:-

- "Expert" system control.
- Fast library search (from RAM memory)
- Intelligent peripheral device control
- High speed communications (file conversion)

Figure 2. Schematic overview of the digital architecture of the VG QUATTRO tandem quadrupole mass spectrometer.

An "expert" system running within a high speed concurrent processing architecture is capable of making sophisticated data dependent decisions in real-time. Our dual detector geometry enables decisions of this type (involving complex changes in scan functions MS/MS-MS) to be implemented within 50ms. Thus both optimum MS and MS-MS data can be obtained from even narrow chromatographic peaks as they elute in real-time. A consequent saving in analysis time is observed compared to less responsive systems that require multiple chromatographic runs to acquire the same rich diversity of data.

ION TRANSMISSION CONSIDERATIONS IN TANDEM QUADRUPOLE MS-MS

T.O. Merren, M.A. McDowall and M. Hammond. VG MassLab Ltd.,
Tudor Road, Altrincham, Cheshire, WA14 5RZ, UK.

The quadrupole filter has been established as a means of containing ions, and it was a logical step to use a small quadrupole as the collision cell for MS-MS applications.

Figure 1.

The daughter spectra obtained albeit reproducible, are very dependent on collision cell conditions. A study of the ion trajectories gives a clear explanation of the transmission characteristics which are most apparent to an operator. A transmission characteristic has been generated from the model and shows very good agreement with the observed characteristic.

Figure 2.

Figure 1 shows three ions traversing the quadrupole in RF only mode. Small excursions from the path at the applied frequency can be seen, but more importantly, there are longer cyclic excursions from the axis. These excursions are of similar length for all ion starting conditions, and therefore nodes and antinodes are formed along the path. This is seen in Figure 2, where one hundred ions have been injected with different starting conditions. The maximum excursions in the RF cycle are plotted as points.

Figure 3.

The trajectories in the quadrupole are stable, but the entrance and exit slits are restricted in order to maintain a higher pressure in the gas cell than in the analyser enclosure by a factor of at least 100. If therefore a maximum excursion occurs at the exit slit, some ions will not be transmitted, as illustrated in Figure 3. Thus at the higher collision energy in the condition of Figure 3 than those in Figure 4, there will be a drop in transmission observed in the parent ion between those two points.

This is exactly what is observed in practice. The figures 4 and 5 show the transmission of mass 502 over two different ranges of collision energy. The continuous curve is derived from the model, and the points from observations. The point marked A corresponds to Figure 1 and points B to Figure 2.

Figure 4. (Quadrupole)

Figure 5. (Quadrupole)

Figure 6.

It is only a parent ion which shows this cyclic pattern, because of the defined entrance image. Daughter ions will have the same kind of trajectories, but ions start at collision, and the cyclic pattern will be smoothed.

The hexapole in RF only mode also will contain ions. It does not have the same focussing characteristics as the quadrupole and does not show the nodes and antinodes characteristic of the quadrupole.

The hexapole therefore shows a smooth characteristic with collision energy. This makes the setting of collision cell conditions much simpler since collision energy can be increased without an oscillating daughter parent ratio occurring. The equivalent characteristic is shown in Figure 6.

Figure 7.

Another characteristic of interest is the response with RF amplitude. The transmission with RF is mass dependent, and therefore the RF amplitude has to be varied with mass to obtain the best transmission. This is shown in Figure 7. It can be seen that more than a factor of 10 in mass between parent and daughter can be accommodated by scanning the RF amplitude with mass.

In conclusion, it is clear that the hexapole has characteristics which are less complex than the quadrupole, and therefore reproducible results can be achieved more readily.

A PENTAQUADRUPOLE MASS SPECTROMETER: INSTRUMENTATION,
SYSTEM CONTROL, AND APPLICATIONS TO MS/MS/MS SCANS

Jae C. Schwartz, Kevin L. Schey, and R. Graham Cooks
Purdue University, Chemistry Dept., W. Lafayette, IN, 47907.

The high transmission, reaction efficiency, and scan speeds, as well as facile computer control, make a pentaquadrupole mass spectrometer^{1,2} ideally suited for implementing new and established MS/MS/MS³ scan types and for demonstrating their applications. A pentaquadrupole instrument (QqQqQ) which utilizes three mass-analyzing quadrupole mass filters and two rf-only quadrupole collision cells has been constructed and is shown in Figure 1. A simple and efficient data system was designed and assembled consisting of a Keithley series 500 measurement and control system, Zenith Z-200 PC, and software written in "C" using the Turbo C programming environment. This inexpensive data system has very good characteristics including 16 bit DAC, 14 bit ADCs, and overall average acquisition speed (while scanning) in excess of 20 kHz.

The entire set of known MS/MS/MS scan modes⁴ can be readily implemented using this system and it has allowed new scans including ones which produce multidimensional data, to be developed. Figure 2 shows an example of a new scan called the selective neutral loss scan. This example utilizes n-decane and scans for all ions which lose (or gain) a particular neutral mass between the first (Q1) and last (Q5) stages of analysis, but which also do so via a particular intermediate ion selected by Q3. The selective neutral loss scan is a highly specific scan combining compound class recognition and particular fragment ion specification. As such, the applications of this scan are limited, but its existence is quite significant as this scan completes the set of the 2ⁿ zero and one-dimensional MS/MS/MS scan types which are shown in Figure 3.

Scans which are two dimensional in mass, i.e. require two mass axes for the display of the data, also exist in the complete set of MS/MS/MS scan types. Just as conventional MS/MS scans such as parent, daughter, and neutral loss scans are subsets of the entire MS/MS data domain, these two-dimensional spectra are subsets of the entire MS/MS/MS data domain. An example of a two-dimensional scan, the familial scan, is shown in Figure 4 for n-decane. This scan completely characterizes intermediate fragment ions of a particular mass for a pure compound or a mixture of compounds by scanning all parent ions and subsequent daughter ions for the chosen intermediate mass. Potential applications of this scan include isomeric and isobaric ion separation with simultaneous identification.

MS/MS/MS has been applied to study ion chemistry important in polyisocyanate characterization by mass spectrometry. Figure 5 shows the application of the reaction intermediate scan to help characterize polymers of n-hexyl-isocyanate. Upon pyrolysis and subsequent electron impact, this compound produces an abundant protonated trimer at m/z 382. This ion fragments by successive alkene losses which can be specifically observed by scanning for all intermediates between the protonated trimer and the completely dealkylated odd-electron daughter ion at m/z 130.

Various MS/MS/MS scans can be used to simplify sequencing of peptides by mass spectrometry. The QqQqQ has been extensively used for these studies⁵ and one example is shown in Figure 6. The reaction intermediate scan is utilized to exclusively observe only certain types of fragment ions, in this case for a particular pentapeptide with molecular weight 579 in a mixture of peptides. By setting Q1 on the M+H⁺ ion and setting Q5 on the fragment ion at m/z 173, a simple spectrum results which readily yields the sequence of the peptide.

Both collision activated dissociation or ion/molecule reactions in either or both collision regions can be utilized in a pentaquadrupole¹. MS/MS/MS under these conditions produces interesting results. When using 1,3-butadiene as both the sample and the neutral reagent gas in both reaction regions, MS/MS/MS scans produce data on gas-phase Diels-Alder and retro-Diels-Alder reactions and related chemistry. Figure 7 shows sequential daughter and reaction intermediate scans for this chemical system demonstrating the various processes which take place.

HIGH RESOLUTION DAUGHTER ION ANALYSIS APPLICATIONS IN HYBRID MASS SPECTROMETRY

B.C. Grant, E.H. McBay, S.A. McLuckey and G.L. Glush
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831

While many different geometries of instruments have been used for MS/MS, most have a limited daughter ion mass resolution. Of the beam type instruments only four sector, some three sector, and selected hybrid instruments have the capability of high daughter ion resolution. Among hybrid instruments, only the QEB instrument in our laboratory has the ability to perform high resolution daughter ion mass measurements. One of the features of hybrid instruments is the possibility of doing MS/MS experiments in which the daughter ions are formed from parent ions with low translational energies (1-100 eV) or high translational energies (3-10 keV). The QEB is thus the only MS/MS instrument in which both collision energy regimes can readily be accessed. This paper compares the sensitivity/resolution of the two operating modes on the QEB and also demonstrates other experiments that take advantage of the high daughter ion resolution capabilities of the instrument.

The QEB has been described in detail previously.¹ Briefly, the Q portion of the instrument is a UTI 100C quadrupole mass filter. The EB portion of the instrument is an AEI MS50. Ions exiting the quadrupole are focussed into a collision cell (reaction region 1, RR1) where low energy collision-induced dissociation (CID) can be performed. Ions exiting the collision cell (daughter or parent) are subsequently accelerated into the MS50. High energy CID can be performed in a collision region (RR2) at the source slit of the MS50. Data were acquired using a Nicolet 4094 digital oscilloscope.

Of particular interest in this study was the relative sensitivity/resolution that could be obtained via high energy CID in RR2 versus low energy CID in RR1. Figure 1 shows the m/z 43 region in the daughter ion spectra of the molecular ion of 3-methyl-2-butanone obtained using 9 keV CID (top) and 55 eV CID bottom. The two peaks are due to isobaric daughter ions $C_3H_7^+$ and $C_2H_3O^+$. The high energy CID spectrum was the best obtainable after considerable effort was made to maximize the intensity of the signal. The low energy CID spectrum is readily achievable and with some effort the resolution of this spectrum can be increased by a factor of two to three. Thus, in this particular instrument we find that the low energy CID provides up to an order of magnitude better sensitivity/resolution (i.e. at a given signal level the resolution is up to ten times better for low energy CID).

The ability to select daughter ions at high resolution allows the QEB instrument to perform high resolution parent ion scans. An example of this, using the same compound as above, is shown in Figure 2. In the upper part of this Figure the $C_2H_3O^+$ m/z 43 ion was selected and it was observed that the parent ions of this were the molecular ion, the protonated molecule (formed by self protonation in the ion source) and an ion at m/z 129, which is assumed to be an ion/molecule reaction product formed in the ion source. When the $C_3H_7^+$ m/z is selected as the daughter ion, the parent ions observed are m/z 71 ($M-15$)⁺ along with the molecular ion and protonated molecule.

A unique variant on the high resolution parent ion scan is the targeted daughter ion mode of operation². In this experiment, instead of scanning the quadrupole it is set in the rf-only mode to pass ions above a desired cut-off mass. By having the quadrupole in the rf-only mode, the transmission of parent ions can be increased by up to and order of magnitude or more providing increased sensitivity, albeit with reduced specificity. To demonstrate this mode of operation the magnet was scanned over the m/z 43 region at rf cut off levels of 70 and 100 amu. The results are shown in Figure 3. At the lower cut-off level, both ions at m/z 43 are observed, as expected since the quadrupole is passing both the molecular ion and protonated molecule. At the higher cut-off level only the $C_2H_3O^+$ ion is observed as the quadrupole is not passing the molecular ion or protonated molecule. The signal is due to the parent ion at m/z 129 and the MS/MS spectrum of this ion is shown on the bottom of this Figure, confirming that it only fragments to the $C_2H_3O^+$ ion.

RESIDUAL GAS ANALYZERS AS INEXPENSIVE SOURCES OF MASS-SELECTED ION BEAMS

Jeffrey R. Gilbert and John Allison, Department of Chemistry,
Michigan State University, East Lansing, Michigan 48824

The ease with which gas phase ionic species can be manipulated continues to stimulate dynamic and spectroscopic studies of charged molecules and atoms. Frequently, a beam of mass-selected ions is required. If the ionic species desired is simple, e.g., Ar^+ , an ion beam can easily be generated - using an electron ionization (EI) or discharge source, for example. However, if polyatomic ions are required, a mass-selection step will probably be required. Thus, "ion beam" experiments frequently become cost-prohibitive, since a mass spectrometer is required. In our present work, an attempt is being made to "freeze" mass-selected ions into an argon matrix at 10 Kelvins for subsequent spectroscopic analysis. This experiment requires two mass spectrometers, since a mass selected beam of counter ions (anions) must also be directed towards the 10 Kelvin target. The decision was made to evaluate residual gas analyzers (RGA's) as the basis for mass-selected ion sources. An RGA is commonly a small quadrupole mass filter, with an open EI ion source, that is mounted on a small flange. It is usually a component of a vacuum system that analyzes background gases. Ions are formed, mass analyzed, and directed towards a collector on the flange.

Our design goals were to 1) redesign the ion source into a closed configuration, which would allow for a substantial pressure differential between the source and the rest of the experiment, 2) turn the assembly around, to produce a directed ion beam without degradation of resolution, and 3) add focusing and deflection optics for conditioning and directing the beam. We have successfully completed these design goals with two RGA's, one of which has a mass range of 1-200 Daltons.

Two tools have been very important in the successful implementation of this work. The first is the ion optics modeling program SIMION (1), which was used to evaluate the effects of source modifications, and for the design of lenses and deflection assemblies after mass-selection. The second is a channel electron multiplier (CEMA) with a phosphor screen, used as a "beam visualizer". This was used for measuring beam divergence out of the quadrupole, which is necessary information for proper modeling, and for performance evaluation of the system when constructed. The CEMA also provided useful insights into how the shape of the "beam" out of the quadrupole varied with m/z .

Figure 1 shows the completed mass-selected ion beam source that was constructed from a Dycor M200 residual gas analyzer. The quadrupole and EI source are the original Dycor components. The device was mounted on a Conflat flange. The ion source was enclosed in a "gas tight" housing, such that high pressures could be maintained within the source (which is required for high ion fluxes) with minimal increase in pressure in the vacuum system. The figure shows a port for gas introduction directly into the ion source. Gas flow is controlled by an external leak valve. Source voltages are introduced through the top flange, while other voltages are introduced through two additional multi-pin feedthroughs. The focusing and deflection optics that were designed using SIMION are mounted on the end of the mass filter. The original Dycor electronics were used to operate the instrument, with minimal retuning of the quadrupole circuits required due to wiring modifications. The design modifications have been met, and mass-selected ion beams (m/z 1 to 200) can be formed from this device, without degradation of the resolution of the original RGA.

NEW B-Q TANDEM MASS SPECTROMETER

H.-J. Laue and K. Habfast, Finnigan MAT GmbH

2800 Bremen, FR Germany

Laboratory work centering around the exact isotopic analysis of uranium, thorium, lead and certain recent applications in geological age dating (U/Th disequilibrium) require the measurement of a minor isotope in the presence of an adjacent major isotope. However, the ratios of interest between 1: 50,000 to 1: 400,000 challenge the capabilities of state-of-the-art magnetic sector mass spectrometers due to the fraction of 1-2 ppm of scattered ions of the major isotope falsifying the measured intensity of the minor isotopes. The common technique for the elimination of scattered undesired ions is the improvement of the abundance sensitivity by employing a second magnetic sector field followed by an electric sector in a so called three-stage (BBE) instrument.

We have designed a new type of a three-stage equivalent isotope ratio mass spectrometer. The system is constructed as an addition to the MAT 262 mass spectrometer equipped with a multicollector array and an ion counter. A quadrupole mass filter is employed as a second stage to eliminate the elastically scattered undesired ions of incorrect mass. Ions of the major isotope travel from the ion source through the magnetic sector field into a Faraday-cup of the multicollector (see Fig.1).

Fig. 1

Ions of the minor isotope pass through the center slit of the multicollector. They enter the decelerating lens system to be focussed into the mass filter quadrupole, which is floated to nearly ion source potential (10 kV). These ions are detected behind the mass filter quadrupole in an ion counting system.

Fig. 2

The extraordinary abundance sensitivity is demonstrated in a mass scan using the standard U005. The U236/U238 ratio of this standard is 0.0000468. Hence, there is a minor isotope to be measured in the close neighbourhood of a major isotope. The magnet and the quadrupole filter is repeatedly scanned from mass 233.6 to mass 237.4 in an accumulated scan. Obviously, the long peaktail produced by the scattered ions of mass 238 disappeared (see Fig. 2).

The abundance sensitivity was measured with a stable ion beam of U005 by tuning the magnet and the quadrupole filter to mass 237. During the integration time of 600 seconds, 503 events were detected at the counter. When the system was tuned to mass 236 more than 807,000 ions were counted. (Abundance sensitivity: 0.03 ppm) With a different set-up of the ion counter, tested on an other mass spectrometer, the dark count noise will be reduced to 90 events during 600 seconds. (Abundance sensitivity : 0.01 ppm).

Performance Optimization of a Kratos MS80RFAQ Mass Spectrometer for High Mass Operation
G. Hansen, K. McKellop; Boehringer Ingelheim Pharm. Inc., Ridgefield, CT

The role of mass spectrometry in pharmaceutical research has until recently been concerned with the analysis of small molecules, with molecular weights less than 1,500 daltons. The majority of mass spectrometers purchased during the early to mid 1980's were ideally suited for this type of analysis, generally possessing a mass range of 1,500 - 2,000 daltons, fast scanning magnets for GCMS, and equipped with EI, CI, and an early version of FAB ionization. Sensitivity for ions above 2,000 daltons was not an overriding concern.

Mass spectrometers designed specifically for high mass analysis with optimized FAB or liquid SIMS ion sources, high mass magnets, and array detection are of course now available. An alternative to the high cost of the purchase of a new system is the optimization of an existing instrument. We wish to report such an optimization of a 6 year old MS80RFAQ hybrid mass spectrometer. Four goals were set in order to meet our objective:

1. Improve MS80 FAB sensitivity
2. Increase intermediate detector sensitivity for MS1 detection of ions > 2,000 daltons
3. Increase final detector sensitivity for MS2 detection of daughter ions
4. Maintain daughter ion resolution and peak shape in MS2 at high collision energy (> 100eV)

I. FAB Source Optimization

The original MS80 source configuration incorporated a standard Ion-Tech FAB11NF ion gun mounted on the top of the source housing. The exit of the ion gun measured 10 cm. from the sample probe (this distance is the maximum limit specified by Ion-Tech). This gun was removed and replaced by a standard Kratos insertion lock. A Phrasor Scientific Capillatron ion gun mounted in a direct insertion probe (DIP-gun) was purchased and introduced through this insertion lock. The sample tip normally mounted on this probe was removed. The distance between the exit of the Capillatron gun and the sample can be varied within the range of 2.5 - 10 cm. by inserting or retracting the Capillatron probe. The gun controller allows operation up to 10KV with independent control of emission current between 10 - 100 μ A.

The standard MS80 FAB source is essentially an open block held at accelerating potential - no extraction lenses are used. This source was replaced by an MS50/890 FAB source which contains additional ion extraction optics. Sample introduction is accomplished through an insertion lock mounted co-axially with the ion exit.

II. Intermediate Detector

The fixed output 8KV power supply for the post acceleration detector (PAD) was replaced by a variable 0 - 30 KV Spellman high voltage DC supply. The existing high voltage feedthroughs were not modified; continuous stable operation is possible with up to 18 KV applied to the PAD electrode. Fig.1 & 2 demonstrate the observation of MH⁺ ions for bovine insulin and the oxidized β -chain of insulin. These observations were not possible prior to these modifications. The total gain in sensitivity at high mass (m/z 3510) realized through these modifications is approx. 100 fold (table 1).

III. Final Detector

Installation of the 30 KV variable output high voltage supply in place of the standard 8 KV supply at the final MS 2 detector had a measurable effect on daughter ion sensitivity. Fig. 3 illustrates the 4 - 5 fold improvement in the intensity of daughter ions obtained in the 150 eV CAD spectrum of m/z 1172, $(Cs(CsI)_4)^+$. Additionally, an improvement in daughter ion peak shape was observed, particularly at higher collision energy (> 100 eV). This may be attributable to a more efficient collection of daughter ions with high axial kinetic energy or the higher PAD voltage may correct for minor misalignment of the PAD dynode.

An Electrostatic Quadrupole Deflector for Mass Spectrometer Applications

Paul Mahaffy, NASA/Goddard Space Flight Center, Greenbelt, MD. 20771

Keith Lal, ST Systems Corp. (STX), Lanham, MD. 20706

INTRODUCTION

Certain mass spectrometer applications may require the interface of two or three ion sources to a common mass filter. In SIMS (secondary ion mass spectrometer) or FAB (fast atom bombardment) experiments, for example, an additional electron impact ionization source may be used to measure residual gas composition.

Electrostatic ion selection from one of two or three sources can be made with the use of a 2-dimensional quadrupole deflector.^{1,2} The energy dispersive properties of this device will be of additional benefit for high mass resolution quadrupole SIMS applications where it is necessary to tailor the emittance of a source to the acceptance of the mass filter.

A quadrupole deflector has been designed for use in a mass spectrometer under development for a NASA mission. The instrument includes two gas phase electron impact ionization sources as well as a SIMS source.³ The quadrupole deflector allows a sequential introduction of ions from each source to the mass filter.

Ion trajectory calculations for various entrance aperture geometries allow fringe field effects to be studied. The ion transmission characteristics of the device developed were also experimentally studied over a 100 eV range of ion energies.

COMPUTATIONAL METHOD

Several configurations of the quadrupole deflector were studied using the electrostatic lens analysis software SIMION developed by D.A. Dahl.⁴ A 120x120 grid density was used.

In the calculation the selected symmetry is planar, and the entrance apertures are modeled as slits parallel to the deflector rod axis. In our experimental implementation, however, these apertures are circular.

The quadrupole assembly chosen to approximate the hyperbolic field consists of 90 degree circular rod sectors where $R_{cyl} = 1.16 R_0$. R_{cyl} is the rod radius and R_0 is the distance from the center of the quadrupole assembly to each rod.

FRINGE FIELD EFFECTS

The trajectories obtained by ray tracing with no entrance and exit electrodes were found to be very close to the trajectories described analytically by Zeman¹. Addition of simple entrance and exit aperture electrodes, however, creates fringe fields which considerably change the characteristics of the quadrupole deflector. In particular, the potential difference between adjacent rods required for 90° deflection is now considerably higher.

The figure below shows trajectories in a configuration where the electrodes associated with the entrance

and exit apertures extend approximately 0.7 mm into the 2.43 x 2.43 cm box defined by the centers of the four deflector rods. The potential on the aperture electrodes is set midway between the two adjacent rod electrodes and the initial ion energy is 50 eV.

There is an optimal extension of the entrance and exit electrodes into the deflector assembly. As these electrodes are extended into the assembly, the average beam deflection angle approaches and then becomes greater than 90°.

EXPERIMENTAL TESTS OF THE DEFLECTOR ASSEMBLY

A deflector assembly was fabricated for experimental evaluation. The distance between the rod centers was 2.43 cm in this device and the circular entrance and exit aperture diameters were 0.3 cm.

The transmission of the deflector assembly was measured using a Cesium thermionic emitter mounted several cm from the entrance aperture, and ion collector plates mounted at each exit aperture. Ion transmission could readily be determined by measuring the total current entering the device with the rod voltages set to zero, then setting appropriate deflection voltages and measuring the current on one of the 90° collector plates.

All voltages were controlled by microcomputer and could be repeatedly set to better than 0.1 V. In the experiments described below, the deflection voltages were symmetric around zero, with equal voltages on opposite plates. The entrance and exit apertures were kept at zero volts for convenience in measuring ion currents.

DEFLECTOR TRANSMISSION CHARACTERISTICS

The characteristics of the fabricated device are demonstrated below. The family of transmission curves are obtained by setting the rod voltages and then

ramping the ion energy.

Also shown below is the variation in the peak width (FWHM) with the energy of the peak maximum.

COMPARISON OF CALCULATED AND MEASURED TRANSMISSION

It is apparent from the trajectory studies that some of the ions may enter the final lens at an extreme angle. These ions are not expected to cause anomalous behavior in the experimental transmission, as the length of the electrode selected for the exit aperture will result in the neutralization of most of these extreme angle ions.

In fact, for the geometry chosen, the transmission variation with ion energy can be calculated and compared with experiment. The results of this ray tracing for a circular entrance area uniformly filled with ions is shown below. The vertical axis (F) is the transmis-

sion divided by the maximum transmission with a fixed 100 V between adjacent rods. The experimental results (solid square points) are compared to the calculation (x symbols). The approximations involved in modeling the cylindrical entrance and exit apertures in 2 dimensions is presumed to account for much of the difference from experiment.

SUMMARY

An electrostatic quadrupole deflector has been developed and shows promise for use in interfacing multiple mass spectrometer ion sources. The presence of fringe fields associated with the entrance and exit apertures, causes the device characteristics to deviate considerably from those of an ideal hyperbolic deflector.

DESIGN OF A FOCUSED CESIUM ION SOURCE FOR CONTINUOUS FLOW LIQUID SIMS

Tao-Chin Lin Wang, S. P. Markey and Riccardo L. Boni
Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892

Continuous flow liquid SIMS (CF/L-SIMS) has offered a method which requires minimal sample preparation and chemical derivatization for quantitative analyses of polar compounds (1). However, these advantages are currently obscured by the rapid consumption of each cesium charge (100 hrs operation), and a higher detection limit than anticipated from static L-SIMS. For the above reasons, a focusing lens system (2) has been designed and built using the existing unfocused cesium ion source (Phrasor Scientific, Inc.) on a Finnigan Mat TSQ 70. The advantages of using a defined focused ion beam for L-SIMS studies have been reported by Stoll et al. (3). The advantages obtainable when such a focused beam is applied to CF/L-SIMS system where the surface of the sample is continuously refreshed is an other objective of this study.

Our goal was to produce a lens system which will project the ions generated from any position of a cesium source surface with any angular deviations from the mean ion axis onto a small (less than 1 mm diameter area) final image where the sample is located. Additionally, to efficiently project the ions, the design should confine the ion paths through the lens system to a space which is close to the mean ion axis. The simulation processes to define ion focusing conditions were performed using the MacSimion[®] computer program (4). The lens system design was evaluated by simulating the ion trajectories of cesium ions with kinetic energy of 0.1 eV emitted from the center of the source surface -60°, 0° and 60° from the mean ion axis and emitted from the extrema of the source surface -60° and 60° from the mean ion axis. It was found that a lens system consisting of an accelerating lens and an Einzel lens (Fig. 1) is able to focus the beam to an area with diameter less than 0.8 mm at the probe tip. The image was approximately the same for these two sets of initial conditions. This image would be observed for any conditions between these limits when the same focusing environments are applied. As shown in Fig. 1, the accelerating lens consists of the cesium pellet assembly, an extraction, a first focusing, and a first grounded element. The Einzel lens consists of the first grounded, a second focusing, and a second grounded element. Also given in Fig. 1 are the dimensions of these elements and an example of their corresponding voltages which were found to produce a defined focused beam at the sample location.

Figure 1 Dimensions and voltages for each cylindrically symmetrical lens element in the focus lens system.

It is important to note that as a result of hardware requirements (e.g. high voltage feedthroughs, steering mechanism, etc.), the cesium ion source has been positioned further from the probe tip target (15.7 cm from the target as compared with 6.8 cm from the target with original cesium ion gun). However, when there exists a long distance between the ion source and the final focus point or the target, it is impossible to achieve focus without having a large image. In this design, an Einzel lens has been added to circumvent that phenomenon such that the ion beam can be projected onto the target without producing an image enlargement. The object image at the first crossover was projected onto the final image plane. One can make the size of the image bigger by adjusting the voltages: V_e , V_{f1} , and V_{f2} ; however, the minimum image size is determined by the size of the source aperture.

As presented in Fig. 2 these lens elements were mounted on a stainless steel cylinder, which is attached to an extended flange by Vespel[®] spacers. The final grounded element was 2 mm away from the source block. The beam steering capability was provided mechanically through a Huntington Laboratories, Inc. 10° Acu-Port (model VF-175-10). The 4 to 6 KeV accelerating voltage was provided from the original Phrasor 10 keV PID power supply; other lens element voltages were obtained by directing this source voltage through a voltage divider with three adjustable voltage outputs.

Figure 2. Mechanical assembly cross-section of the cesium gun and focusing lens system.

The characteristics of the focusing lens system was first studied by removing the source block and placing a NaI doped filter paper or tantalum pentoxide refractory film at the target plane. The size of the focused beam could then be optimized by adjusting V_e , V_{f1} and V_{f2} while looking at the yellow ion beam image as ions irradiated the NaI doped filter paper through the glass view window of TSQ 70. At optimal conditions, the voltages applied were in good agreement with theoretical predictions. A permanent image was obtained when tantalum pentoxide refractory film was used instead of NaI. The image produced when the unfocused gun at its original position is compared with the image from the same ion gun equipped with the lens system and displaced 8.9 cm in. A 20 to 100 fold reduction in image area size (as opposed to 200 fold reduction predicted from theoretical calculations) at the target plane has been achieved with this lens system. As a result, significant extension in the cesium charge life time and a consequent reduction in the maintenance cost is anticipated.

Fig. 3 (a) and (b) compares the spectra obtained without and with focusing effects when approximately the same cesium ion currents were used. Both spectra were produced from 5 ng MHPG sulfate (3-Methoxy-4-sulfatoxyphenylethyleneglycol) injected into a 6-7 $\mu\text{L}/\text{min}$ flow stream contained 20% glycerol/ H_2O . Obviously, a defined and focused beam with a higher current density gives 30 times increase in signal-to-noise ratio when compared with the signal from the unfocused ion beam. Furthermore, a smaller region of secondary ion generation resulting from a focused primary ion beam produces narrower and less tailing CF/L-SIMS signals. Further optimization of the beam irradiation position and beam size on the probe tip through the steering mechanism is in progress.

Figure 3. Spectra obtained when 5 ng MHPG sulfate is injected: (a) with original unfocused cesium ion gun and (b) with focusing lens system on the same gun.

ACKNOWLEDGEMENT

We thank P. J. Todd, Oak Ridge National Laboratory, for his valuable suggestions for the lens design and its applications. We also thank B. L. Bentz, David Sarnoff Research Center, for providing the tantalum pentoxide refractory films and William Frasure, Analytical Specialties Co., for power supply modifications.

MASS SPECTROMETRIC DETECTION OF THIN LAYER CHROMATOGRAPHY USING PULSED LASER
EVAPORATION WITH UV LASER IONIZATION

Liang Li and David M. Lubman, Department of Chemistry
The University of Michigan, Ann Arbor, MI 48109

Pulsed laser desorption/evaporation is used as a means of volatilizing thermally labile analytes directly from thin layer chromatography plates. The neutral plume is then entrained in a supersonic jet expansion where it undergoes rapid adiabatic cooling and subsequent UV laser ionization at 266 nm in a time-of-flight mass spectrometer. Using this method, we have been able to detect labile molecules such as catecholamines, indoleamines, aromatic amino acids, dipeptides and neuroleptic drugs vaporized directly from TLC plates with observation of only the molecular ion, M^+ , in a time-of-flight mass spectrometer (TOFMS). The detection limit ranges down to the subnanogram level and the quantitation curve is linear over 4 orders of magnitude. The laser ionization is spectroscopically selective against the TLC stationary phase which is also vaporized in the desorption process as opposed to other desorption methods such as SIMS and LDMS where this may appear as a strong background in the mass spectrum. In addition, using laser ionization we can detect laser desorbed species from TLC such as amino acids and peptides which are not easily detected in laser desorption from the TLC plates using CI detection. The unique feature demonstrated here is the ability to obtain sharp spectra as a function of wavelength for the analyte desorbed and entrained in the jet expansion for specific identification using R2PI spectroscopy. We have used this method to uniquely identify various indoleamines and catecholamines based on their fingerprint cold spectra. In addition, using jet cooled ionization spectroscopy we have been able to optically separate and identify compounds such as indoleacetic acid and tryptophol in the TOFMS, although these compounds were not separated in the TLC plate.

The idea of selective spectroscopic detection is illustrated in Figure 1. These spectra were obtained by placing a 2 μ l sample solution containing 10 μ g each of indole-3-acetic acid and tryptophol onto a TLC plate with a microliter syringe and developing the plate with 50% EtOH/50% ethyl acetate. The unresolved TLC spot is then prepared by cutting out the spot and attaching it to an injection probe for introduction into the mass spectrometer system. In these experiments, ~ 5-10 μ l of glycerol is coated onto the spot. The glycerol dissolves the spot and allows for repetitive desorption for performing spectroscopy. By monitoring the molecular ion intensity produced by R2PI in the TOFMS as a function of wavelength using a gated integrator, we obtain sharp wavelength spectra of tryptophol (Figure 1a) and indole-3-acetic acid (Figure 1b). These spectra can unambiguously identify these compounds in combination with mass spectrometry. The corresponding TOF mass spectra are shown in figure 2a and b.

Figure 1. R2PI jet-cooled spectra of (A) Tryptophol, (B) Indole-3-acetic acid desorbed from a TLC plate.

Figure 2. R2PI/MPI mass spectra of tryptamine analogs after TLC separation for: (1) Tryptophol. This mass spectrum was obtained by selective laser ionization at 285.75 nm ($P = 5 \times 10^6 \text{ W/cm}^2$). (2) Indole-3-acetic acid. This spectrum was obtained by selective laser ionization at 285.30 nm ($P = 5 \times 10^6 \text{ W/cm}^2$).

Direct FAB-MS From Empore™ TLC Sheets

Robert D. Minard and Edward J. Long

Department of Chemistry, Pennsylvania State University, University Park, PA 16802

Thin-layer chromatography is a fast, simple, and effective technique for the separation of mixtures. In addition, it is a highly versatile technique which can be applied to a wide range of analytes. A significant shortcoming of TLC, however, is the limited variety of "in-situ" detection methods available, that allow the unambiguous identification of the separated components.

Mass spectrometry could be ideally suited for TLC detection due to its sensitivity and specificity. Its combination with other separation techniques such as GC and LC has yielded powerful methods of analysis for multicomponent samples. Early attempts at TLC-MS involved scraping the separated component with the silica substrate from the TLC plate and analyzing it by electron ionization using a direct-insertion probe.^{1,2} More recently, techniques have been reported where the TLC plate is scanned past a source of thermal desorption energy, after which a chemical-ionization reagent gas transports the desorbed material into the ion source.^{3,4} Since many materials separated by TLC are relatively nonvolatile, fast-atom bombardment (FAB) is well suited for direct analysis of TLC spots. Chang, et. al.⁵ and Bare, et. al.⁶ accomplished this by covering the FAB probe tip with double-faced adhesive tape and pressing the probe tip against the TLC spot to transfer the material to the probe for analysis.

Our approach to TLC-FABMS utilizes the unique properties of the recently developed Empore™ TLC sheets. Each Empore™ TLC sheet is comprised of a chemically modified 8-micrometer silica, or C-8 bonded silica, particles which are bound tightly in a dense "web" of micro-polytetrafluoroethylene fibrils.⁷ This web removes the need for both a binder and a glass or plastic support. As a result, the spots on Empore™ TLC sheets can easily be cut out and analyzed without flaking off the stationary phase. After development in a suitable mobile phase, the spots were cut out with an X-acto™ knife and mounted on a copper FAB probe tip with double-faced adhesive tape. The FAB matrix liquid, thioglycerol + 1% oxalic acid, was applied around the outer edges of the cut-out spot to wash the analyte toward the center. Better results were obtained if the matrix was diluted 1:2 with methanol, since the solution was then less viscous and more readily absorbed into the TLC sheet.

Good results were obtained for a separation of the ionic dyes Rhodamine B, Fluorescein, and Fast Green on an Empore™ C-8 bonded silica TLC sheet. (Fig. 1) Intense pseudomolecular ion peaks are indicated for each of these three compounds, which were present in amounts of approximately 15 micrograms per spot. The highly polar or ionic nature of these compounds requires FAB ionization. Positive results were also obtained for a mixture of the alkaloids haemanthidine and haemanthamine separated on an Empore™ silica TLC sheet. (Fig. 2) Although these alkaloids could be analyzed by conventional ionization methods, the direct FAB-MS method offers a straightforward approach to molecular weight confirmation.

Caprioli, et. al.⁸ demonstrated the use of a sample introduction probe for FAB-MS that permits a continuous flow of solution to be brought directly into the ion source. Preliminary experiments in our laboratory indicate that continuous-flow FAB (FFAB) could also be a useful TLC detection method. A standard KRATOS flow probe with a 50-micrometer capillary was used. About 4 or 5 microliters of a 30-35% glycerol in methanol matrix solution were added externally to the sample spot on the TLC sheet. The tightly bound nature of the stationary phase caused the matrix liquid to bead up on the TLC sheet, thus extracting a portion of the sample spot into the matrix. Introduction of the sample was accomplished by dipping the capillary into this "bead" of matrix and sample for 10 seconds. Figure 3 shows the spectra obtained for Rhodamine B and Fluorescein from "dips" off the TLC sheet. Attempts to carry out this experiment using conventional HPTLC plates were not successful, however. The less tightly packed stationary phase of the HPTLC plates absorbs the matrix liquid rapidly, spreading out the sample spot. As a result, it was difficult to draw any of the solution into the source with the capillary.

COMPARISON OF LC/MS PARTICLE BEAM SPECTRA WITH DCI AND DEI PROBE SPECTRA. Matthew J. Dilts, and Thomas Marecic, Extrel Corp., 240 Alpha Drive, Pittsburgh PA 15238

INTRODUCTION: This study compares EI and CI spectra obtained from particle beam introduction to spectra obtained from DCI probe introduction. A wide variety of compounds of environmental, pharmaceutical, and industrial interest have been analyzed successfully. In most instances, the spectra obtained with the particle beam interface have demonstrated enhanced volatilization over those obtained from the DCI probe. Mass spectra have also been obtained for higher molecular weight compounds with the particle beam interface. For example, polystyrene (MW 2000) has shown the $n = 14$ oligomer under standard electron impact conditions (1).

EXPERIMENTAL: All worked described was performed on an EXTREL ELQ 400-1d differentially pumped mass spectrometer equipped with EI/CI switchable source interfaced with a Varian 9010 liquid chromatographic system by means of the ThermoBeam LC/MS Interface. The DCI data was aquired using a Vacumetrics DCI probe and controller. Data was acquired under full scan conditions from 80 to 1500 AMU at 1000 AMU/sec.

OBJECTIVES: Demonstrate the ability of the particle beam interface to generate EI and CI spectra from flow injections. To compare EI and CI spectra obtained from a DCI probe with those obtained from the particle beam interface. Also to determine if there are differences in the spectra due to enhanced volatilization or thermal degradation.

RESULTS: Both techniques gave comparable EI and CI spectra (see figure). With the particle beam interface the analysis was faster and easier than with the DCI probe. Some of the compounds, for example, Cyclophosphamide fragmented differently with the particle beam interface. The spectrum obtained with the particle beam was more representative of an electron impact spectrum. The spectrum obtained from the DEI probe showed signs of thermal degradation.

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

CONCLUSION: The particle beam interface and the DCI probe gave comparable spectra for both Chemical and Electron Impact Ionization. For the compounds studied only subtle differences were noted in the spectra. Of the two techniques the particle beam interface was less cumbersome to operate and appeared to be more amenable to automation

Comparison of GC/MS and GC/MS/MS for the Analysis of CGS-18416A

M. J. Hayes, L. Khemani and D. Gaudry, Development Department,
Pharmaceuticals Division, CIBA-GEIGY Corp., Ardsley NY 10502

CGS-18416A (Fig 1) is a benzoxazole derivative that has been shown to be an effective antagonist of electroshock-induced seizures. It has potential applications for the treatment of grand mal epilepsy¹. The structures of the drug and its internal standard are shown below.

During the course of method development it was determined that the compound produced structurally diagnostic fragment ions under MS/MS conditions. We therefore examined the utility of this methodology, both as a potential quantitative approach and for its application to future metabolism studies.

Extraction - The extraction procedure consisted of an acidic wash step followed by extraction at pH 11 into 25% ethyl acetate in pentane. The extract was then concentrated and analyzed directly. The extraction recovery from human plasma was 90%.

Chromatography - Due to the strongly basic character of this compound, chromatography on conventional 0.25 μ m columns gave severely tailed peaks and reduced column lifetimes. The use of a short column with a 3 μ m film thickness solved these problems and kept the analysis times reasonable (5 min). GC was done with a 10m methyl silicone column (3 μ m film). The injector and transfer line were at 290°C. Temperature programming was done from 100°C (1 min) to 270°C at 40°C/min.

Ionization - A variety of ionization methods were examined in order to obtain the optimum sensitivity. These included EI, positive and negative ammonia, methane, and nitrous oxide CI. Positive ammonia at 0.2 torr was significantly more sensitive than the others. The $[M+H]^+$ ions were monitored at m/z 248 and m/z 252 for the compound and internal standard respectively.

GC/MS - The method was initially developed using GC/MS. With the experimental conditions described above, the method was validated for sensitivity accuracy, and reproducibility. The GC/MS method resulted in a limit of quantitation of 200 pg/ml of plasma with a corresponding CV of 8.6%. Figure 1a shows a chromatogram of a plasma extract at the limit of quantitation. Table 1 shows the quality control summary from three consecutive runs.

GC/MS/MS - In the GC/MS/MS work, all analytical conditions up to and including the ionization method were the same as for GC/MS. In order to obtain the maximum sensitivity, the collision cell conditions were optimized for daughter ion intensity. The nature of the collision gas, the pressure of the gas and the collision energy were all examined.

The optimum CID conditions were found to be argon at 0.1 torr with a collision energy of -5V. Under these conditions, the CID spectrum resembles the EI spectrum. They both show the molecular ion as well as fragments at 69 (imidazole ring) and 180 (benzoxazole ring).

Quantitation was done using the m/z 69 daughter ion for both the compound and the internal standard. This gave a limit of quantitation of 10 ng/ml and a detection limit of 2 ng/ml (S/N 3:1). Figure 1b shows a chromatogram of a plasma extract at the limit of quantitation (10 ng/ml).

Table 1

Quality Control Summary for
CGS 18416A GC/MS Method Validation

Added (ng/ml)	% Found	C.V.	n
0.2	99.5	8.6	16
1.0	98.3	8.8	16
5.0	101.5	5.4	16
50.0	107.3	3.7	16
overall	101.7	7.6	64

Figure 1. Selected ion chromatograms of CGS 18416A plasma extracts spiked at the limit of quantitation for two different techniques a) GC/MS, concentration 0.2 ng/ml b) GC/MS/MS, concentration 10 ng/ml.

Conclusions - In applications requiring quantitative analysis, the GC/MS approach offers significantly greater sensitivity over GC/MS/MS. There are no interferences that would require the significantly greater selectivity afforded by GC/MS/MS. The limit of quantitation is 200 pg/ml with excellent accuracy (99.5%) and reproducibility (CV 8.6%) at that concentration.

For qualitative studies such as *in-vivo* or *in-vitro* metabolism, the MS/MS provides structurally diagnostic daughter ions that can aid in the discovery and structural analysis of metabolites. The above MS/MS data provide the optimum experimental conditions for conducting such studies using either daughter or parent ion techniques. It also demonstrates that quantitation can be directly and reliably performed in such studies at concentrations as low as 10 ng/ml.

**DIRECTLY COUPLED SUPERCRITICAL FLUID EXTRACTION-GAS
CHROMATOGRAPHIC/MASS SPECTROMETRIC ANALYSIS OF ORGANIC COMPOUNDS
FROM SOLID SAMPLES**

David J. Miller, Steven B. Hawthorne, and Mark S. Krieger,
University of North Dakota
Energy and Mineral Research Center
Grand Forks, ND 58202

The extraction and concentration of organic analytes from sample matrices is often the most time consuming and error prone step in an analytical protocol. Conventional techniques such as Soxhlet extraction and sonication require large volumes of pure solvents and extraction times of hours to days. The resulting extract must then be concentrated prior to analysis, which can lead to sample loss and/or degradation. Supercritical fluids have solvent strengths approaching those of liquid solvents. The solvent strength of a supercritical fluid is directly related to its density and can be modified by changing the extraction pressure or temperature. Mass transfer is enhanced by the lower viscosities and higher solute diffusivities of supercritical fluids. Common supercritical fluids (CO_2 and N_2O) are gases at room temperature, which makes sample concentration relatively simple and allows supercritical fluid extraction to be directly coupled to Gas Chromatography/Mass Spectrometry (SFE-GC/MS).

All GC/MS analyses were performed using a Hewlett-Packard Model 5985B equipped with a model 5890 GC on-column injector. Electron impact ionization spectra were acquired at 70 eV with a scan range of 50-350 amu. Capillary fused-silica DB-5 columns supplied by J & W Scientific were used.

All supercritical fluid extractions (SFE) were performed using an ISCO Model $\mu\text{LC}-500$ syringe pump. The extraction cells (Figure 1) were constructed from Parker brand 316 stainless steel fittings and had sample volumes of approximately 0.1 to 0.5 mL. Supercritical pressures were maintained inside the extraction cells by using 15-cm lengths of small inside diameter (15 to 30 μm) fused-silica tubing (F in Figure 1). Temperature was maintained at 45 $^\circ\text{C}$ by inserting the extraction cell into a thermostated tube heater.

Directly coupling the SFE to the GC column was accomplished by inserting the SFE outlet restrictors into the GC column through the on-column injection port. The GC oven was cooled during the extraction to trap the extracted analytes inside the GC column at the outlet of the SFE restrictor. At the conclusion of the extraction step, the restrictor was removed from the column and the supercritical fluid was allowed to flush from the GC column for 2 to 3 minutes prior to the initiation of a conventional GC/MS analysis.

The ability of coupled SFE-GC to yield chromatographic peak shapes comparable to those obtained using conventional on-column injections of a liquid solvent extract (methylene chloride) is shown in Figure 2 by the analysis of the spice, basil. SFE-GC analysis yields a chromatogram that compares favorably with one from an on-column injection of the unfractionated methylene chloride extract. The SFE-GC technique required only 35 minutes to extract, concentrate, and perform the GC separation, while the methylene chloride extract required ca. 8 hours to extract, concentrate, and analyze. The ability of supercritical fluid extractions to yield quantitative recovery is demonstrated by the lack of significant peaks in the second 10 minute SFE-GC extraction and analysis of the sample.

SFE-GC/MS analysis of a variety of sample matrices including environmental solids (cigarette smoke particulates, contaminated soil, and soot), sorbent resins (wood smoke and roofing tar volatiles from polyurethane foam sorbent plugs), and food products (chewing gum, orange peel, and sage) demonstrates the ability of supercritical fluid extraction coupled with gas chromatography/mass spectrometry to extract, concentrate, and obtain GC/MS data in a fraction of the time (< 1 hour) that is required for conventional liquid solvent extractions. Maximum sensitivity is also achieved since all of the extracted analytes are quantitatively transferred into the GC column, resulting in part-per-billion sensitivities with milligram sample sizes. Replicate analyses show good reproducibility and quantitative values obtained from the analysis of spiked samples and a NIST certified standard (urban dust, SRM 1649) show excellent agreement with known values.

Figure 1. Supercritical fluid extraction cell for coupled SFE-GC/MS analysis. The components of the cell are (A) 1/16 in. female NPT x 1/16 in. tubing union, (B) $\emptyset$.5 μ m x 1/8 in. o.d. stainless steel frit, (C) 1/16 in. male NPT x 1/16 in. tubing union, (D) 15% graphite/85%polyimide ferrule, (E) 1/16 in. nut, and (F) fused-silica capillary restrictor. All fittings were stainless steel Parker brand.

Figure 2. Comparison of chromatographic peak shapes resulting from SFE-GC/FID analysis (300 atm CO_2 for 10 minutes) and conventional on-column injections of a methylene chloride extract of 1 mg of basil. The middle chromatogram shows the second SFE-GC/FID extraction and analysis for the sample. Tentative identifications are based on SFE-GC/MS analysis of replicate samples.

COUPLING OF SUPERCRITICAL FLUID CHROMATOGRAPHY AND SUPERCRITICAL
FLUID EXTRACTION WITH SECONDARY ION MASS SPECTROMETRY

B. Wencławiak, W. Sichtermann, A. Benninghoven
Physikalisches Institut, Wilhelm Klemm Str.10,
D-4400 Münster, FRG

Supercritical Fluid Chromatography (SFC) and Supercritical Fluid Extraction (SFE) with carbon dioxide as mobile phase have been described in a number of papers [1-3]. This paper describes the first results of SFC-SFE coupled on-line and off-line with secondary ion mass spectrometry (SIMS).

The on-line interface and the modifications on the SIMS instrument were designed to allow a fast exchange of restrictors, whilst maintaining the required low pressure in the SIMS. The inlet system for supercritical CO₂ was used to deposit different analytes on a silver target contained in a UHV quadrupole secondary ion mass spectrometer. The target was continuously exposed to the SFC-eluate and simultaneously bombarded with primary ion current densities ranging between 10⁻⁵ and 10⁻⁹ A cm⁻², corresponding to sputter rates between 1 and 10⁻⁴ monolayers s⁻¹. At high current densities the target could be cleaned within seconds (e.g. between two SFC peaks) at low current densities the analyte accumulates on the substrate and complete spectra can be obtained. Analytes studied include PAH's (pyrene, chrysene etc. fig.1) and some di-alkane-phthalate esters (fig.2). Without optimization low nanomol quantities could be easily detected. The analytes could be identified due to mass fragments similar as in EI/MS. SIMS showed additional cationized (argentated) fragments. For the SFE-SIMS experiments the extract was either directly deposited onto the silver target or collected in a sample vial with chloroform and an aliquot of the solution was pipetted onto the target.

Experimental:

SIMS: UHV mass spectrometer, quadrupole mass filter, pressure during measurements 4 x 10⁻⁵ hPa, turbo pump (plus cryo pump for on-line experiments).

PI: 3 keV [Xe]⁺ or [Ar]⁺, ion current densities 3 x 10⁻⁹ A cm⁻².

Target material: Silver

Scanning time: 0.3 s amu⁻¹

Column: Scientific Glass Engineering, 0.1 mm ID, 1m.

Valve: Valco C14W 0.2 ul

Mobile Phase: CO₂, 9.8 MPa, 40 C

Results:

- a) On line coupling of SFC / SIMS is possible. The necessary low pressure for SI conditions can be maintained with properly adjusted flow rates.
- b) Off line coupling is also possible for SFC and SFE. The sample can be deposited either directly out of the restrictor onto a target or pipetted after collection in a solvent.

AN OPTICAL CCD CAMERA INTEGRATED WITH A SECONDARY ION MASS
SPECTROMETER FOR ANALYSIS OF PLANAR CHROMATOGRAMS

Stephen M. Brown, Steven J. Doherty and Kenneth L. Busch
Department of Chemistry, Indiana University, Bloomington, IN 47405.

Two-dimensional imaging analysis of organic and bio-organic thin-layer chromatograms and electropherograms by secondary ion mass spectrometry has been described in a number of fundamental and application papers from our group over the past few years. For complex mixtures, and larger chromatograms, the time required to locate component spots and bring them to the point of analysis can become quite lengthy. Practically, all chromatograms are pre-screened visually before placement with the mass spectrometer.

It seems obvious that an optically-based imaging system should be integrated with the SIMS analysis of chromatograms. This arrangement would allow the user to more easily locate component spots on a TLC plate.

The design of our second generation chromatography/SIMS instrument included the option of placing other detector modules in the z-axis normally occupied by the quadrupole mass analyzer. We describe here the replacement of the quadrupole with a charge-coupled device (CCD) camera assembly. Figure 1 shows the chromatography/SIMS instrument with the quadrupole installed and subsequently replaced with the CCD assembly. This arrangement allows for component spots on a TLC plate to be located by visual light, UV radiation, or by reversible general and specific color-developing reagents.

We have determined that three detection schemes are sufficient to detect all compounds. We first exploit the fact that we are using TLC plates coated with a fluorescent coating. Illuminating the plate with 254 nm UV light yields a bright plate with dark spots corresponding to the component spots. Figure 2 shows a plot of light intensity versus pixel number for one particular row of the pixel array that intersects the component spots of a plate containing differing amounts of testosterone, using UV illumination. (This type of plot will herein be referred to as a row-plot). If a particular compound does not occlude the fluorescence of the plate, and hence is not detectable by this method, the compound may iodine stain. Exposing the plate to iodine vapors turns the component spots brown. Visible light can now be used for the detection. Figure 3 depicts the row-plot of four "onium" salts detected using this iodine staining technique. And finally, if iodine staining fails, a specific color-developing reagent can be used. For instance, reacting polycyclic aromatic hydrocarbons with 2,4,7-trinitro-9-fluorenone yields purplish spots.

The CCD camera also gives us data complementary to the mass spectrometry data. For instance, some compounds, such as some polysulfonated dyes, are not particularly amenable to SIMS analysis, but are able to be detected visually using the CCD. Conversely, a compound may not be detected optically, but may yield a usable mass spectrum.

The inherent high sensitivity of the charge-coupled device lends to significantly lower detection limits in the analysis. Figure 4 shows a row-plot of approximately 390 pg of oxazine 4 perchlorate, a laser dye, detected using 366 nm UV radiation. This signal to noise ratio, along with the fact that this row-plot only intersects 1/25th of the total sample, corresponds to a detection limit of about 7 pg (24 femtomoles!).

Evaluation and Optimization of a CCD Detector for SIMS

David S. Mantus, Lisa K. Turner, Yong - Chien Ling, and George H. Morrison
Baker Laboratory of Chemistry, Cornell University, Ithaca, NY 14853

In an effort to improve the integrity of the final mass-filtered image in ion microscopy, our laboratory has developed a charge-coupled device (CCD) detection system for SIMS (1). The system replaces the microchannel plate/ fluorescent screen currently in use with a single, back-side illuminated CCD. The direct detection of keV ions by a CCD demonstrates their potential utility in mass spectrometric applications.

Back-side illuminated devices are CCDs which have been thinned to the p-Si/ p⁺-Si interface. Incoming radiation strikes the back-side and does not have to penetrate the thick gate structure. It is such a device which has been shown to be sensitive to keV ions.

The sensitivity of CCDs to low energy ions can be examined in two parts: signal electron formation, and signal electron detection. The formation of electrons derives from the inelastic loss of energy as the ion traverses the device. The location and amount of electrons produced depends strongly on the nature of the ion. Much theoretical attention has been given to these ion-solid interactions and our model of the CCD can incorporate many of the contemporary theories. Other factors which can affect the total inelastic loss are dead layers of native oxide, and ion reflection at the surface. Detection of signal electrons is independent of their origin and is controlled by the internal parameters of the CCD. The ability of the CCD to capture and store charge is its charge collection efficiency (CCE). The CCE is depth dependent and drops dramatically at the back-side. By incorporating these factors into our model we can understand the CCD's performance and design improvements.

Under ion bombardment the detector displays the superior qualities inherent to CCDs (1). Detector linearity is excellent and spans a broad dynamic range (Fig. 1). The noise behavior of the device is easily characterized and understood. Three simple domains exist: read noise, shot noise, and fixed pattern noise caused by pixel inhomogeneities. The CCD has a distinct mass dependence which agrees very well with calculations from our performance model. Its greatest weakness is sensitivity. The CCE at ion penetration depths is on the order of 1% or less. Increasing the CCE near the back-side is the key to sensitivity enhancement.

The potential well at the native SiO₂/Si interface at the back-side drains signal electrons and is responsible for the low CCE. Increasing the CCE is possible by altering the structure of the CCD's surface (2). Enhancement is a two step process: 1) a quality oxide roughly 30 Å thick must be grown; 2) the oxide is 'charged', flipping the interface potential. Charging can be achieved temporarily by a UV light flood (2) or permanently with the deposition of a thin layer of Pt (3). Termed a 'flash gate' the 15 Å of metal can boost the CCE to 100%. We are currently refining oxide growth techniques in an effort to enhance CCDs via the flash gate procedure.

Oxide growth must be carried out in a contaminant-free environment; and the procedure must not damage the delicate CCD. Our procedure employs 200°C steam under an Ar atmosphere. Test structures are being constructed to assess the method. In addition, these structures can be exposed to the ion beam to explore possible damage to the flash gate.

CCDs have strong potential as detectors in ion microscopy, and in mass spectrometry in general. The devices retain their positive attributes under keV ion bombardment; sensitivity being the one exception. Enhancement to sensitivity is possible and this avenue is being explored. The basic architecture of CCDs is also being refined and redeveloped. Progress in this area may lead to devices which do not require enhancement at all.

Ruska Laboratories, 3601 Dunvale, Houston, Texas*

Thermal Chromatography (TC) is a unique method for disassembling materials using accurate and reproducible heating programs. The all-fused-quartz systems for TC/FID and TC/MS that comprise the Ruska Thermo-Chrom and Thermo-Chrom Spectrometer Interface (TCI) respectively eliminate sample contact with metal surfaces and enable rapid independent heating and cryogenic cooling of all zones. The trap, splitter, and gas chromatograph between the sample heating chamber and the mass spectrometer allow concentration and separation of species evolved during TC/MS. Under computer control, temperature programming on the TCI can be divided into any number of steps or "thermal slices," allowing identification of species evolved within specified temperature ranges.

Using thermally shielded ~85 inch long quarter-inch stainless steel tubing to house the capillary gas chromatographic (GC) column, we have directly connected a Ruska Thermo-Chrom Spectrometer Interface to a Hewlett-Packard (HP) 5985B quadrupole mass spectrometer. The column emerges from the Ruska oven inside the transfer line, passes through the HP GC interface oven, and enters the mass spectrometer vacuum manifold through one of the ports in the flange that forms the HP GC/MS connection. The two GC columns enter the mass spectrometer ion source in parallel, and switching between TC/MS and GC/MS is simply a matter of turning down the helium flow in one column and turning it up in the other. No degradation in performance of either technique has been noted with this configuration. As shown in the figure below, cold spots have been eliminated from the transfer lines, and we are able to see hydrocarbon peaks from the TC/MS analysis of polyethylene out to C_{38} .

**TC/MS ANALYSIS OF POLYETHYLENE
DEMONSTRATING EFFICIENCY OF TRANSFER LINE**

We have used thermal chromatography to study differences in the outgassing characteristics of PVC insulation of wire used in electrical circuits that develop high potentials. Thermal profiles of insulation taken from wire supplied by several vendors were obtained used TC/FID. These profiles, different in shape for the different vendors' materials, showed that the insulation degrades in two steps: a small but significant amount of material is evolved between 30° and 300°; between 450° and 550° C the bulk evolves. Differences in shapes of the curves at low temperature indicate differences in the composition of semivolatiles of the different vendors' polymer formulations. To study the compositional differences, a two slice TC/MS method was developed, shown in the upper half of the figure below: Slice I is the range 30° - 370° C; Slice II 300° - 625° C. While the sample was being heated, the GC column was held at -35° C to trap evolved species. At the completion of each sample heating, the column was heated, yielding chromatograms like those shown in the bottom half of the figure. As expected, semivolatile additives such as flame retardants, lubricants, and antioxidants were found in the Slice I chromatogram, while in Slice II, species related to PVC degradation were observed. The species identified from the spectra obtained in Slice I for each sample were different, confirming the TC/FID indication of compositional differences among the samples.

TEMPERATURE PROGRAM FOR "TWO SLICE" TC/MS METHOD

"TWO SLICE" TC/MS ANALYSIS OF PVC WIRE INSULATION

A DATA SYSTEM FOR DAUGHTER-ION MEASUREMENTS WITH A REFLECTING TIME-OF-FLIGHT SPECTROMETER:

W. Ens, Y. Mao, X. Tang and K.G. Standing; Physics Dept. University of Manitoba, Winnipeg, Canada. R3T 2N2

Introduction:

Recent improvements in time-of-flight mass spectrometry have placed increasing demands on the required data systems. A high range spectrum with moderate resolution may require a few hundred thousand channels (usually at 4 bytes per channel). Thus a spectrum can easily require 1 Mbyte of memory; in our case a typical size is 1/2 Mbyte. The measurements of daughter ions described here require a time digitizer (TDC) with inputs for 2 separate detectors, rapid processing to detect correlations and large memory to store multiple daughter ion spectra. Development of electronics has, of course, also been rapid and we present an inexpensive system that satisfies the criteria mentioned.

Daughter ion mass spectra from a selected parent ion are normally obtained with a tandem instrument where one parent is analyzed at a time and the daughter ion spectrum is obtained by scanning, unless an array detector is used. A time-of-flight spectrometer with an ion mirror provides an alternative method of obtaining daughter ion spectra, i.e. it acts as a tandem spectrometer [1].

Fig. 1 shows a schematic diagram of the spectrometer (Manitoba TOF II). Mass resolution up to $m/\Delta m = 10,000$ (FWHM) at m/z 650 has been achieved; typical resolution for organic molecules up to m/z 3000 is about 5000 (FWHM). Of central importance to the daughter ion measurements is the grid at the back of the mirror that allows neutral daughters to be detected in detector 1.

The neutral daughters from metastable decay between the target and the mirror retain the velocity of the parent so their flight time (measured in detector 1) identifies the parent ion. Any ions detected in detector 2 in the same event (primary pulse) are assumed to result from the identified parent. (This assumption is accurate if the primary ion current is low). Since the daughter ions have only a fraction of the parent energy, the mirror - an energy selector - separates them on the basis of their mass. A daughter ion spectrum for a given parent may then be recorded by considering only those events in which a neutral is detected at the selected parent flight time. An important difference from normal tandem mass spectrometry is that any number of such daughter ion spectra may be recorded simultaneously.

FIG 1: Schematic of TOF II

FIG 2: Data System

The Data System:

The data system is shown in Fig. 2. It is based on the Atari Mega 4 computer (based on a 68000 processor running at 8 MHz). To handle the large spectra, it was important to select a processor with 32 bit addressing. The 4 Mbytes of RAM on the Atari are all directly addressable.

The LeCroy 4208 TDC has a common start and up to 8 separate stop inputs. For daughter ion measurements it is configured to use only 2 inputs, each of which can accept up to 4 stops for each start. At present we use an INCAA CAPRO 68K CAMAC controller to read the TDC and transfer the data to the Atari through a Kinetic Systems 3063 IGOR (input-gate output-register). This arrangement was convenient because the CAPRO was available. However, we intend to implement a direct Atari-to-CAMAC interface that has recently become available.

For data storage we use a Supra FD-10, 10 Mbyte extended high density 5 1/4" floppy drive. This has a speed comparable with that of hard disks and is suitable for both archiving spectra and for logging direct event-by-event data (see below).

Real Time Correlations:

Up to now we have recorded daughter ion spectra in real time. That is, after each primary ion pulse, the computer looks for neutrals in preselected time windows and sorts the flight times of the ions accordingly. At 2 kHz repetition rate, there is enough time between primary ion pulses for any number of correlations to be checked; the only limitation is the available memory for the daughter ion spectra. Fig. 3 shows the daughter ion spectra for two components of tyrothricin (a natural mixture of 9 cyclic decapeptides), recorded at the same time as the parent spectrum.

FIG 3: Daughter ion spectra of tyrothricin

Event logging:

An alternative to detecting coincidences as they occur is to log each event on disk as a group of neutral and ion flight times. Then the experiment may be "replayed" at a later time and any daughter ion spectra may be extracted. An event-by-event data log thus contains information for a complete MS/MS map from a single experiment. The code for this procedure is now being tested. Preliminary measurements have confirmed the feasibility of using the 10 Mbyte floppies for this purpose; each floppy can store about 20 minutes of data.

Alternate spectra:

Controlling an experiment largely from software allows considerable flexibility. We have begun laser dissociation of desorbed secondary ions. The laser is pulsed on every second primary ion pulse and the trigger pulse is used by the computer to identify the laser-on event. Thus normal SIMS and laser dissociation spectra may be taken on alternate pulses under otherwise identical conditions [2].

Resolution of Daughter Ions:

As another example of the flexibility of our system, we are now developing a software method of improving the resolution of the daughter ions. Part of the broadening of daughter ion peaks is caused by the kinetic energy released in the break-up. This gives one fragment slightly higher velocity than the center-of-mass, and the other slightly less. By observing the position of the neutral fragment in a defined window, a correction can be made to the flight time of the correlated ion.

In summary, a powerful data acquisition system for a reflecting time-of-flight mass spectrometer has been assembled using an inexpensive computer and commercially available components.

A NEW TIME-OF-FLIGHT SECONDARY ION MICROSCOPE

B. Schueler, D.A. Reed, and P. Sander, Charles Evans & Associates,
301 Chesapeake Drive, Redwood City, CA 94063, USA

We have developed a new stigmatic imaging time-of-flight (TOF) secondary ion microscope. Unlike most TOF instruments built to date, this mass spectrometer is capable of transporting a magnified stigmatic image of the secondary ion emission pattern of the sample to an imaging ion detector, simultaneous with the acquisition of secondary ion mass spectra. Secondary ion mass spectra and images may be recorded at primary ion doses of less than 10^{12}cm^{-2} . Under these analysis conditions only about 0.1% of the sample surface are bombarded by the primary ion beam. Low primary ion doses are essential for true surface analysis and for the analysis of organic materials. For organic surface analysis, e.g. biological surfaces, the additional information of the lateral ion distribution can help to identify correlated ion species as they would arise from molecular fragmentation.

A schematic diagram of the instrument is shown in Figure 1. The ion optical system of the primary ion gun focuses a pulsed (approx. 1.4ns f.w.h.m.) beam of Cs^+ ions onto a sample area of 50-1000 μm diameter. Secondary ions are electrostatically accelerated to 4.5keV and imaged by the immersion lens. This image is projected by either one of the following transfer lenses (STL2 or STL3) into a system of three hemispherical 90° electrostatic analyzers (ESA), which transports the final secondary ion image onto the detector. A "contrast diaphragm" (CD) and an energy slit are placed into the secondary ion crossover points to provide radial (perpendicular to the spectrometer axis) and axial ion energy filtering - if desired. A field aperture is placed close to the entrance of ESA1 to limit the imaged sample area. This spectrometer system provides first order time (energy) and lateral focusing with small residual second order aberrations.

A dual microchannel plate (DMCP) detector is used in conjunction with a resistive anode encoder (RAE) as position sensitive detector. The timing signal for ion arrival is extracted from the DMCP and digitized by a time-to-digital converter (TDC) of 156ps resolution. The corresponding position information is obtained from the RAE and processed with a position computer. Both position and time information are stored by a computer system and made available for evaluation. Mass spectra and several mass separated secondary ion images can be simultaneously recorded.

Figure 1: Schematic diagram of the TOF secondary ion microscope.

When the first transfer lens (STL2) is activated in conjunction with the immersion lens, a 200 μm diameter area of the sample is imaged onto the detector. This corresponds to a spectrometer magnification of $m=60\times$. Mass resolutions of $m/\Delta m=3100$ (Figure 2) have been obtained with this configuration at mass 28 (^{28}Si), still limited by the duration of the primary ion pulse. In this operation secondary ion image resolutions of approx. 3 μm

can be achieved with ion transmission losses of some 30% (filtering with CD) to reduce aberrations caused by the imaging lenses. Axial energy filtering (energy slit) is usually not employed. When STL3 is activated together with the immersion lens, sample areas of $60\mu\text{m}$ diameter ($m=270\times$) are imaged to the detector and image resolutions of some $1\mu\text{m}$ can be obtained with transmission losses of the order of 60%. Mass resolutions of $m/\Delta m=1800$ (at ^{28}Si) are obtained in this configuration. For both configurations the mass resolution of the secondary ion images is identical with the mass spectral resolution.

Figure 2: Section of a mass spectrum taken from a silicon wafer surface to demonstrate the mass resolution. The analyzed sample area was $200\mu\text{m}$ in diameter.

Figure 3 shows examples of mass resolved positive secondary ion images of an etched Al pattern on a SiO_2 substrate. The image fields are $200\mu\text{m}$ in diameter. The images were recorded using charge compensation by a low energy (20eV) pulsed electron gun and pulsing the accelerating potential⁽¹⁾. Figure 3a shows the clearly recognizable pattern of Al on the surface. Al can be clearly separated in the ion images from the C_2H_3 ion. Figure 3b demonstrates the deterioration of the image contrast when both Al and C_2H_3 are included. This loss of contrast occurs no matter how good the lateral resolution of the image may be, and demonstrates one advantage of high mass resolution imaging. This capability becomes important when atomic contaminants in e.g. polymers are to be analyzed. Figure 3c shows as expected that C_2H_3 is homogeneously distributed across the sample surface. It should be mentioned that in this application the total secondary ion images (the sum image of all ions emitted) did not exhibit any recognizable surface structure.

Figure 3: Mass resolved ion images taken from an Al pattern on SiO_2 using low energy (20eV) electron charge compensation. The image fields are $200\mu\text{m}$ diameter. Darker regions correspond to higher ion intensity.

IMPLEMENTATION AND ASSESSMENT OF BEAM DEFLECTION TIME-OF-FLIGHT MASS SPECTROMETRY FOR TIME ARRAY DETECTION IN GC-MS APPLICATIONS

Gary A. Schultz⁺, Ron Tecklenburg, Jr.^{*}, J.F. Holland^{*}, J.T. Watson⁺, and J. Allison⁺
Departments of Chemistry⁺ and Biochemistry^{*}

Michigan State University
East Lansing, Michigan 48824

A conventional time-of-flight (TOF) mass spectrometer has been modified for beam deflection, as opposed to ion source pulsing, for use with an integrating transient recorder (ITR) to accomplish time array detection. In time array detection (TAD), it is essential that all ions from each extraction pulse of the ion source reach the detector in optimal focus. Such mass-independent focusing is required so that all of the ions in each transient mass spectrum can be detected with adequate resolving power.

The beam deflection TOF instrument described here consists of a continuous ion source which was originally designed for a magnetic mass spectrometer. Ion current continuously passes through the slits of the ion source into an electrode assembly which deflects the beam creating time-resolved ion packets which enter the field-free drift region of a two meter flight tube. At the end of the flight tube the ions strike a flat CEMA channel plate detector. The output from the detector is fed to an eight-bit ADC which operates at 200 MHz as the front end of the ITR that has been developed in the MSU Mass Spectrometry Facility. A schematic diagram of this instrument configuration is shown in Figure 1. The resolving power achieved with this instrument is in excess of 1000 as computed by the peak width at half height formula of mass spectral peaks in the analog mass spectrum of xenon. The mass spectral peak shapes are symmetrical at low and high mass in the mass spectrum of perfluorotributylamine as ionized by electron impact, indicating that the ion focus is adequate across the mass range. It is important to realize that these data were collected from a time-of-flight mass spectrometer with a gas phase ion source and without the use of time-lag focusing.

A major goal of the Mass Spectrometry Facility at MSU is to exploit the rapid spectrum generation capacity of a TOF instrument for GC-MS. As has been recognized for the last 25 years, it is necessary to acquire the mass spectrum of a gas chromatographic component as quickly as possible to minimize distortions among the mass spectral peak intensities due to changes in the partial pressure of the analyte in the ion source during the period required to record the mass spectrum. The problem of a changing partial pressure of the analyte in the ion source during GC-MS has become more and more severe as improvements have been made in capillary column GLC. As the peak widths in a capillary chromatogram approach one second, many mass analyzers are not capable of scanning the mass axis quickly enough to capture an unskewed mass spectrum, at least not without incurring problems with ion statistics.

In TAD, the ITR, designed and developed at MSU, acquires and sums consecutive transient spectra from the mass spectrometer detector continuously. The ITR is capable of generating as many as 1000 summed mass spectra per second. The design goals for the particular application to GC-MS are to provide 20 summed spectra per second which should be more than adequate to accommodate changes in sample concentration in the ion source during the emergence of a component from the capillary gas chromatograph. Each of the summed spectra in this case are the sum of 250 transient mass spectra which reach the detector following each extraction pulse of the TOF ion source.

In a preliminary evaluation of the beam deflection TOF instrument for GC-MS applications, 200 ng of methyl palmitate was applied to a 30 meter DB-1 0.32 mm id capillary column at 180° with programming to 250°C at a rate of 16° per minute. During the emergence of the methyl palmitate from the capillary column, approximately 50 mass spectra were recorded. As shown in Figure 2a, a reconstructed total ion current chromatogram illustrates the chromatographic profile of the methyl palmitate entering the TOF ion source. As can be seen in Figure 2a, the methyl palmitate emerged from the column during the acquisition of scans 70 through 120. The peak for methyl palmitate in this reconstructed chromatographic profile is approximately two and one half seconds in width. Figure 2b is the mass spectrum which was acquired during scan #95 which occurs near the apex of the elution profile. Scan #95 consists of the sum of 250 transient mass spectra. The mass spectrum in Figure 2b is recognizable as that of methyl palmitate in showing a molecular ion peak at m/z 270 with peaks corresponding to the loss of a methoxyl group at m/z 239 and loss of C_2H_5 at m/z 241. Also discernible is a significant peak at m/z 143, m/z 87 and, of course, the base peak at m/z 74. Mass spectra in the other 54 scans which were compiled during the emergence of methyl palmitate are similar in appearance although the S/N is not so good as that in Figure 2b. An important aspect,

however, is that the relative peak intensities in each of the other 50 or so mass spectra are not skewed in their relative intensities even though they were acquired during periods where the change in partial pressure of the analyte was greater than that in scan 95.

In conclusion, these preliminary data are encouraging in that they show that the instrumental configuration for beam deflection TOF-MS provides good quality mass spectral information which is focused properly in a time frame suitable for TAD. These results also indicate that the perceived benefits from TAD in GC-MS have been achieved. The success of the beam deflection approach to TOF-MS indicates that existing TOF instruments can be modified in this way to take advantage of the benefits of TAD in GC-MS applications. The beam deflection approach to TOF-MS also offers the possibility of extending the TAD benefits to other continuous forms of ionization such as CI or FAB-MS which would benefit from the ion statistical and temporal advantages of TAD.

Time-resolved ion momentum spectrometry (TRIMS) is a tandem mass spectrometry technique where mass analysis is produced by simultaneously measuring the momentum and velocity of an ion. In this hybrid instrument the ion beam leaving the magnetic sector is time-encoded by means of electrostatically sweeping the beam modulation assembly. Using time array detection (TAD), all the information produced by each sweep is captured for each increment of the magnetic field strength. Thus the full B-t data field can be collected much more quickly with better signal-to-noise ratios than with conventional time slice systems.

As fragment ions are produced either by metastable or collisionally-induced decomposition, the kinetic energy released due to isotropic effects manifests itself in the TRIMS experiment along lines of constant B times t. By measuring the peak width along this line for a daughter ion, the kinetic energy released (T) can be calculated.(1) A TRIMS instrument with a pulsed source has been successfully used to measure kinetic energy release as a function of ion lifetime.(2) The values obtained using TRIMS/TAD with post-sector beam deflection are comparable to those obtained by other methods such as IKES and MIKES.(3)

All experiments were performed on an LKB-9000 magnetic sector instrument modified for post-sector beam deflection with a flight path length of 1.6 meters.(4) All data collection was done in TAD mode using an integrating transient recorder (ITR) developed in this laboratory. The pertinent data is extracted from the B-t field and downloaded to a PC-AT compatible computer for further processing.

An acceleration energy of 3500 V, a source temperature of 200C and an emission current of 60 mA was used for all experiments. The magnetic field was DAC-controlled by the ITR and the field strength recorded using a Hall probe. For each DAC step 1000 transients were summed for optimum signal-to-noise ratios. After extracting energy vs. intensity pairs for each daughter ion peak, a 15 point Savitsky-Golay algorithm was used to facilitate measurement of the peak width.

In TRIMS the energy of an ion (E) is a function of B/t and is given by the following expression:

$$E = 1/2 B r d^2 / t \quad \text{or} \quad (1)$$

$$E = B/t (k) \quad (2)$$

where r is the radius of the magnetic field and d is the flight path length. Thus by calculating k for the stable ions at energies of 3500 eV, the energies for all daughter ions can be obtained. Along the lines of constant B times t, the intensities of ions on these isomass lines represent the spread in energies. This is in contrast to pulsed-source TRIMS experiments where the energy spread is along lines of constant B over t.

The energy released (T) in the fragmentation processes of a stable ion is obtained from the following equation:

$$T = (m_1^2 eV / 16 m_2 m_3) (\Delta E / E)^2 \quad (3)$$

where $\Delta E = \Delta E_{\text{obs}} - (m_2/m_1) \Delta E_{\text{stable}}$ (4)

and m_1 , m_2 and m_3 are the parent, daughter and neutral loss masses, respectively, eV is the energy of the parent ion leaving the source, E is the energy of the stable ion and ΔE is the width of the daughter ion energy profile measured at half-height and corrected for the energy distribution of the parent ion.

Kinetic energy release measurements were made for the decomposition of several stable ions with T values reported in the literature. Shown in Figures 1 and 2 are the energy profiles of the parent and daughter, respectively, of the unimolecular loss of chlorine from 2,4 dichlorotoluene. The energy release for this reaction was calculated to be 28.0 ± 2.0 meV where the uncertainty was due to the error in measuring the peak height of the daughter profile which resulted in a spread in the width at half-height. This value compares well with that reported in the literature (28.6 meV).⁽³⁾

TRIMS has been shown to be a useful technique for making kinetic energy release measurements. By using the TRIMS/TAD system the energy distributions can be both accurately and rapidly determined.

Mass Dependence of Focusing Parameters in Time-of-Flight Mass Spectrometry

ERIC D. ERICKSON, GEORGE E. YEFCHAK, AND CHRISTIE G. ENKE
Department of Chemistry, Michigan State University, East Lansing, MI 48824

In conventional time-of-flight mass spectrometry (TOFMS), temporal focusing of isomass ions having different energies is obtained by the use of a delay time between the formation and extraction of ions from the source, known as time-lag focusing [1], and by the adjustment of extraction grid potentials. Time-lag focusing relies on the movement of the ions as a consequence of their initial kinetic energies, hence its effects are mass-dependent. This mass-dependence is clearly demonstrated in Fig. 1 where the m/z 502 and 503 ions of perfluorotributylamine are shown with the time lag adjusted for two different regions of the spectrum.

The mass-dependence of the time-lag focusing technique is inconsequential when scanning detection schemes are used where only one m/z value is monitored for each extraction of ions from the source. In these cases, focusing parameters can be changed with successive extraction pulses to obtain optimum focusing for each m/z being monitored. Mass-dependent focusing is not adequate for time-array detection schemes, however, where many ions are monitored after each ion extraction pulse [2]. While the search continues for mass-independent methods of focusing [3-6], we have been examining an alternative in which different values of time lag and other instrumental parameters are used for successive ion extraction pulses, each of which gives acceptable levels of signal quality over a portion of the relevant range of m/z values. The total spectrum can then be reconstructed using the focused regions from each transient.

The size of these focused regions and the parameters which affect them have been investigated through the use of a digital simulation which models a CVC 2000 TOFMS instrument. This simulation employs normal (Gaussian) distributions of initial ion positions and velocities in the source to calculate probabilities of various arrival times at the detector. These probabilities represent ion intensities measured on the actual instrument. Probabilities at the peak maximum and the valley between adjacent m/z values are used to identify m/z ranges which achieve unit mass resolution at an acceptable valley height. Losses of ion intensity from migration out of the ionization region during the time lag results in a skew of the peak shape. The characterization of useful mass regions therefore includes the minimization of this form of signal degradation as well.

Identification of optimal mass regions is illustrated in Fig. 2. All ions to the left of the resolution curve have at least unit mass resolution with a 10% valley definition. All ions between the two intensity curves have no more than a 10% loss in peak intensity. The overlap of these two regions defines the useful m/z regions for each value of time lag. With the extraction potentials used to generate Fig. 2, as few as three time-lag adjustments are needed to cover the m/z range from 50 to 700. This figure also reveals the maximum m/z that will have acceptable signal quality with these parameters.

Figure 2.

The effects of ion extraction potentials and non-ideal extraction pulse shapes on intensity and resolving power have been examined. Changing the grid potentials alters the shape of the overlap region (Fig. 2) and thus affects the size of the useful m/z regions as well as the overall m/z range. Resolving powers obtained using this simulation match values collected using the commercial instrument within experimental error.

POST-SOURCE PULSE FOCUSING: A SIMPLE METHOD TO ACHIEVE IMPROVED
RESOLUTION IN A TIME-OF-FLIGHT MASS SPECTROMETER: G.R. Kinsel and M.V. Johnston;
Dept. of Chemistry and Biochemistry, CIRES, University of Colorado, Boulder, CO 80309-0215.

Post-Source Pulse Focusing (PSPF) is a simple variation to time-lag focusing in which the focusing voltage pulse is applied to a short field free region after the ions have been accelerated from the source region by a conventional static electric field. No major modifications of the mass spectrometer source region or electronics are necessary. Mass resolution of 1000 should be readily attainable and for certain applications much higher resolutions are predicted. The two major drawbacks of time-lag focusing are eliminated. Since the ions are accelerated using a conventional static electric field, no extraneous ion loss occurs due to a time delay. Also, all ions which have exited the acceleration and pulsing region will show equivalent resolution to a conventional static field (SF) TOFMS. All ions within the pulsing region will show substantial resolution improvement. The total mass region affected may be adjusted by increasing or decreasing the length of the pulsing region.

The method by which PSPF resolution improvement is achieved can be visualized in the following manner (See Figure 1). Once all ions of an isomass packet have entered the field-free drift tube of the TOFMS, both the initial velocity and temporal contributions to mass resolution can be viewed in terms of spatial distortions of individual ion pairs within an isomass packet. In other words, an ion having an initial velocity towards the detector, $+v$, and an ion having an equal initial velocity away from the detector, $-v$, enter the drift tube with exactly the same velocity, merely separated by the amount of time required for the $-v$ ion to initially turn around and return to its original starting point, ΔT_{TA} . If these two ions are viewed in the drift tube from a frame of reference moving at the same velocity as the ions they appear to be spatially defocused. An analogous argument can be made for the temporal contribution to resolution. If an accelerating voltage is now applied to the pair of ions, the trailing ion will be accelerated and achieve a slightly higher velocity than the leading ion. This additional velocity will cause the trailing ion to eventually catch up to the leading ion. Through proper choice of the voltage pulse the point at which these two ions become coincident can be adjusted to coincide with the plane of the detector. Since PSPF is designed to primarily compensate for the velocity and temporal components of resolution it will be particularly well suited for applications where σ_{spatial} is small (surface desorption/ionization) or where σ_{velocity} is large (GC-MS and thermal desorption MS), or where longer ionizing pulses are desired.

Computer modeling has been used to investigate the effects of varying different parameters while employing the PSPF technique.¹ It has been shown that using available electronic equipment and a standard TOFMS design, for typical conditions a resolution of ca. 1100 can be achieved using a focusing pulse of 136 V. If σ_{velocity} is increased to values typical for GC-MS, the resolution achievable remains relatively unaffected at ca. 1000. If σ_{spatial} is reduced to values typical for

surface / desorption ionization resolutions of 10,000 or greater are expected. Further studies have shown that the temporal component of resolution are indeed compensated for using PSPF, even to the extent of making the width of the detected ion signal narrower than the width of the ionizing pulse. In addition, methods for focusing up to 80% of the mass spectrum have been demonstrated. Variations of other parameters have been discussed which can be used to achieve even higher resolutions using PSPF. These results have all been contrasted to resolutions using static field TOFMS.

Experimental support of the theoretical basis for PSPF-TOFMS has been achieved (See Figure 2). These spectra show the parent ion of naphthyl-acetate at m/z 168 using SF and PSPF TOFMS. The PSPF spectrum was generated using an extremely unstable pulsed voltage supply and it is expected that even better resolution can be achieved. Even under these less than ideal conditions however, the resolution improvement using PSPF is clearly evident.

ORGANIC SECONDARY ION TIME-OF-FLIGHT MASS SPECTROMETRY WITH A FOCUSED LIQUID METAL ION PRIMARY BEAM

L.F. Jiang, T.Y. Yen, D.F. Barofsky
Department of Agricultural Chemistry
Oregon State University, Corvallis, OR 97331

We have designed and constructed a pulsed secondary ion time-of-flight (TOF) mass spectrometer to investigate the physical and chemical processes governing the ejection of organic secondary ions from liquid and solid matrices bombarded by fast atoms or ions. In order to examine emission and ionization mechanisms under a variety of well defined dynamical conditions, we desired that the energy, flux density, particle mass, and particle type (atomic or molecular) of the primary beam be variable as broadly as possible. Furthermore, we wanted our mass analysis to extend at least to M , 10,000, to be highly sensitive, and to be capable of detecting metastable ions. We decided to couple a focusing liquid metal ion (LMI) column to a Wien filter to meet our requirements for the primary beam and to use a TOF tube with an electrostatic mirror to meet our requirements for mass analysis.

The LMI column, a commercial (FEI Company) single-lens unit, is capable of delivering a positive ion beam of 0.1-10 nA into a spot on the sample-target $\leq 10 \mu\text{m}$ in diameter; under continuous bombardment this corresponds to current densities in the range of 1-70 mA cm^{-2} . The column can accelerate its beam through potentials up to 25 kV. The LMI beam can be rastered; hence, the system can be operated in a scanning ion microscope mode by using the TOF-analyzer's channel plates to detect secondary electrons as shown in Figure 1. This feature facilitates tuning the LMI column and aiming at very small samples. A LMI beam is comprised of atomic, molecular, and cluster ions of various charge states. In order to conduct experiments with a single, known primary species, the LMI beam is passed through a small Wien filter (Colutron Model 600), which disperses the beam into its component parts. Figure 2 shows a spectrum of a tin-LMI beam produced on the system; the rich variety of particles available for mechanistic studies is evident.

Pulsed secondary ionization is normally accomplished by rapidly sweeping an ion beam across a slit at regular intervals, Figure 3a. A novel feature of our instrument is the use of the sample zone itself to determine the duration of secondary ionization event. This is accomplished by sweeping the finely focused LMI beam across the sample which is deposited on a small diameter ($\sim 10 \mu\text{m}$) wire or narrow edge ($\sim 10 \mu\text{m}$), Figure 3b. If it were used on instruments designed for analytical purposes, this approach could eliminate the need for the complicated and expensive mass and energy filters used to compensate for the spreading that occurs in primary ion packets formed by conventional ion pulsing techniques, and because the secondary ions emerge from virtually a point, it should be easier to achieve mass resolution near the electronic limit. Moreover, it should be possible to achieve secondary ion emission rates comparable to plasma desorption and conventional pulsed secondary ion TOF from sample areas 2-3 orders of magnitude smaller than required for those methods.¹

The time of flight mass analyzer is modeled after the Manitoba design.² Our flight tube is 34 cm long and has a 90° electrostatic mirror to permit study of metastable ions. Flight times are measured with a TDC (LeCroy Model 4208) and analyzed on an Atari Mega 4 computer system with software provided by the Manitoba group.³ We have just begun testing the instrument and do not as yet have any performance data. Nonetheless, the performance characteristics of the mass analyzer are reasonably predictable: unit resolution should be achievable up to m/z 500 without and up to m/z 1,000 with the aid of the ion mirror; errors in mass assignment should be ≤ 0.01 mass unit; and compounds with molecular weights up to $\sim 10,000$ daltons should be detectable.

EXTENDED LIFETIME ELECTRON MULTIPLIERS

R.L. ROY, E.A. KURZ, AND T.J. LOREY

Detector Technology, Inc. 12 Common Street, Brookfield, MA 01506

INTRODUCTION

Continuous dynode electron multipliers (CDEMs) have been used in mass spectrometers and surface instruments since the early 1970s. At the March '89 Pittsburgh Conference, Detector Technology, (DeTech™) introduced the Extended Life CDEM Series. This includes the Segmented CDEM⁽¹⁾ and the EverLast™ CDEM⁽²⁾ which incorporate the only major design innovations in CDEMs since their original development by the Bendix Research Labs in the early 1960s. Both of these inventions dramatically increase the life potential for continuous dynode electron multipliers. Each detector design has undergone extensive in-house testing and evaluation. Field tests and lifetime qualifications are currently being performed in a number of instruments by both manufacturers and users. Results to date, of all of these tests are discussed and summarized in this report.

(1) Joint Patent Pending, DeTech and Finnigan Corporation (2) Patent Pending, DeTech

THEORY

As discussed in a previous paper (1), the gain degradation (lifetime) of CDEMs has been found to depend upon the integrated number of electrons and ion impacts per unit surface area. Therefore, by designing a multiplier with increased surface area or replaceable surface area, one will effectively increase the lifetime of the multiplier. Computer modeling of the multiplication process revealed that an unrestricted electron cloud will rapidly expand to dimensions much greater than those of standard CDEMs. The model results show that after a gain of only 4000 the electron cloud has spread to over a 10mm full width at half maximum. Thus a detector with extended active surface area (compared to present CDEMs) should have an increased life when operated with the same input and gain. Other work has shown that the area of greatest charge concentration i.e.; the output end of the electron multiplier, is the location of the most damage during normal use of the CDEM. As the secondary emission ratio of the multiplier surface slowly decreases from the output toward the input, an overall decrease in gain results. An increase in detector voltage is then required to adjust the gain back to acceptable levels. Thus, a detector with a replaceable output segment will virtually duplicate its original gain, and then repeat its lifetime gain curve as each new segment is added.

EXTENDED LIFETIME DETECTOR SERIES

DeTech's Extended Lifetime Detector Series incorporated these developments into the new EverLast and Segmented CDEMs. As will be detailed, both of these detectors exhibit dramatically extended lifetimes compared to other available electron multipliers. Other important characteristics of detectors, such as noise, gain vs. voltage, and detection efficiency equal or exceed those of CDEMs presently in common use. The geometric aspects of these detectors have been adapted to CDEM specified hardware configurations, thus, direct retrofits are available for most equipment.

THE EverLast™ CDEM

The EverLast CDEM incorporates the theory discussed above directly in its manufacture. The EverLast is produced with a rectangular cross section that dramatically increases the active inner surface area. As the space charge progresses down this tube it expands across the total ID surface available. All tests were run, maintaining a gain of 10^6 . The term relative life is used as opposed to absolute life which depends upon a great many factors, such as operating pressure and proper handling. Absolute life can also vary with application. These tests were performed in a controlled, clean environment under conditions which can be repeated precisely for comparison purposes. Under these conditions, the EverLast CDEM's lifetimes averaged eight times greater than that of standard CDEMs. Customers in the field can expect to achieve similar results. This type of multiplier has a great potential for reducing equipment maintenance time and costs, while also reducing equipment downtime. Additional assets of the EverLast may also be apparent. The increased surface area allows a factor of 10 increase in the detector strip current. This in turn results in an increased output current since in a continuous dynode electron multiplier, the linear output is limited to approximately 10% of the strip current. For applications which require higher dynamic range, the EverLast configuration will increase this capability by the same factor of 10, or up to 20uamp output current. The EverLast design will be an asset in higher temperature applications. Many systems are being designed with the detector location running at an elevated temperature to reduce the problem of condensibles. The increased surface of the EverLast will allow for greater radiative cooling than standard designs of the past.

THE SEGMENTED CDEM

A second design for an extended lifetime CDEM has been jointly developed by Detector Technology, Inc., and Finnigan Corporation, San Jose, CA. In this device, the multiplier is constructed in two sections (segments). The rear segment of the CDEM is designed for easy and inexpensive replacement. Since the number of electrons rapidly increases as the electron cloud proceeds through the channel, the damage to the surface is greater further down the channel. Thus, the major factor limiting multiplier life is surface degradation occurring in the rear of the device. Simple replacement of the rear segment extends the lifetime of the detector. Tests performed at DeTech have revealed that the initial rear section of a properly designed device can be replaced three times before surface damage to the input section becomes the limiting factor and the entire unit must be replaced. When the exhausted rear segment is replaced the voltage required to produce a given gain drops dramatically back to almost the original voltage required. A gain of 10^5 was used throughout the tests. In-house testing has shown an increase in lifetime of a factor of 3 to 4. As with the EverLast, the actual increase observed in the field will vary somewhat with the application.

FIELD TESTING

DeTech has developed a dependable and reproducible, very high count rate, accelerated life testing procedure. This method was used for all the internal work. With the exception of work performed by Dr. Jon Amy at Finnigan, all field testing will be completed using normal rates. The results of field tests to date have been positive and follow:

FINNIGAN CORPORATION Dr. George Stafford of Finnigan is developing a segmented design for use in the Finnigan TSQ-70. Dr. Amy has evaluated a Segmented CDEM in an accelerated life test for this application using an engineering TSQ-70 and Finnigan 4500 electronics. Gain throughout the tests was calculated using analog methods incorporating an electrometer, which was installed to measure input and output current for the multiplier. Results were recorded at both 10^4 gain and 10^5 gain. He has reported the following: "Replacement of the back segment restored initial gains for four segments with applied voltage differences of less than 200 volts per segment. The data leads to the conclusion that the assumption that most of the gain is in the back section is valid. Replacement of this section is a practical method of restoring multiplier gain, and can be done four times with usable results."

VESTEC CORPORATION A Model 1340 EverLast has been installed in a Vestec Model 210 Mass Spectrometer at the Vestec Applications Lab. Dr. Marvin Vestal reports that in start-up operation this detector is similar to previous standard DeTech multipliers. Lifetime evaluations will be carefully tracked in this instrument for comparison to earlier work.

COMPUCHEM LABORATORIES Jim Chambers has been installing DeTech CDEMs in CompuChem instruments for four years and their Labs keep a record book for each instrument. CompuChem has complete history records, and can apply information with a large statistical base. Jim has pointed out that CompuChem has many instruments running on a 24 hour per day shift, and they put a large number of samples through their mass spectrometers. CompuChem can be considered to be a very tough test case for lifetime of multipliers. Lee Gregory installed an EverLast multiplier Model 1306 into an HP 5970 MSD. "Initial turn on indicated a low level of noise at a voltage of 1600, which was the voltage required to meet tune parameters. Over a period of several months, this new multiplier has continued to operate the same as the original equipment multipliers with a noise level that is equal to or less than the original. An important factor that we have seen is that the voltage level applied has remained fairly constant over a time of three months as compared to other units where the voltage has increased by four to six hundred volts over the same time frame. These facts lead us to believe that the new DeTech multiplier can give us an extended lifetime with a low level of electronic background noise."

SUMMARY

At this writing, both the EverLast and Segmented designs are living up to the extended lifetime expectations of original theory. A growing sampling of these detectors are in use, and a number of applications are being closely monitored. The results continue to be tabulated and published. Results to date show that performance parameters have either equalled or exceeded past performance in both designs, and models are compatible for retrofit in present equipment. The evaluations point out that the use of these new detectors will not only be cost saving, but will allow the mass spectrometer scientist to focus on the chemistry of his work with a major reduction in equipment maintenance considerations and details.

HIGH SENSITIVITY ION DETECTOR PARAMETER STUDY

Julius Perel^a, John F. Mahoney^a, Terry D. Lee^b and Kassu Legesse^b
^aPhrasor Scientific Inc., 1536 Highland Ave., Duarte, CA 91010
^bCity of Hope, 1450 E. Duarte Rd., Duarte, CA 91010

Positive ion detection in mass spectrometry primarily relies upon the production of secondary electrons released from ions impacting a surface. The initial impact surface is either a Daly dynode (Ref. 1) or the surface of an electron multiplier. Since the secondary electron coefficient (the number of secondary electrons per impacting ion) is dependent upon the ion velocity, detection has been extended to high mass by applying high voltage to the conversion dynode to increase the impact velocity. Until recently, little attention has been paid to the production of secondary ions or to the tailoring of the work function of the dynode surface to favor the production of secondary particles including electrons and negative ions (Ref. 2).

Daly reported (Ref. 1) that large molecular ions produce more secondary electrons than single atoms or diatomic molecules even when impacting at the same high kinetic energy where the higher mass ions have the lower velocity. More recently, by both lowering the surface work function and increasing the impact kinetic energy, the authors substantially increased the detection signal for biomolecular ions (Ref. 2). For detection systems already employing post acceleration dynodes, lowering the surface work function resulted in a multiplication of the detector gain by more than an order of magnitude above 2,000 amu. For detectors that solely rely upon the electron multiplier accelerating voltage to produce the impact velocity (such as quadrupoles), the addition of a conversion dynode resulted in a multiplication of the gain by an order of magnitude at low mass and two orders of magnitude above 600 amu (Ref. 3).

In the present work, detection systems were designed to further examine this latter approach using different dynode geometries and a range of operating voltages on HP5982 and HP5988 quadrupole mass spectrometers. The results indicate that a large increase in signal and in signal-to-noise ratio was possible using a conversion dynode for all of the ion-producing modes of operation such as EI, CI, FAB, Thermospray and Particle Beam.

To measure the increase in signal, PFTBA was tested in the EI mode to compare the regular mass spectrometer detector with the experimental dynode detector. The experimental detector was also operated at zero dynode voltage, which simulated the regular detector and produced similar spectra. Figure 1 shows spectra produced at zero and at 9kV dynode voltages. The overall gain in signal and high mass enhancement is clearly observable. The gain is also seen in Fig. 2, which shows two curves for the average ratios of abundance with and without high voltage on the dynode for selected PFTBA peaks. A very small PFTBA peak at 564 amu was selected to illustrate the increase in signal-to-noise ratio with and without high voltage at the dynode (see Fig. 3). The spectral peaks were adjusted to have comparable abundances in order to convey the difference in noise levels. Figure 4 shows FAB spectra with and without dynode voltage applied, displaying the significant improvement gained by using this detector. FAB noise ordinarily observed on quadrupole mass spectrometers is strongly attenuated at certain dynode voltages. This phenomena and other features of the conversion dynode, along with the effect of low work function surfaces, are under further investigation in our laboratory.

A FLEXIBLE ARRAY DETECTOR OF EXTENDED MASS RANGE FOR A HIGH PERFORMANCE TANDEM MASS SPECTROMETER J.A. Hill, J.E. Biller, S.A. Martin, K. Blemann, Dept. of Chemistry, MIT, Cambridge, MA, 02139
M. Ishihara, JEOL, Akishima, Tokyo 196, Japan

INTRODUCTION Array detectors can be employed to utilize the more or less limited focal plane of Nier-Johnson type mass spectrometers. This results in an increase of sensitivity due to the simultaneous recording of a set of ion beams, and better S/N ratio due to the integrating properties of such detectors. Previously, we designed and constructed an array detector covering 6.6% of the mass range. That detector was placed into the focal plane of MS-2 of our JEOL HX110/HX110 mass spectrometer¹. Its major advantage is the 50-100 fold increase in sensitivity.

We now have redesigned this detector to record a variable and much wider mass range. It incorporates a novel ion-optical concept² which utilizes a pair of quadrupole lenses placed after the magnetic sector (Fig. 1) to vary the dispersion as well as the angle of the focal plane, which is then located at a fixed center point 12.7 cm in front of the normal collector slit. This makes it possible to move the detector into position with out interfering with the slit assembly. The design of the detector permits computer controlled setting of any desired angle via a stepper motor, while simultaneously applying the proper potentials to the quadrupole lenses. If the conventional slit/electron multiplier detector is to be used, the quadrupole lenses are grounded and the array detector moved out of the way of the principal beam using a linear motion feed through. The theoretical mass range accessible by this principle is 1:1.4 (i.e., 40% of the spectrum), limited by the width of the flight tube at the end of the magnet gap. We have presently achieved well focused ion beams covering the range of 1:1.055 at a detector angle of 17.7° to about 1:1.30 (i.e. 30%) at an angle of 40°.

RESULTS AND DISCUSSION Our main interest is in the recording of MS/MS (CID) spectra over a wide mass range, from m/z 60 to the $(M+H)^+$ precursor ion, while retaining unit mass resolution. The wide mass range at 40° detector angle is important at low mass to minimize the number of segments that need to be recorded, but a smaller range (therefore, angle) must be used at the higher mass range to retain resolution which is then limited by the 2048 elements of the 2" Reticon photodiode array. Two different angles generally permit minimizing the number of segments to be recorded for a single CID spectrum. As an example, that obtained with a peptide of $(M+H)^+ = m/z$ 2465.2 is shown in Fig. 2. For this spectrum the first 13 segments were recorded at a 40° angle ($R=1.29$) and the next five at 28° ($r=1.12$)

It has to be kept in mind that the kinetic energy of product ions in a CID spectrum varies and is proportional to the mass ratio of product/precursor ions. This energy spread has to be minimized to assure that all ions of the mass range to be recorded pass through E_2 and are properly refocussed on to the focal plane by the quadrupole lens system. This phenomenon becomes more severe with increasing mass range covered by the detector. For this reason we use 10 kV accelerating potential in MS-1 and operate the collision cell at 8 kV above ground.

This variable range array detector can also be used advantageously to record conventional FAB mass spectra. At wide angle (large range) a survey spectrum of low resolution ($R=500$) is obtained by stepping through a few magnetic field settings (in this situation the resolution limit of the photodiode array is irrelevant). When a peak is observed, it is roughly centered by changing the magnetic field (Fig. 3a). Stepwise decrease of the angle (and appropriate change of the lens potentials) permits "zooming-in" on the unresolved isotope cluster (Fig. 3b), which then can be resolved by changing the fixed ion source slit from 500 to 10,000 resolution (Fig. 3c,d). Simply increasing the integration time regains most or all of the signal intensity lost by narrowing the slit. To aid in integrating for longer times, the photodiode array has been cooled to about 0°C. This allows for integration up to 15x longer than with the detector at room temperature (Fig. 4).

In all cases the JEOL data system steps either B_1 (for conventional spectra) or $E_2/B_2 = \text{const.}$ (for CID spectra) to the appropriate center mass for

each segment. A separate dedicated computer controls all functions of the detector and the data are instantly transferred via DECnet to a VAX 750 for processing to the complete mass spectrum.

SUMMARY The array detector described offers an increase in speed and sensitivity with which conventional and tandem mass spectra of large molecules can be recorded. The most important features are the following:

(1) The complete system can be installed between the exit of the magnet and the collector slit of the JEOL HX110 mass spectrometer without any further modification of the instrument.

(2) The portion of the mass spectrum covered can be varied from a ratio of 1:1.055 to 1:1.3 (possibly to 1:1.4) by adjusting the angle of the detector assembly and the potentials on the quadrupole lenses.

(3) Complete spectra can be recorded either at a fixed angle or the angle can be changed (generally once or twice during the spectrum) to make use of a high ratio for low mass and a lower ratio at high mass to retain unit resolution (and sufficient mass accuracy) at higher mass. The fast, precise and reproducible setting of angle and lenses potentials are made by the computer which controls all functions of the detector.

(4) Survey spectra of a wide mass range are obtained with a few segments at high angle (wide mass range). Once a signal is detected the system zooms in on it by decreasing the angle and, therefore, the mass range recorded. Mass assignments are made at the lowest angle (highest dispersion).

A VERSATILE ARRAY DETECTION SYSTEM

Reinhold Pesch, Gerhard Jung, Klaus Rost, Karl-Heinz Tietje
Finnigan MAT GmbH, Barkhausenstr. 2, D-2800 Bremen 14/FRG

One of the most effective ways to increase the overall sensitivity of a magnetic sector mass spectrometer (MS) is the simultaneous detection of ions of different mass. This can be accomplished with a position resolving detector placed in the focal plane of the MS.

A number of different technical approaches have been used to implement focal plane detectors (1). Up to now commercial devices have been built around photo diode arrays (2). These systems suffer, however, from an inherent noise problem and the inability to perform a continuous wide mass range scan. The latter problem can only be circumvented by a series of static measurements.

We have designed a new focal plane detector, based on the principle of position and time resolved ion counting (PATRIC) which is able to acquire data by continuously scanning over the complete mass range. The detector is part of a new high performance sector field mass spectrometer, the Finnigan MAT 900. In the environment of the MAT 900 the detector covers a mass range of 8 % of the center mass.

The new detector is characterized by single ion sensitivity, full scan capability and the potential for post-acceleration.

Position determination:

Ions are converted into electron pulses using two micro channel plates (MCP's). A typical gain factor is 10^6 electrons per ion.

The electrons are collected on a multi-anode collector plate (Fig. 1). The anodes (conductive strips) of the collector plate are connected to each other by identical capacitors (Fig. 2).

The position of each ion impinging on the first MCP is determined by calculating the ratio of electrons flowing to either end of the collector plate.

This calculation is done for every ion arriving at the detector (ion counting).

Scanning operation:

Since the response time of the system is extremely rapid (5 usec), it is known for each ion where and when the ion hits the detector. These two pieces of information enable the detector to function in a scanning mode.

In an exponential magnet scan all masses move over any given point of the detector with a constant speed. However, masses move over different points of the detector with different speed. The change in speed can be described with an exponential function.

In order to be able to scan and maintain resolution, it is necessary to exactly track the course of every mass over the detector. This is accomplished by a ring buffer mechanism. The buffer addresses are switched synchronously with scanning speed. The change in speed of every mass over the detector is compensated by an appropriate (exponential) detector internal mass calibration. Data from a wide mass range scan are shown in Fig. 3.

Detection of high molecular weight ions by channelplate detectors

E. Niehuis, M. Deimel, A. Benninghoven

Physikalisches Institut, Universität Münster
Wilhelm-Klemm-Str. 10, D-4400 Münster, FRG

By the optimization of excitation parameters and sample preparation the mass range of the various desorption methods is extended year by year. The mass range of the time-of-flight analyzer is in principle unlimited, but the detection of high molecular weight ions becomes a serious problem.

The critical step in ion detection by electron multipliers is the ion-electron-conversion. The kinetic ion induced electron emission is a mass and velocity dependent process. Threshold velocities of some 10^6 cm/s have been reported in the literature [1,2]. Therefore high mass ions must be postaccelerated to high energies.

We have studied the mass discrimination of a channelplate detector in a high performance TOF-SIMS instrument. The design of the detector provides a postacceleration to energies up to 20 keV for positive and negative secondary ions. The velocity dependence of the detection efficiency was determined for polyatomic ions of different composition like polymers and clusters in the mass range up to 7000 u.

Measurements on Cr-clusters show that the electron yield of a molecule is the sum of the electron yields of the molecule's atoms: $\gamma_{mol}(v) = \sum_{atoms} \gamma_{at}(v)$.

Different polymers have been selected to study the mass discrimination of the detector. From the velocity dependence of the measured secondary ion intensities the detection efficiencies have been determined. These detection efficiencies are shown in fig. 1 for different oligomers of the polymer krytox. At $v = 1 \cdot 10^6$ cm/s the detection efficiencies are still above 0 so that a detection of high molecular weight ions is possible for velocities below $1 \cdot 10^6$ cm/s. In the mass range between 69 and 169 u threshold velocities of $2.5\text{--}4 \cdot 10^6$ cm/s have been obtained.

These measurements allow the determination of the detection efficiency as a function of mass for different postacceleration voltages (see fig. 2). No mass discrimination in the mass range up to 6500 u has been observed at the highest postacceleration voltage (20 kV).

Investigations of different polymer materials with, however, the same masses give raise to the assumption that the sample composition has a strong influence on the electron yields. From figs. 1 and 3 it can be derived that the electron yield and therefore the detection efficiency of fluorine containing polymers is higher than that of other materials. For substances which do not contain electronegative atoms (e.g. F) mass discrimination even below 6000 u has to be expected.

The development of photodiode array-based (PDA) detectors for use on commercial mass spectrometers has been reported in the literature. Cottrell and Evans¹ reported on the design and fabrication of a detector for use in simultaneous detection of at least 4% of the mass range at a specific mass. Hill et al.² subsequently reported the development of a 2" MCP / 2" Photodiode array-based detector which permitted simultaneous detection of 6.6% of the mass range. This same detector was later utilized for the detection of greater than 20% of the available mass range when special ion optics were incorporated into the design of the tandem mass spectrometer in which it was installed.³

We have completed the fabrication of a PDA-based detector which has the capacity for simultaneous ion detection of 10% of the mass range of a conventional mass spectrometer, in this case a JEOL HX110. Two 37.5mm by 10mm active surface area microchannel plates (MCP) Chevron type, were placed end-to-end as shown in figure 1 to form a 75 mm MCP surface. The MCPs were mounted on a second set of identical MCPs to permit a gain of 106 in the detector. The microchannels are 1mm in depth with 12.5 micron diameter. The MCP sandwich was subsequently mounted on a continuous fiber optic element, the front surface of which has been coated with P-31 and aluminized to permit the conversion of secondary electrons to light which could be input to the PDA.

FIGURE 1.

MICROCHANNEL PLATE ASSEMBLY

One end of a 3 inch fiber optic block was drawn down to 2 inches. The 3" end of the resulting fiber optic taper was mounted to the P-31 coated fiber optic faceplate. The 2" end of the taper was coated with a resistive finish to permit adequate grounding of the taper. A Reticon 2048 self scanning linear photodiode array was mounted to the fiber optic taper using a specially designed mounting bracket (figure 2). The incorporation of this 3:2 reducing taper results in the collection of a wider dispersion of ions than could be collected using a commercially available PDA and a forward geometry mass spectrometer of standard configuration. In

addition, the 3:2 taper also results in the collection of a greater percentage of available ion current in the horizontal z-axis. This greater collection efficiency may permit detection of up to 50% of the available ions.

Figure 2

The incorporation of a mechanism of rotation into the detector was completed so that acquisition of mass spectra under conditions of the "enhance resolution" experiment could be completed.⁴ This scanning mode is operational when a tandem mass spectrometer is operated as a single mass spectrometer ion optics system. The utility of this scan mode is that higher resolution measurements can be made without significant diminution of ion intensity. The angle to which the detector must be set for this experiment is 14 degrees off the incident ion beam.

Data acquisition and control of the PDA were completed with a Princeton Instruments ST-120 controller. (Princeton Inst., Princeton Junction, NJ.). This controller was interfaced to a Compaq 286 microcomputer. Software provided by PI and Galactic Enterprises, Salem, NH. was modified to complete data acquisition and reduction.

The effect of the fiber optic taper is to increase sensitivity by resulting in the collection of a greater percentage of the available ion current by the detector. The collection of up to 10% of the mass range of the HX110 mass spectrometer is also possible with this device, thus reducing the time required for collection of a complete mass spectrum.

PERFORMANCE RELATED CHARACTERISTICS OF
LINEAR ARRAY DETECTORS FOR MASS SPECTROMETRY

John W. Gray and John B. Hooper
Galileo Electro-Optics Corporation
Sturbridge, Massachusetts 01566

Recent years have witnessed a rising interest in array detectors for applications in mass spectrometry. The major advantages of these detectors are increased sensitivity and spectrum acquisition speed. Although the concept has been around for some time, recent advances in component technologies has made the design and implementation of an Electro-Optical Ion Detector (EOID) System much more practical than was heretofore possible.

The performance of any EOID System depends upon such factors as application, instrument geometry, sample size, etc, however, the major components are similar in most cases. A typical detector consists of a combination of microchannel plate electron multipliers, phosphor screen, fused and flexible fiberoptic components and a photodiode or CCD array readout. The two primary design variations for current EOID systems place the solid-state readout either inside or outside the vacuum chamber. Each of these designs has certain advantages and disadvantages. Locating the readout inside the vacuum reduces the number of component and optical interfaces, however, most PDA or CCD device packages are not well suited to vacuum environments and cooling of the device in vacuum can be extremely complicated. On the other hand, placing the readout outside the vacuum eliminates the problems of vacuum incompatibility and excessively complicated cooling, but requires additional fiberoptic components with consequent loss of optical signal in transmission through these added elements.

Major system design considerations for an EOID concern the interfaces between the various electronic and electro-optical elements. In general there are six types of interfaces of concern in current EOIDs:

1. Ion/Microchannel Plate (MCP)
2. MCP/Phosphor Screen
3. Phosphor Screen to Fiberoptic
4. Fiberoptic to Fiberoptic (fused and/or flexible)
5. Fiberoptic to Solid-State Readout
6. Air/Vacuum (electrical or fiberoptic)

Factors affecting system performance to be considered during design of the EOID include the following:

1. Ion detection efficiency and channel size of the MCPs.
2. Charge spreading between MCPs or between MCP and phosphor screen.
3. Phosphor grain size and other phosphor screen characteristics.
4. Characteristics of the epoxy bonds between fiberoptic elements.
5. Fiber size and numerical aperture (NA) of the fiberoptic elements.

Typical interfaces and parameters of concern are illustrated in Figures 1 & 2.

Clearly, the optimization of these parameters is not a trivial task and is further complicated by the fact that most of the system components are non-standard in terms of performance or geometry. Progress toward optimization and standardization is being made, however, and the next generation of EOIDs promises improvements in overall system performance (such as detection efficiency and spatial resolution) as well as cost.

DESIGN OF AN ION OPTICS USING A QUADRUPOLE DOUBLET(QPD)
FOR ZOOMING MASS RANGE ON AN ARRAY DETECTOR

M.Ishihara, F.Kunihira, K.Otsuka, Y.Kammei, E.Kubota, Y.Itagaki,
T.Higuchi and B.D.Musselman
JEOL LTD., 3-1-2 Musashino, Akishima, Tokyo 196, JAPAN.

The sensitivity of a conventional sector type mass spectrometer is increased by a factor of 10 to 100 by using an array detector placed in the focal plane (1). This method could provide new application capabilities. For example, MS/MS system equipped with an array detector (2) can be routinely used for the pico to femto mole level peptide sequence analysis.

For the conventional system, the mass range covered by the array detector is limited and fixed about 5%. Therefore, it requires many times of repetitive measurements to cover an entire mass range. To overcome this tedious time and sample consuming procedure, it is necessary to develop a mass spectrometer which can focus a wide mass range on the array detector. On the other hand, the mass resolution which is limited by the space resolution of the array detector is inversely proportional to the mass range.

Taking account of those factors, we have designed a novel ion optical system (Fig.1) which can easily vary the focusing mass range on the array detector. Basically the new system consists of a double focusing mass spectrometer and an electrostatic quadrupole doublet(QPD) placed in the third field free region. Thus existing mass spectrometer (i.e. JEOL HX110) can be modified to a new optical system. This modification does not affect any original performance of the instrument; when the quadrupoles are set to the ground potential, the new system will return exactly to the original ion optical system.

The mass range is continuously varied by the QPD without moving the detector position P1. Fig.2 shows the simulated ion trajectories under typical QPD conditions. The mass range covered by a 2"-detector under conditions of (a),(b) and (c) are 25%, 12% and 4%, respectively. The inclination angle (θ) of the focal plane depends on the mass range (R). We found that the relation between R and θ is given by

$$R = L/K \tan \theta \sin \theta$$

where L is a detector length and K is a constant depending on the individual instrument.

(Since the scale of the vertical direction is different from that of the horizontal, the angle θ shown in Fig.2 is not correct.)

DESIGN, CONSTRUCTION AND CHARACTERIZATION OF ION DECELERATION LENSES:
WHAT ARE THE SIMPLICITY/PERFORMANCE TRADEOFFS?

Paul J. O'Connor and John Allison, Department of Chemistry
Michigan State University, East Lansing, MI 48824

Construction of a hybrid instrument of BEOQ geometry is currently underway in our laboratory for the study of the kinetic energy-dependence of gas phase ion/molecule reactions. A Varian MAT CH5-DF instrument (BE) provides a 3 kV ion beam, which must be decelerated to 1-100 eV and introduced into an rf-only octopole (O) collision cell. Reaction products will be analyzed by the quadrupole (Q) mass filter and Daly detector which complete the ion path through the instrument. For similar applications, a variety of deceleration lens designs have been successfully utilized. They are often fairly complex, however, requiring 30 or more lens elements and exponential fields to achieve deceleration without producing a severely divergent beam. When precise ion energies need not be known, or highly focused beams are not required, deceleration lens of simpler designs may be used. We have investigated the performance of both simple and "complex" deceleration lens systems using the ion optics modeling program SIMION (1), to determine what features of these systems are critical in achieving their performance. Our conclusion is that in some cases lenses with 30 or more elements perform well not because of the exponential fields, but because of the large aperture sizes relative to the dimensions of the ion beam traversing the assembly. If the ion beam samples the center of the field within the lens, where the lines of constant potential are flat and perpendicular to the direction of ion motion, then deceleration without divergence can be achieved. These insights lead to the construction of the deceleration system shown below. The design is shown in Figure 1 and the results of SIMION modeling are shown in 2. In Figure 2 an ion beam with an initial kinetic energy of 2800 eV enters the alignment stage, where X-Y deflection plates center the beam when necessary. Also shown in 2 are the lens components, ion trajectories, and selected lines of constant electric potential. It is clear that there is substantial curvature in the equipotential lines in the deceleration stage, and this curvature can yield a severely divergent beam. However, with the focusing stage before the deceleration stage, the beam dimensions can be decreased in this critical region, causing all of the ions to move up the center of the "potential hill" created by the lens. The resulting ion beam, having been reduced to an energy of 30 eV, exits with minimal divergence.

The device shown in Figure 1 has been constructed. Its performance was evaluated using a Channel Electron Multiplier Array (CEMA) with a phosphor screen, which allows for "beam visualization". The 3 KeV ion beam from the CHS mass spectrometer had dimensions of 4 x 0.75 mm, and a half-angle divergence of 0.25° . It was found that a static einzel lens potential of 5 kV (focusing stage) provided good focusing of the beam into the deceleration stage, and yielded a cylindrically-symmetric ion beam with final energies variable from 10-140 eV with a half-angle divergence of less than 5° in this energy range, which is suitable for injection into the octopole collision cell. Thus, we believe that deceleration lenses need not be complex for high performance operation, when the design/performance aspects are well-understood.

IONIZATION TECHNIQUES BASED ON PROPERTIES OF SUPERCRITICAL FLUIDS:
II INSTRUMENTATION.

by
William Larkins, Jr. and Susan V. Olesik
Department of Chemistry
The Ohio State University
Columbus, Ohio 43210

The ideal "hyphenated" technique for the interface of chromatography to mass spectrometry for high molecular weight, highly polar compounds has the following properties. 1) The separation process is highly efficient. 2) The interface between the chromatography and the mass spectrometry is easily made. 3) The ionization process is capable of ultra-soft ionization, as well as, highly controlled energetic ionization. 4) The interface and the ionization processes are well suited for high performance mass spectrometers, such as FT-ICR or magnetic sector instruments.

We are developing new ionization techniques that are based on specific reactions that are invoked in gas phase ion clusters. The charge and the size of the clusters are controlled by varying the properties of the solvent before point of expansion into the mass spectrometer.

In this report, the instrument that is used for the development of these techniques was described in detail. The instrument consists of three chambers. In the first chamber the ions are initially formed. The second chamber provides significant ion focussing and deceleration. Finally, the third chamber provides mass spectral analysis by use of an Extrel high-mass quadrupole.

The design of the decelerator lens system was described in detail in this report. The initial stage of the design work was to start with an exponential decelerator originally designed by Vestal et al. (1). In our system a greater extent of deceleration was necessary. Also, the ion beam divergence was greater than that in Vestal's system. SIMION was used design a new exponential decelerator that provides high deceleration rates in less space than in the work of Vestal et al. (1).

HIGH ENERGY DYNODE (HED) ELECTRON MULTIPLIER DELIVERS INCREASED HIGH MASS SENSITIVITY FOR QUADRUPOLE MASS SPECTROMETERS.

Paul C. Goodley, John Fjeldsted, and Stuart Hansen, Hewlett-Packard Co., 1601 California Ave., Palo Alto, CA 94304

Previous work by Daley has shown substantial sensitivity increases for quadrupole mass spectrometers by the use of post mass filter acceleration devices. The increased sensitivity can be realized by adding a carefully shaped and positioned High Energy Dynode (HED) near a standard Continuous Dynode Electron Multiplier (CDEM).

The increase in sensitivity using the HED can be attributed to the fact that high mass ions having low initial velocities through the quadrupole analyzer, can be accelerated to a sufficiently high velocity to cause efficient conversion of ions to electrons at the CDEM.

Typical quadrupole mass analyzers yield best resolution at ion energies of five of ten volts. The detection systems used in most quadrupole mass spectrometers are the continuous dynode electron multiplier types which is operated between 1.5 and 3.0 kV. The CDEMs detection ability is highly dependent on the product of mass times velocity. Consequently, for higher mass ions with low velocities, the impact onto the entrance horn of the CDEM at two or three kilovolts of energy, is insufficient to yield a high conversion ratio of ions to electrons. Lower conversion rates of ions to electrons reduces the total current output from the CDEM and therefore the measured ion abundance. Higher ion velocities cause an increase in the conversion to ions to electrons resulting in higher measured ion abundance and higher signal-to-noise ratios.

By adding a HED near the horn of standard CDEM and setting the polarity of the HED to the opposite sign of the ion being analyzed, the ions are directed onto the dynode instead of the horn of the CDEM. The dynode has an operating potential of 2 to 10 kV to provide a high acceleration for increasing the ion velocity and conversion to electrons. The more efficient conversion of ions-to-electrons occurs at the dynode rather than the horn of the CDEM. The newly created electrons pass through the electrostatic field of the horn of the CDEM where further cascading the secondary electrons as the multiplication process occurs throughout the CDEM.

A diagram of the HED coupled with the common CDEM is shown in Figure 1. The dynode material was carefully chosen and positioned. The material and the surface of the dynode were shown to have a dramatic effects on the work function resulting in conversion rates from less than one to more than one. High fields which caused field emissions and high background noise levels were reduced by obtaining a 10 to 20 micro inch finish on the HED and all parts associated with HED system.

Figure 2 shows a plot of the signal abundance vs voltage applied to the HED for ion m/z 502 from a tuning compound. The plot shows the increased S/N which can be gained for the higher mass ions as the voltage on the dynode is increased. For this example, more than a factor of 25 increase can be observed.

ION TRAJECTORY MODELLING IN AN ION MOBILITY
SPECTROMETER EMPLOYING NONLINEAR ELECTRIC FIELDS

Brian A. Eckenrode, Scott A. McLuckey, and Gary L. Glish
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831

Ion mobility spectrometry (IMS) can be thought of as time-of-flight mass spectrometry at atmospheric pressure. The techniques for using ion mobility at atmospheric pressure for spectrometry have been well established (1). IMS can be used for the detection of trace constituents of organic compounds in gaseous mixtures. Detection is achieved by ionizing trace molecules via ion/molecule reactions, the product ions of which subsequently drift through an electric field and are separated in time due to their velocity differences. The basic IMS instrument consists of a sample inlet, reaction region, shutter grid, drift region, and detector. In conventional IMS, a uniform or linear field, typically 200 V/cm, is applied across the drift region and the various ions from the sample separate according to their mobilities.

The performance of a conventional IMS system is limited in both resolving power and sensitivity. The shutter grid pulse width controls the sensitivity and resolution. A long shutter grid pulse is desired to allow more ions into the drift region and therefore, provides greater sensitivity, but a short pulse is required for greater resolution. Thus, IMS performance is a compromise between these two parameters.

An approach that uses linear and nonlinear electrical fields to control ion movement in the detection volume has been used to increase the performance of IMS systems (2). The ions of a particular mobility, K_0 , are located at a particular position in the drift region at each instant in time. Their motion can be changed and they can be moved to a different location in the drift region at a later time. This is achieved by providing the proper field between the present and desired location. Examples of drift field voltage control at various instances in time are shown in Figure 1. A linear and forward decreasing ramp can be used, followed by either a nonlinear or linear reversed field, which is then followed by a third ramp to move the selected ions toward the detector (see Figure 1A). By reversing the field at specific times, certain K_0 's can be isolated. If the field at the detector end is the reverse of the field at the shutter grid end (creating an ion well) ions will tend to drift toward the junction of the two fields. If the field strength is increased gradually, more ions will be accommodated and they will also have a reduced spatial distribution. From here they can be ramped toward the detector with a consequent increase in both sensitivity and resolution (see Figure 1B).

We have studied, via SIMION (3), ion trajectories under various dynamic electric field configurations in an IMS instrument. We have found that with proper timing of the field control (employing the user programming option available in SIMION), various K_0 's can be isolated. Modelling has enabled us to explore different electrode voltage magnitude and timing controls. This has allowed us to observe the resulting positional differences among ions of the same K_0 (with slightly different entrance angles and positions) for various electrode voltage changes. Table I gives the results of separating ions of the same K_0 with no angular divergence (ion number 1) from those that have a small divergence (ions numbered 2 or 3). The drift field begins with a linear decreasing ramp and is followed by a nonlinear field reversal that is active for 2 msec. This field sequence would be used to separate higher mobility ions from those of lower mobility. The ion separation can be optimized by adjusting the shape of the nonlinear field. Two conclusions that can be drawn from these data are: (1) with the same reversal function, it is advantageous to start the field at a later time, and (2) for a given

reversal duration, it is advantageous to use a higher order function for the adjustment of the electrode voltages. The duration of the field reversal affects the spatial dispersion of the ions although the flight time differences were small when compared to the nonlinear field results.

Table I

Field Reversal Start Time (msec)	$\Delta x_{1,2}$ (mm)	$\Delta x_{1,3}$ (mm)	Function

POTENTIAL DISTRIBUTION

Exact analytical solutions to Laplace's equation are often difficult for geometries with irregularly shaped electrode boundaries even after applying techniques such as conformal transformation. In such cases it is possible to solve Laplace's equation numerically, by iterative evaluation of finite difference equations using relaxation methods. We have applied this approach to calculate the potential distribution within the real bounded quadrupole geometry. This configuration differs significantly from the ideal unbounded quadrupole case which consists of four hyperbolic cross section electrodes which extend asymptotically to infinity. Consequently differences in the potential distribution between the real and ideal cases are expected. We have applied the mathematically satisfying method described by Govorkov [1] for the solution to Laplace's equation in cylindrical polar coordinates.

The integrity of the relaxation method was tested by comparing results from a numerical solution with those calculated by analytical solution to the Laplace's equation for a mathematically well defined electrostatic analyzer (ESA). We found the relaxation had an accuracy of better than one part in 10^9 volt.

The potential ϕ , within four circular rod electrodes is given in polar co-ordinates by the multipole series expansion :

$$\phi = (U + V \cos \omega t) \sum_{n=0} C_n (r/r_0)^{2(2n+1)} \cos [2(2n+1)\theta]$$

The values of the coefficients C_n determine the magnitude of the higher order terms in the expansion and are therefore an indication of how the field differs from the hyperbolic potential distribution (A perfect hyperbolic field is defined when the value of the coefficient C_0 is unity and all the higher order coefficients are zero).

Comparison of the fitted potentials for the round rod electrode geometry with the ideal hyperbolic distribution reveals the regions where the potential distribution has the maximum deviation from the hyperbolic case. The best agreement, i.e. least difference is towards the center of the electrodes.

It is an experimental observation that reducing the entrance aperture into the quadrupole increases resolution, albeit with a penalty in sensitivity. This is consistent with restricting ions to the most ideal or hyperbolic central part of the field. The value of ratio r/r_0 determines the optimum condition for the circular rod approximation to the ideal hyperbolic field and historically the literature contains confusing ratios. We determined multipole coefficients for two r/r_0 values and this allowed other ratios to be linearly interpolated and in particular the value for $C_0 = 1$ was found for $r/r_0 = 1.1483$ which differs from that given by Denison [2], $r/r_0 = 1.1468$. In his work Denison states that the best approximation to the hyperbolic field quadrupole occurs when the value of the C_1 coefficient is zero. Here we observed that when C_0 is unity as required for the ideal hyperbolic case, then C_1 is non-zero. Equally using Denison's criterion that $C_1=0$ we find that C_0 now deviates from unity indicating the optimizing of the ratio r/r_0 for minimum deviation from the ideal hyperbolic case is in reality a subtle operation which has not yet been achieved. As pointed out by Denison [2], the internal radius R , of the earthed vacuum housing should be large enough to minimize field perturbations at the center of the quadrupole field formed within the electrodes. The ratio R/r_0 should be greater than 3.5 and we have used values of $R \sim 10r_0$.

TRAJECTORY CALCULATION : (A Finite Element Method)

The relaxation method has allowed the potential distribution within the quadrupole to be found and subsequent determination of coefficients in the multipole expansion allows the potential to be calculated at any point within the inscribed radius. The electric field components E_x and E_y are obtained through partial differentiation of the expression for the potential.

Since ;

$$E_x = -\partial\phi/\partial x \quad \text{and} \quad E_y = -\partial\phi/\partial y$$

So,

$$\partial\phi/\partial x = (U + V \cos \omega t) [C_0 (2x \cos 2\theta + 2y \sin 2\theta)/r_0^2 + \dots +]$$

and

$$\partial\phi/\partial y = (U + V \cos \omega t) [C_0 (2y \cos 2\theta - 2x \sin 2\theta)/r_0^2 + \dots +]$$

Thus the components of the acceleration a_x and a_y can be found:

$$a_x = zE_x/m \text{ and } a_y = zE_y/m$$

Now if we consider the Newtonian equations of motion then we can determine the distance traveled by an ion from the following expressions ;

$$s_x = u_x \Delta t + 0.5 a_x \Delta t^2 \text{ and } s_y = u_y \Delta t + 0.5 a_y \Delta t^2$$

where s_x and s_y are the resolved components of distance traveled by a particle in a time interval Δt , and u_x u_y are the initial particle velocity components (at the beginning of Δt) and a_x , a_y the acceleration components. Hence the resultant positional increments of a particle or ion subjected to acceleration in the x and y directions for a time Δt is calculated assuming rectilinear motion. It is essential to make Δt sufficiently small that changes in the field are negligible during the time interval and the overall particle trajectory is found by tracing successive positional increments Δs , using Newtonian equations for motion.

To ensure the trajectory is determined accurately it was found necessary to divide the z axis of the quadrupole into 300,000 finite elements corresponding to time intervals, $\Delta t = 2.742 \times 10^{-10}$ s for $u_z = 4.0$ eV for a rod length of 22.6 cm.

The accuracy of the finite element method was evaluated by comparing the trajectory of an ion in a pure hyperbolic potential distribution by both the Newtonian treatment and the analytical solution of the Mathieu equations. The hyperbolic potential is generated by taking the only the first term in the multipole expansion with $C_0 = 1$. Under these conditions both methods give essentially identical particle trajectories as shown in Figure 1 for the Mathieu solution. This establishes the validity of the Newtonian method and allows the trajectories of ions in the non ideal quadrupole field to be calculated by substituting the fitted coefficients into the multipole expansion for the potential. The x and y electric field components acting on an ion in the quadrupole now include terms that are dependent on both the x and y position. The effect of the round rod electrodes on the ion motion is shown in Figure 2 and contrasts significantly with the trajectory in the hyperbolic field, Figure 1.

SUMMARY

1. The ray tracing method allows individual ion trajectories to be determined in the round rod quadrupole geometry, however it does not conveniently describe the general transmission characteristics of the mass filter in the manner given by solution to the Mathieu equation. In order to map the stability diagram we have systematically traced ion trajectories for a series of different initial positions, energies and entry angles.

2. Significantly the apical region of the circular cross section rod quadrupole was found to be rounded and without the apex point described by the Mathieu stability diagram. This is consistent with previous findings by Dawson [3]. Moreover the round rod stability diagram was found to lie within that for the Mathieu solution consistent with a reduced transmission for the round rod case compared with the ideal case.

3. The use of circular cross section electrodes in a quadrupole mass filter has been shown to give rise to distortions of the sixth, tenth, etc order. Studies have calculated the degree of sixth order distortions produced by round rods and indicate that at high resolution precursor peaks may arise. Only resonance lines that pass near or through the apex of the stability diagram are important because they are intersected by the mass scan line. These resonance lines mark positions where the ion trajectories are unstable and appear as dips in the peak shape.

upon an Intel 8085 CPU controls DAC offsets, DAC enabling, scan, scan step time and settling time counters, and provides a sampling trigger for a PC which can be used to set all front panel controls. The data signal is fed to a Compaq 16 MHz AT-class 80386-based PC via a Data Translation DT2801-A board with a programmable gain buffer. Normal, daughter and parent ion scans were obtained and signal averaged using ASYST, a high level scientific software system.

Figure 3 shows the signal averaged (7scans) normal mass spectrum of a phosphatidylethanolamine mixture. The peak at 718.5 amu corresponds to the MH^+ ion of PE with palmitic and oleic acid, while those at 692.5 and 689.5 represent minor components. The loss of the phosphoethanolamine head group from these three components results in peaks at 577.5, 551.5 and 549.5 amu. The B/E spectrum (sum of 20 scans) for the 718.5 amu peak shown in Figure 4 reveals only a single fragment peak at 577.5, and confirms the fact that the other peaks in the normal spectrum result from minor components, and not fragments.

An Improved Interface Design for Determining Radiochemical Purity by Radiogas Chromatography/Mass Spectrometry (RGC/MS). Patrick E. Kastl, Patrick W. Langvardt, Michael J. Bartels and Kathy A. Brzak. The Dow Chemical Company, Midland, MI

Radioisotopes are commonly used as a means for monitoring the fate of a chemical in a complex matrix. Therefore, determination of identity and the radiochemical purity of these materials is crucial when describing movement through a biological or environmental system. Radiochemical purity is often determined directly by a chromatographic method such as high performance liquid chromatography (HPLC) with an on-line flow through radioactivity detector or by thin layer chromatography (TLC) with a radioactivity scanner that allows for direct quantitation on a solid support. These methods are very versatile and sensitive in detecting small amounts of impurities, however, both HPLC and TLC are usually not useful for volatile compounds.

The objective of this work was to design an simple, maintenance-free interface between a Panax radiogas detector and a Finnigan 4600 GC/MS. The interface was designed to allow either simultaneous or independent operation of the radiogas detector and/or the mass spectrometer. This interface was also designed to allow for quantitative recovery of the injected radioactivity.

The interface was constructed with two (2) glass-lined stainless steel tees that are used to split the gas streams between the mass spectrometer, the radiogas detector and the recovery port (see Figure 1). During a RGC/MS analysis the first tee is used to split the GC effluent between both the radiogas detector and the mass spectrometer so as to simultaneously obtain a radio- and mass chromatogram. A vacuum divert line is also connected to this tee and is used to divert the solvent. The fused silica capillary line from this tee to the radiogas detector or the mass spectrometer may be disconnected and plugged thereby allowing independent operation of either. The second tee is used to route the radiogas detector gas stream (split at the first tee) to either the combustion furnace or to the recovery port. During a RGC/MS analysis the recovery port is plugged so that all the gas flow goes to the furnace and then the radiogas detector. During a radioactivity recovery check the fused silica capillary line to the mass spectrometer and the line after the furnace are disconnected and plugged thereby routing all the GC effluent through the recovery port. The recovery port was built with Cajon o-ring fittings that hold two 150 mg air sampling tubes which are used for collecting radioactivity. Following collection these tubes are solvent extracted and the radioactivity is counted by liquid scintillation counting. Both the Panax furnace and the recovery port are mounted on a separate interface oven cover to allow easy installation and removal. Fused silica capillary tubing was used for all the connections and the size used determined the split ratio.

Representative radiolabeled materials analyzed by RGC/MS include ^{14}C styrene oxide, ^{14}C 1,2-dichloromethane, ^{14}C 1,3-dichloropropene and ^{14}C 1,2-dichloropropane. Some of these materials were shown to contain radiolabeled impurities not originally reported by the manufacturer. Typical radioactivity recovery for compounds with boiling points below 200°C have ranged from 99 to 108% of the total radioactivity injected. To date, the RGC/MS interface has been installed and removed more than 30 times without requiring maintenance.

CHARACTERISTICS OF A HIGH RESOLUTION ICP-MS INSTRUMENT

N Bradshaw, N E Sanderson, J E Cantle

VG Elemental Limited, Ion Path, Road Three, Winsford, Cheshire CW7 3BX, UK

Inductively coupled plasma source mass spectrometry has evolved over the past seven years into what is today possibly the most powerful elemental analytical technique available to the analyst.

All the current commercial instruments use the quadrupole mass analyser which allows the analyst to resolve mass peaks of approximately one mass unit with high ion transmission. This means that polyatomic species with the same nominal mass as the analyte isotope of interest will contribute to the measured signal assigned to that isotope.

Spectral interferences have been the subject of considerable investigation from the inception of the technique and an understanding of potential interferences is essential to the analyst. Whilst computational techniques can be applied to allow spectral correction these are not valid when the magnitude of the signal due to the interference is very much larger than the analyte signal. Such is the case when the interfering polyatomic results from matrix species for example. Other polyatomics can result from the introduction of solvent into the plasma and from the plasma gas itself.

We have developed an ICP-MS instrument utilising a high resolution double focussing mass analyser to resolve such interferences. The instrument consists of a standard VG argon inductively coupled plasma system utilising the Fassel type plasma torch. Sample introduction to date has been by nebulisation of solution in the usual manner. The plasma is coupled to the mass spectrometer by means of a Campargue type supersonic beam interface and a differential vacuum pumping system. The ion energy is infinitely variable up to 6keV and beam shaping optics are used to match the circular section ion beam from the source to the rectangular cross section required by the mass analyser. This ensures that ion transmission and hence sensitivity are maximised.

Resolution is easily adjustable by remotely controlled preset slit assemblies, between low resolution (a mode of operation analogous to that of the quadrupole mass analyser) and high resolution (up to 8000, 10% valley). As there is an inverse relationship between resolution and transmission the low resolution mode is more sensitive and high resolution operation is reserved for the difficult matrices or elements. For example, using a resolution of 4000, Si, S, V, Fe have all been completely resolved from the interferences that normally trouble them. In these cases limits of detection are now a few picograms/ml i.e. factors of 10 - 100 better than in conventional ICP-MS.

The use of the double focussing mass spectrometer has shown further advantages over the quadrupole. The background levels in quadrupole based ICP-MS systems have been reported as between 10 and 100 Hz. This background is universally distributed across the mass range and is believed to be mainly due to UV photons striking the continuous dynode detector and producing a cascade of electrons which register as an ion signal in the counting system. Although the pulse counting detector in our instrument is of a similar form, the long ion flight path, together with the ion optics configuration acting as optical baffles, means that no photons are incident on the detector. The measured background is 0.1 Hz and approaches the dark current limit for such detectors. The instrument also utilises an on-axis Faraday detector for ion beam measurement in order to extend the instrument dynamic range to 10 orders of magnitude.

The different mass response of the double focussing analyser leads to a mass response curve with a form different from that of the quadrupole ICP-MS systems. Greatest sensitivity is found for high mass isotopes. At present, limits of detection of 10 - 50 femtograms/ml have been achieved in low resolution mode.

The requirements with regard to the energy and trajectory of ions entering such an analyser are very different from the quadrupole analyser. The development of a source to give the high ion energies (typically greater than 4keV for high sensitivity) required has necessitated further investigation of the operation of the plasma sampling process and its interaction with the electrostatic focussing of the ion beam. These results show that the plasma sampling interface performs in a way similar to that in the PlasmaQuad instrument and that the acceleration of the ion beam does not appear to affect figures of merit such as the levels of doubly charged ions formed.

The analytical performance of the system has yielded information with regard to the source and nature of polyatomic species. This is of interest to users of the current range of commercial instrumentation in recognising potential problems in analyses and also demonstrates the benefits that high resolution ICP-MS offers the analyst.

ICP-MS MEASURABILITY LIMITS
IN CONCENTRATED SOLUTIONS

C. BEAUGRAND, T. DELAPORTE, G. DEVANT
S.N. NERMAG 49 QUAI DU HALAGE 92500 RUEIL FRANCE

The inductively coupled plasma source associated with the mass spectrometer technique (ICP-MS) is mainly known for the low detection limits (D.L.) it can achieve (sub ppt). D.L. may be defined as the calculated concentration of a pure element which produces a signal equal to twice the standard deviation of the background fluctuations.

Real life samples are trace elements contained in a heavy matrix. A more realistic criterion is then the measurability limit (M.L.). This is the concentration of an analyte that yields an intensity signal equal to the intensity of the background. This value is closely related to the degree of slope of the calibration curve.

With heavy matrix, sample dilution is required in order to obtain a concentration acceptable for the ICP nebulizer, torch and MS interface (possible clogging of orifices, plasma extinction or instability). The drawback is that ultimate dilution of the sample is dictated by the measurability limit of the apparatus used.

It is then important that the apparatus can work with the highest matrix concentration possible during all the time required for the measurements.

Our instrument, the PLASMASS use a standard C1 Meinhard nebulizer and a 1 mm diameter sampling hole but works at 40.68 MHz and use an analog mode of detection. We investigated the response of our instrument and present here three set of results .

The first one come from two different solutions : a matrix of Fe at 5 g/l and a matrix of NaCl at 5 g/l. Several elements (up to 11) have been observed during the same run. For quantitation purpose various low concentrations have been used. For each element the quantitation curve has been drawn. We used AUTOQUANT software for NaCl solution (area calculation), and SPECTRAL software for Fe solution (peak height calculation). For measurability limits calculations a statistical treatment has been used . Results are sum up in the following table.

The second set come from a solution with a Se matrix at 10 g/l. We looked for an identification of unknown elements by scanning a large mass range. We used the SPECTRAL software. On the one hand we recorded the matrix only spectrum (blank) on the other hand the unknown solution. The difference between the two

shows the unknown elements. A semi-quantitative estimation gives sub ppb level for P, Ag, Cd, Os and Pb.

The last set use the SCOPE software for instant display of analysis.

It shows various analysis of real sample as 0.1 µg/l of Zn in a Cu matrix of 0.01 g/l (see fig 1); or 10 µg/l of Mn in a 1 g/L Fe matrix ;or 10 µg/l of B in a red wine sample.

PRECISE MASS MEASUREMENT OF FAB IONS USING AN ALTERNATING SAMPLE PROBE AND PEAK MATCHING ON THE KRATOS MS50

Alan Hogg, Dept of Chemistry, Univ of Alberta, Edmonton, Alberta, CANADA T6G 2G2

Objective

For several years FAB ionization has been used in this laboratory to obtain molecular weights for a range of compounds which cannot be handled by other techniques.

High resolution mass measurements using the peak matching technique have been made on a few unknowns in order to obtain elemental compositions but the reference ions used have been from the matrix or reference compounds mixed with sample. The results have been generally unsatisfactory because of difficulties in maintaining both sample and reference ions of suitable intensity during the measurement.

An alternating probe has therefore been built which allows the sample and reference to be deposited on separate surfaces and it has been used in conjunction with a new FAB source and gun mounted on a modified MS50 source housing. The details of construction and the results obtained are described.

The Alternating Probe

The probe consists of a 0.478" diameter shaft through which a 0.063" diameter inner rod passes. The end of the shaft carries an O-ring seal mounted slightly eccentrically relative to the axis of the shaft. The inner rod passes through this O-ring which is lightly lubricated with polyphenyl ether so that it provides a good vacuum seal but allows the rod to be rotated freely. At the vacuum end the rod carries a high voltage insulator and a clamp which allows sample/reference tips of various configurations to be mounted. For the initial experiments a simple cylindrical copper tip is used with two flat faces at 70° to the normal. The eccentricity of the shaft is such that the centre of either of the faces can be aligned with the centre line of the shaft by rotating the rod.

The other end of the rod is attached with a sleeve to a stub shaft carrying a gear wheel. This wheel meshes with a larger gear which can be rotated through a few degrees of arc by the action of a 24 vdc solenoid. A return spring reverses the motion when the solenoid is deactivated. The gear ratio and a mechanical stop are arranged so that the rod rotates exactly 180° when the solenoid is activated. A green LED lights when power is applied to the solenoid and a red LED is wired via a phototransistor sensor so that it will light only if power is applied to the solenoid but the gear mechanism does not complete its proper travel.

Power for the probe solenoid is derived from the MS50 via a relay which operates in parallel with the relay which selects the high mass/low mass position in the peak switching circuitry. A reversing switch allows the solenoid to be activated at either high or low mass.

The FAB Gun

A compact saddle-field FAB gun of a design similar to that already described [A.M.Hogg, Int. J. Mass Spec. Ion Phys., 49 (1983)25.] has been built. It has an integral flange with an O-ring groove and uses only two bolts to mount it to the source housing. It is therefore a very simple matter to clean or replace insulators or electrodes. A simple metal manifold supplies xenon to it via a Negretti needle valve. A standard Spellman power supply [RHR10P60/CR] provides the high voltage, normally 8kV at 1mA.

The Source Housing

The MS50 has been modified so that a source flange with an integral insertion lock can be mounted. This lock is used to admit the alternating probe and a very simple source assembly consisting basically of an extraction slit and two beam centering plates is mounted on the flange. A spring-loaded wiper applies the full accelerating voltage to both the probe tip and the extraction slit.

The FAB gun is mounted through a new port drilled between two of the existing source ports in the housing and a 3" diameter window has been added to one side of the housing so that the probe tip and source region can be clearly seen. The collimating magnets are normally removed to improve visibility and reduce the chance of high voltage breakdown.

Results and Discussion

Our earlier experience with exact mass measurements on FAB produced ions using a simple sample probe showed that devising a particular reference for each measurement attempted was too cumbersome a procedure for routine work. With the alternating probe, the ideal reference would be an alkali halide applied dry to the reference surface and left there for long periods while only the sample in liquid matrix on the other surface is replaced between experiments. CsI is the obvious choice for a reference but it suffers from the sole drawback that its series of cluster peaks are 260 daltons apart. This means that large ratios on the decade box may be required for ions which fall far from CsI clusters and measurement errors in peak matching generally become larger as the ratios used increase. The problem of course becomes less at higher masses and that is where most of the measurements will generally be required.

We have found that systematic errors in the MS50 peak matching system can be kept stable and linear over wide ratios provided both the Y and Z deflection plates are set to ground potential. The loss in sensitivity a 10,000 resolving power that this entails is negligible if all the other tuning parameters are carefully adjusted. It is then possible to use a CsI cluster as a low reference, measure the ratio to the next higher cluster before and after sample ratio measurements (normally just a rapid check), and use a simple linear correction for all the intermediate ratios.

Mixtures of alkali halides have been used as a reference but the advantage of closer spaced ions does not outweigh the simplicity of the single component except at very low mass. Pure NaI has also been used and it has the added novelty of producing a bright yellow glow in the fast atom beam.

Accuracy of measurement is partly dependant on the time spent making it. If the 0.1 ppm decade is not used, a quick measurement on the MH^+ ion of a peptide in the 1000 dalton range can be made with a single sample loading and is accurate to about 3ppm. If such a measurement is followed by withdrawing the probe, adding more matrix, and a very careful match made with a 3 sec sweep of the oscilloscope, 3Hz bandwidth and use of the 0.1 ppm decade, the measurement accuracy can generally be improved to 1 to 2 ppm.

The MS50 used for this work will soon be modified with a fully laminated magnet, shock mounts and a digital mass readout all of which should make this technique more routine and reliable.

FIELD DESORPTION OF ORGANIC POLYMERS

S C Davis, University of New South Wales, Australia presently at Kratos Analytical

S Evans and G Elliott, Kratos Analytical, Barton Dock Road, Urmston, Manchester M31 2LD, UK

Introduction

Field desorption (FD) is a useful ionisation method for many non-volatile compounds, e.g. peptides, porphyrins and carbohydrates. The method typically produces molecular ion species $[M]^+$ and/or pseudomolecular ion species such as $[M+H]^+$, $[M+Na]^+$, and can therefore provide molecular weight information. FD remains the ionisation method of choice in mass spectrometry of many synthetic organic polymers.

Experimental

A field desorption source is available on the Kratos Concept mass spectrometer. The FD source (Figure 1), as with the range of other ionisation sources offered on Concept, can simply be clipped into the source chamber of the mass spectrometer to allow quick and easy source switchover. The source is actually a dual source and can be operated in a FAB mode. This feature enables easy calibration at high mass. The FD emitter is introduced into the source on a probe via an insertion lock. The FAB source ion optics are located in front of the FD source optics, the FAB probe being introduced via a side insertion lock.

Results

Results for several organic polymers are shown in Figures 2-6. Figure 2 shows the FD mass spectrum of a sample of polypropylene glycol (av. mol. wt. 1000) from a single scan. Figure 3 shows the FD mass spectrum of a sample of poly (2,2,4-trimethyl-1,2-dihydroquinoline) from an integration of 15 scans. Figure 4 shows the FD mass spectrum of a sample of polystyrene (av. mol. wt. 2800) from an integration of 5 scans. Figure 5 shows the FD mass spectrum of a sample of polyoxyethylene terephthalate - "POET" polymer from an integration of 34 scans. Figure 6 shows the FD mass spectrum of a polysulfone polymer. As can be seen from the spectra the method is able to provide information on the actual molecular weight distribution obtained from the manufacturing process.

AN AUTOMATED SOLIDS INSERTION PROBE SYSTEM FOR AN ORGANIC MASS SPECTROMETER.

D.C. Smith, V. Gould and H. Mistry.
VG MassLab Ltd., Altrincham, Cheshire, UK.

A high throughput of routine probe samples is a common feature of many laboratories, particularly those in the pharmaceutical industry. This repetitive and tedious procedure involves little operator skill and is therefore ideally suited to some form of automation.

We have developed an automated solids probe system that automatically produces mass spectra and, if required, library search results for each of a batch of solid samples.

A laboratory robot is used to manipulate loaded sample tubes and to remove tubes after analysis. The solid sample insertion probe is automatically admitted to and withdrawn from the ion source using a pneumatically driven multi-position linear actuator. Water cooling and a powerful heater close to the probe tip provide precise control of sample temperature.

The introduction lock is of conventional design. The ball valve is pneumatically operated and the rough pumping is controlled by a solenoid valve. The complete system has been designed to be fitted to the mass spectrometer without interfering with other inlets.

The samples are first loaded into conventional sample tubes in the normal manner. Each tube is then loaded into a stainless steel sample tube carrier. (A separate carrier is used for each sample.) The carriers are placed, in order, on a rack ready for analysis.

The purpose of the sample carrier is two-fold:

The internal profile of the carrier ensures that the sample tube is accurately located to engage with the hole in the tip of the probe.

As each sample is placed within its own sample carrier, the possibility of cross-contamination between samples is eliminated.

The sequence of operation is as follows:

- 1] The laboratory robot picks up the first carrier from the rack and transports it to the tip of the probe.
- 2] The carrier is pushed over the tip of the probe, locating the sample tube in the tip.
- 3] The carrier is withdrawn leaving the tube in position. The tube is pushed fully home using the rim of the empty carrier before the carrier is returned to the rack.
- 4] The probe moves to the first stage of the vacuum lock and the roughing valve opens. When the roughing pressure is sufficiently low the ball valve opens and the probe moves into the ion source.
- 5] If necessary the probe tip is heated to evaporate the sample. Data is acquired in the normal manner.
- 6] The probe is withdrawn to the intermediate position and the vacuum valves close. The probe then moves to the rest position.
- 7] The sample tube is removed from the probe and returned to the rack. The next carrier is picked up and the cycle repeats.

A complementary system is available to allow liquid samples to be automatically injected onto the probe tip. Both systems allow repetitive, routine sampling to be carried out automatically, leaving the operator free to concentrate upon evaluating the results. In addition to relieving the tedium of manual probe operation, laboratory productivity can be significantly improved.

Prediction of Relative Sensitivities in Electron Ionization Mass Spectrometry. Charles Allgood and Burnaby Munson, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716.

One problem in the quantitation of complex mixtures by any technique is the uncertain availability of the standards which are needed to establish the sensitivities or the relative sensitivities of the compounds in the mixture. Methods of predicting relative sensitivities or correlating sensitivities with molecular structures are of great importance in reducing the necessary number of standardization experiments. With the extensive use of gas chromatography electron ionization mass spectrometry (GC/EIMS) for the quantitative analysis of complex mixtures, the ability to predict the sensitivity of a compound based upon molecular properties would be extremely useful, particularly for environmental and fossil fuel samples for which individual components are not available.

If there are no significant mass discrimination effects in the mass spectrometer, then the total sample ionization as measured at the detector is proportional to the total sample ionization in the source of the mass spectrometer with very similar, if not identical proportionality constants for all compounds. In the present GC/EIMS experiments, performed on a Hewlett Packard Mass Selective Detector, the total ion current, TIC is obtained for each mass spectrum by summing the ion currents of all sample ions registered at the detector. These total ion currents are summed for each component over the time it elutes from the GC. From the ratios of total areas for mixtures of known composition, one can calculate the ratios of sensitivities and of ionization cross sections.

The tuning parameters for the HP MSD varied significantly over the period in which these measurements were made but the relative abundance of the fragment ions in PFTBA, remained fairly constant. For example, the abundance of the ions at m/z 219 (relative to the ions at m/z 69) ranged from .72 to .87 with an average value of $.76 \pm .07$. The relative abundance of ions at m/z 502 ranged from .05 to .14 and had an average value of $.10 \pm .03$. The variation in tuning parameters did not have a significant affect on either the short, medium, or long term reproducibility of the technique. The average standard deviation was about 3% for the short term and 15% for the long term experiments.

In order to assure no losses were occurring due to adsorption of high molecular weight compounds a set of experiments were done in which the temperature of GC/MS transfer line and the ion detector were varied $\pm 40^\circ\text{C}$ from their standard temperatures (280°C). The data showed no major variation in this range of temperatures. The value for the relative sensitivities of the higher molecular weight, less volatile esters were somewhat lower in the experiments using the lowest temperature (240°C) for the transfer line, then at 280°C or 320°C , however there was no indications of significant adsorption losses of these compounds at the temperatures routinely used in these experiments.

A comparison was made between the relative sensitivities for one set of compounds measured on two different mass spectrometers, the MSD and a Dupont magnetic mass spectrometer. The results are in very good agreement, the average ratio of the two results being nearly unity, 1.02 and the differences between the values being less than the uncertainties in the measurements. Other samples were introduced from a solids probe and also gave results in good agreement with the MSD indicating no significant discrimination effects of differential loss processes in the experiments.

The relative sensitivities obtained in these experiments can be compared to previously measured ionization cross sections (1) after appropriate scaling to a common reference compound. The average value for the ratios of these two sets of data was 0.98 with a standard deviation of ± 0.06 .

Linear correlations between the sensitivity or ionization cross section for a wide variety of compounds with a number of easily obtainable molecular parameters (molecular weight, carbon number, molecular polarizability) have been observed. The molecular polarizability, which can be calculated from the molecular formula, appears to give the most reliable prediction for the relative sensitivity of a compound in these GC/EIMS experiments.

Internal Standard System for Use with APCI Mass Spectrometers

P.R. Nelson
R.J. Reynolds Tobacco Co.
BGTC 611-13/102E
Winston-Salem, NC 27102

At R.J. Reynolds, a SCIEX TAGA 6000 tandem mass spectrometer is used to sample environmental tobacco smoke (ETS) produced in a 16 m³ stainless steel test chamber. Real-time measurements of ETS constituents are typically obtained over a 0.5-4 hour sampling period. Our experience has shown that during this period, sensitivity of the spectrometer can slowly drift by as much as 10%. In addition, some analytes are plagued by interferences from other major constituents of the ETS matrix, and occasionally, abrupt changes in sensitivity occur.

A system to overcome changes in instrument sensitivity was developed. A steady concentration of an internal standard is blended with air sampled from the environmental chamber. Response of the spectrometer to the standard is used to correct data obtained for other analytes. Results from tests of this system with d5-pyridine as the internal standard are presented here. Pyridine vapor was generated in the chamber, and the internal standard was used to correct both natural and electronically induced changes in instrument sensitivity.

Figure 1 shows a block diagram of the internal standard system. The internal standard is generated in a Kin-Tek precision gas standards generator. A Kin-Tek d5-pyridine permeation tube (1021 ng/min @ 60°C) was placed in the generator. The temperature in the generator was set to 30° to reduce the permeation rate of the standard (est. ≈180 ng/min). In the work described here, flow through the oven was set at ≈250 ml/min, and dilution air was not used. The output stream from the generator was connected to the bottom of a "T" fitting. Diluted air from the ETS chamber was also drawn through the fitting. The combined flow passed through a 30 cm length of Teflon® tubing which was connected to the APCI source of the spectrometer.

Real time data was obtained with SCIEX's MIXTUR program. Internal standard data was collected in the first of eight reaction monitoring channels. Following a run, the raw data was converted to an ASCII file with MITEXT, a program specially written by SCIEX for that purpose. The data was then downloaded to a PC, and internal standard correction was performed using a program written in this lab.

Figure 2 shows an example of the application of the internal standard to the correction of both long term sensitivity drift and sudden changes in instrument sensitivity. The progressive separation of the two lines, particularly at 12-60 minutes, is due to drift in the spectrometer sensitivity. The sudden drop and rise in the uncorrected line at 60 and 180 minutes was induced by manually changing the potential on one of the lenses. The sudden changes shown here are of greater magnitude than those naturally observed in this lab. The internal standard was able to correctly for both changes in sensitivity induced in this manner.

Use of the internal standard to correct the concentration of pyridine measured in an ETS matrix is illustrated in Figure 3. The chamber was operated at one air change/hour during this test. Two Kentucky reference 1R4F cigarettes were smoked in the chamber between minutes 12-20. Pyridine is generated during the entire smoking interval. However, the concentration of nicotine present in the chamber during this test was sufficient to suppress the ionization of pyridine. Both pyridine and d5-pyridine have similar ionization characteristics, and it can be assumed that, in the presence of interferences, the signal from each of these compounds will be decreased by the same relative amount. Following correction of pyridine concentrations with the internal standard, the concentration profile obtained is consistent with the steady generation of pyridine over the smoking interval followed by decay due to dilution with incoming air.

The internal standard system described here provides a simple, reliable method for correcting sensitivity changes of an APCI mass spectrometer. Use of the system to overcome abrupt changes in sensitivity, sensitivity drift, and matrix interference have been demonstrated. The system consists of a stable source of internal standard (with sensitivity similar to the compound being analyzed) and necessary plumbing to introduce the standard into the gas sample being analyzed in the APCI ion source.

NON-CONTAMINATING CI MASS CALIBRATION
STANDARDS FOR QUADRUPOLE AND MAGNETIC INSTRUMENTS

Fong-Fu Hsu*, Andrew N. Tyler** and William R. Sherman*,
Departments of Psychiatry* and Biochemistry**,
Washington University School of Medicine, St. Louis, MO 63110

In an attempt to compare quadrupole and magnetic spectrometers for sensitivity in the mass range 1000 to 2000 daltons we found the widely-used calibrant tris(perfluorononyl) triazine to give much lower ion currents at m/z 1466 and m/z 1066 on a Hewlett Packard 5988A quadrupole instrument in positive ion electron ionization than was obtained on a VG ZAB SE magnetic instrument under the same conditions. Severe contamination occurred on both instruments, with visible residues accumulating on cool surfaces of the HP 5988A during use. The problem appeared to be due to low quadrupole sensitivity for this compound requiring large amounts of the calibrant to be introduced in order to obtain useful spectra. In an effort to obtain a less contaminating calibrant we investigated perfluoroacyl carbohydrates in this regard. Objectives in the design of a better calibrant for use in this mass range were volatility, usefulness via the direct insertion probe inlet and a spectrum with an adequate number and distribution of ions of significant intensity to be useful in calibrating magnetic instruments.

PROCEDURE: Cellobiose (4- $\{\beta$ -D-glucosido $\}$ -D-glucose) was converted to both homogeneous cellobiose octa(heptafluorobutyrate) and to the mixed ester heptafluorobutryl/pentafluoropropionyl (HFB/PFP) cellobiose as follows: 20 mg of the carbohydrate was heated for 48 hours at 60 degrees with 0.5 ml of acetonitrile and 0.5 ml of either heptafluorobutyric anhydride or a 3:1 (v:v) mixture of HFB anhydride and PFP anhydride. The derivatized substances have been found to be stable for several months at -20° C. if stored in the original reaction mixture.

RESULTS

NEGATIVE ION CI: The negative ion methane CI spectrum of octa (heptafluorobutryl) cellobiose on the ZAB had intense ions at M^{-} (m/z 1910) and $[M - HF]^{-}$ (m/z 1890). The same ions appeared in the spectrum from the 5988A with reversed intensities (m/z 1910 $>$ 1890). Other high-mass ions in the spectra from both instruments were m/z 1713 ($[M - C_3F_7CO]^{-}$), m/z 1697 ($[M - C_3F_7COO]^{-}$), m/z 1694 ($[M - F - C_3F_7CO]^{-}$) and m/z 1677 ($[M - HF - C_3F_7COO]^{-}$).

POSITIVE ION CI: In positive ion methane CI the ZAB SE spectrum of octa(heptafluorobutryl) cellobiose had ions of useful intensity at $[MH - HF]^{+}$ (m/z 1891) and ions resulting from the losses of heptafluorobutyric acid at m/z 1697, m/z 1483 and m/z 1269.

POSITIVE ION EI: These spectra had no high-mass ions of useful intensity on either instrument.

NEGATIVE AND POSITIVE ION CI OF THE MIXED DERIVATIVE OF CELLOBIOSE: In the negative ion methane CI spectra of heptafluorobutryl/pentafluoropropionyl cellobiose well-distributed ions of good intensity were obtained on the ZAB SE. The negative ion spectrum on the Hewlett Packard 5988A was similar in intensity to that of the ZAB but with differences in the fragmentation pattern as noted. The positive ion methane CI spectrum of the mixed derivative on the ZAB SE was similarly constituted with many ions of useful intensity. A characteristic of these spectra that makes them useful, aside from intensity of the ions, is that the mixed derivative spectra are made up of ions 50 u apart (i.e. the difference in mass between heptafluorobutyric and pentafluoropropionic acids) that result from molecules with different HFB/PFP ratios. Typically a 50 microgram sample introduced by an unheated probe and with a source temperature of 100° (HP) or 150° (ZAB) gave useful spectra for tens of minutes. Residual calibrant was not a problem, even the strongest ions were not evident once the probe was withdrawn.

Listed below are the calculated mass values and intensities of negative and positive ions in the spectra of the mixed heptafluorobutyl/pentafluoropropionyl derivative of cellobiose obtained by methane chemical ionization on a ZAB SE.

NEGATIVE ION CI (CH₄)

POSITIVE ION CI (CH₄)

THE DYNAMICS OF IONS IN THE DRIFT REGION
OF A CORONA TYPE MS SOURCE:
SOME MATHEMATICAL MODELS
MARK BUSMAN AND JAN SUNNER,
DEPARTMENT OF CHEMISTRY
CURT VOGEL, DEPARTMENT OF MATHEMATICS
MONTANA STATE UNIVERSITY
BOZEMAN, MT 59717

Techniques using high pressure ion sources are becoming increasingly important in mass spectrometry. Examples are atmospheric pressure ionization mass spectrometry (API/MS) usually with a corona discharge and electrospray (ESP) mass spectrometry. In both of these techniques, because of high pressure, ions are transported through the source by ion drift in electric fields and by diffusion in concentration gradients,

$$J = \rho \kappa E - D \nabla \rho$$

where J is the ion current vector, ρ the number of ions per unit volume, κ the coefficient of ion mobility, E the electric field vector. Also, with corona discharges or electrospray, only ions of one polarity are present in the source. Typically, the associated space charge is the main factor determining the potential distribution and the electric fields in the source. Then the motion of the ions is determined more by the space charge distribution than by the potentials applied to the ion source walls, to extraction electrodes or to discharge needles or capillaries. The relative importance of the space charge effect depends on particular experimental parameters. Important factors are, for example, the discharge current, the applied electrode potentials, and the size and geometry of the ion source. In the extreme case where all electrodes and ion source walls are at the same potential (a field free source) ion transport will be determined solely by the space charge. There is presently very little information on space charge effects in mass spectrometry sources.

Here, we present a study of the effects of space charge on ion transport in high pressure sources.

A complete mathematical description of ion motion can be obtained by combining Maxwell's equations for electrodynamics with the Navier-Stokes equations for fluid dynamics. We are primarily interested in steady state behavior, and we assume that ion concentrations are sufficiently low that viscous effects are negligible. This results in considerable simplification of the model.

The relationship between the charge density ρ and the electrostatic potential, or voltage, u is given by Gauss' law

$$-\nabla \cdot \nabla u = 4\pi \rho / \epsilon$$

Here ϵ is the electric permittivity of the medium and is assumed to be constant. $E = \nabla u$ is the electric field.

The continuity equation

$$\nabla \cdot J = 0$$

essentially says the amount of current entering an infinitesimal volume element equals the amount of current leaving the element. The current density is given by

$$J = \rho \kappa \nabla u - D \nabla \rho$$

The first term represents ion drift, or transport, due to the electric field. The second term represents diffusion of ions resulting from the concentration gradient. κ is the coefficient of ion mobility, and D is the diffusion coefficient. Both κ and D are assumed to be constant. A further simplification in the model occurs if we ignore diffusion effects and set $D=0$. We refer to this as the diffusion free case.

For very special geometries and for the diffusion free case ($D=0$), we can obtain analytical solutions to this system. We present results for the following geometries in three dimensional space:

1. Two planes, both perpendicular to the x-axis.
2. Two concentric cylinders with circular cross sections centered at the z-axis.
3. Two concentric spheres centered at the origin $x=y=z=0$.

These geometries, while not exactly corresponding to any real physical system, help to give some indication of the effect that space charge can have in various types of sources. Furthermore, these analytical solutions set the groundwork for the extension of the method, both toward more realistic geometries and to a system incorporating diffusion effects.

This work offers some obvious areas for extension. First, the method needs to be made applicable to a wider variety of source geometries. However, this will require a great leap in mathematical complexity. Rather than utilizing the analytical methods, the solutions are going to need to be approximate. We have utilized Galerkin methods to discretize the system. We select basis functions satisfying homogeneous Dirichlet boundary conditions. The system can then be solved by iterative methods. There are several issues to address in the implementation of this method. One of the most important is the choice of appropriate basis functions and boundary functions. Taking into account the symmetry of system can reduce the dimension of the problem which consequently reduces the computational complexity.

Second, it would be desirable to extend the method to time dependent systems. Many applications would benefit from further understanding of non-steady state ion drift. Progress has been made in modelling such behavior in the most elementary geometries.

Third, for many situations, the neglect of diffusion is not realistic. The incorporation of diffusion represents another substantial increase in the mathematical complexity of the problem. Such complexity taxes the practicality of the problem from a computational standpoint.

INSTRUMENT-INDEPENDENT CAD DATABASE FOR IQQ INSTRUMENTS:

Richard I. Martinez and B. Ganguli
Chemical Kinetics Division
National Institute of Standards and Technology
(formerly National Bureau of Standards)
Gaithersburg, MD 20899

Dynamically-correct (i.e., instrument-independent) branching ratios can be measured in XQQ (QQQ, BEQQ, etc.) tandem mass spectrometers (MS/MS) under single-collision conditions. That is, a kinetics-based measurement protocol can provide accuracy and precision for CAD measurements within XQQ instruments. This protocol can be used to develop an instrument-independent MS/MS database (library) for XQQ instruments. To do so, the key MS/MS parameters must be properly selected to compensate for (a) the reaction-induced mass discrimination within Q2 (the rf-only quadrupole mass filter which contains the collision region), for (b) the intrinsic mass discrimination within the Q3 mass analyzer, and (c) for the kinetic energy of the product ions entering Q3.

For the collisionally activated dissociation (CAD) of CH_3CO^+ at a center-of-mass interaction energy $E_{\text{cm}} = 2.4\text{--}38.6$ eV [the range of collision energies used for CAD], the sum of the branching ratios equals 1.00 ± 0.05 for all the fragment ions observed. That is, the rate of reactant ion decay equals the rate of product ion formation. For the source compounds studied [ethanol, oxirane, cis-2,3-epoxybutane, and $\text{CH}_3\text{CO-X}$ (where $\text{X} = \text{H}, \text{CH}_3, \text{CH}_2\text{CH}_3, \text{CH}_3\text{CO}, \text{CH}_3\text{COCH}_2$, and C_4H_9)], the reactant ion entering Q2 appears to be pure CH_3CO^+ . The collisional activation converts a small fraction of the CH_3CO^+ entering Q2 into the other $\text{C}_2\text{H}_3\text{O}^+$ isomers prior to their fragmentation. The product ion distribution for the CAD of $\text{C}_2\text{H}_3\text{O}^+$ at $E_{\text{cm}} = 2.4\text{--}38.6$ eV is quite different from that observed at 4–8 keV. The energy dependence of the branching ratios for $\text{C}_2\text{H}_3\text{O}^+$ from $\text{CH}_3\text{CO-X}$ source compounds is quite distinct from that observed for $\text{C}_2\text{H}_3\text{O}^+$ from ethanol or ethylene oxide (a carcinogen), or for the isobaric C_3H_7^+ from n-pentane. Hence, one can use the CAD of 43° to distinguish $\text{CH}_3\text{CO-X}$ compounds from other source compounds, including sources of the isobaric C_3H_7^+ . Therefore, the energy dependence of the branching ratios may provide a MS/MS "fingerprint" for ionic substructures. The "CBRIS" database format (Table 1) is proposed for the development of an instrument-independent CAD database of Characteristic Branching Ratios of Ionic Substructures.

Table 1. Proposed "CBRIS" Database Format ^{1,2,3}

Parent Ion: $\text{C}_2\text{H}_3\text{O}^+$ (m/z 43) ^{4,5} **Notes:** 9, 99, 999 ⁶
Source Compound: 2,3-butanedione (99.9%)
Ionization Mode: 70 eV electrons

E_{cm} (eV)	σ (Å ²)	α (13°)	β (14°)	γ (15°)	δ (26°)	ϵ (27°)	ζ (28°)	η (29°)
2.4	15 (20)	0	0	0.999 (2)	0	0	0	0.0010 (50)
19.3	22 (10)	0.0127 (15)	0.0493 (6)	0.915 (2)	0.0101 (7)	0.0013 (10)	0.0005 (35)	0.0114 (7)
38.6	21 (10)	0.0227 (10)	0.0750 (6)	0.839 (2)	0.0436 (6)	0.0055 (20)	0.0055 (20)	0.0086 (15)

- 1 CBRIS= Characteristic Branching Ratios of Ionic Substructures.
- 2 For this example we show the branching ratios (α - γ) vs. the center-of-mass collision energy (E_{cm}) for the CAD of ($C_2H_3O^+$) from the source compound biacetyl.
- 3 The numbers in the square brackets represent the maximum uncertainty in the cross section σ and in the branching ratios (α - γ), expressed as a percentage of each σ and of each branching ratio (e.g., for biacetyl at $E_{cm}=2.4$ eV, the maximum uncertainty in γ is $\pm((2\%)/100) \cdot \gamma$; i.e., $\gamma = 0.999 \pm 0.02$).
- 4 A reference citation would be provided for each CAD spectrum to identify the source of the data.
- 5 For the CAD of any given parent ion (e.g., $C_2H_3O^+$), appropriate corrections must be made for contributions from the concurrent CAD of isobaric ions (e.g., $C_2H_7^+$), regardless of their source. The isobaric ions may be co-produced in the ion source (i) from the source compound (e.g., ionization of $CH_3C(O)C_2H_7$ will produce both CH_3CO^+ and $C_2H_7^+$) and/or (ii) from a neutral impurity in a source compound (e.g., for a butanol impurity in a 2-butanone source compound, the butanol generates $C_2H_7^+$, while the 2-butanone generates CH_3CO^+). Fortunately, the CAD spectra of CH_3CO^+ and $C_2H_7^+$ are easily distinguishable. That is, for the CAD of $C_2H_7^+$, $C_2H_3^+$ (m/z 27) is the major CAD fragment for $E_{cm} = 2-80$ eV. By contrast, for the CAD of $C_2H_3O^+$, $C_2H_3^+$ is not produced at $E_{cm} = 2.4$ eV, and is only a very minor fragment for $E_{cm} > 2.4$ eV. Unfortunately, even minor impurities can contribute disproportionately to the CAD spectrum of a source compound because of differences in the CAD dynamics of isomeric and/or isobaric ions. Because of this problem, it is advisable that both the source compound and the target gas be of high purity ($> 99.95\%$). Otherwise, the impurities must be characterized so that appropriate corrections can be made for their contribution to the observed CAD spectrum.
- 6 The "Notes" field would be used to refer a user of the database to any information of special significance about the parent ion (e.g., structure of the ion, etc.). The notes enumerated in all the "Notes" fields of the CBRIS database would be collected together in a separate "NOTES APPENDIX". For the example given here, Notes 9, 99, and 999 would be found in the "NOTES APPENDIX", and might contain the following types of information.

Note 9: For a given E_{cm} , the branching ratio for each fragment ion is substantially the same for all CH_3CO-X source compounds (e.g., biacetyl, acetone, acetophenone, etc.). The reactant ion entering Q2 appears to be pure CH_3CO^+ in every case.

Note 99: The energy dependence (magnitude and direction) of the branching ratios is distinctly different for the isobars $C_2H_3O^+$ and $C_2H_7^+$. Hence, one can readily distinguish $C_2H_3O^+$ from $C_2H_7^+$.

Note 999: One can readily distinguish ethanol, oxirane, and cis-2,3-epoxybutane from each other, and from CH_3CO-X source compounds on the basis of the energy dependence of the branching ratios for the CAD of $C_2H_3O^+$.

STRUCTURE DETERMINATION OF PEPTIDES AND PROTEINS
BY HIGH PERFORMANCE TANDEM MASS SPECTROMETRY

Klaus Biemann

Dept. of Chemistry, Mass. Institute of Technology, Cambridge, MA, 02139.

High performance tandem mass spectrometry has emerged as a powerful method for the determination of the structure of oligopeptides, namely, the sequence of the amino acids and modifications, if any, of the latter. The use of two double focusing mass spectrometers in tandem permits the selection of the ^{12}C specie of the isotopic $(\text{M}+\text{H})^+$ cluster as the precursor, which then results in a monoisotopic (devoid of isotope clusters) product ion (CID) spectrum. This approach results in a high reliability of the mass assignment for all peaks; the collisions occur at high energy (1-10 kV) which results in highly reproducible spectra, the features of which are very characteristic. From the study of the CID spectra of a few hundred peptides of known or originally unknown sequence and ranging from 5 to 25 amino acids in length, a set of general fragmentation processes and their dependence on peptide structure were deduced (1-3). This knowledge has been incorporated into a computer algorithm which allows the semi-automatic interpretation of the CID spectra of peptides in terms of their sequence (4).

A general strategy for the determination of the primary structure of proteins was developed based on this methodology for peptide sequencing (3). Briefly, the protein is digested first with trypsin, the complex mixture of tryptic peptides fractionated by HPLC into simpler mixtures, which are then subjected to tandem mass spectrometry for the determination of the sequence of each constituent peptide. This set of data is then augmented by similar experiments involving one or more other proteolytic enzymes of different specificity, which results in the formation of a set of peptides of very different sequences. The cumulative information derived from all these CID spectra generally permits the assembly of the complete sequence of the protein.

One example is the determination of the primary structure of the glutaredoxin isolated from rabbit bone marrow (5). This protein was not amenable to the conventional Edman degradation and therefore assumed to be blocked at the N-terminus. One of the CID spectra revealed an N_α -acetylated alanine (Fig. 1) which, therefore, must correspond to the N-terminal peptide. The complete sequence of 106 amino acids was derived from a total of 35 such spectra (Fig. 2).

One of the advantages of high energy collisions (>1 kV) is the formation of fragment ions (designated d_n and w_n), which are due to cleavage of the side chain of the amino acid at which the peptide backbone has been split (2,6). These processes permit the differentiation of the isomeric amino acids leucine and isoleucine. In the case of the rabbit bone marrow glutaredoxin, 15 of the 19 leucines and isoleucines could be differentiated in this manner but the peptides containing the remaining four did not give rise to either d_n or w_n ions. For these the formation of d_n ions was forced by formation of their N_α -(trimethylammonium)acetyl derivative, a reaction which places a fixed charge at the N-terminus of the peptide (7). The spectrum of the derivative of the octapeptide (positions 56-63) is shown in Fig. 3.

When this work was completed it revealed the close homology of the rabbit bone marrow glutaredoxin with that isolated from calf thymus (8), except that the latter had a rather different N-terminus (pyroGlu-Ala-Ala--) and was missing the four amino acids Thr-Val-Pro-Arg, which occupy positions 68-71 in the bone marrow protein. It was a simple matter to correct this discrepancy by tandem mass spectrometry of a chymotryptic digest of the calf thymus protein. The results revealed that the N-terminal sequence is actually Ac-Ala-Gln-Ala-- and that the missing four amino acids are present at the predicted positions (9).

Recent developments in detector technology have led to an increase in the sensitivity of our JEOL HX110/HX110 tandem mass spectrometer. An array detector covering 6.6% of the mass spectrum per step (10) made it possible to obtain excellent CID spectra with 10 pmol of peptide (11). An improvement which allows one to record up to 30% of the mass spectrum per

step (12) further improves the sensitivity and/or recording time.

This decrease in the amount of sample required makes it necessary to be able to manipulate protein digests at the picomole level and to introduce the resulting peptides into the mass spectrometer without losses or contamination. This has been accomplished by direct or indirect coupling of a packed capillary HPLC column to the ion source of MS-1 of the tandem system. For relatively simple mixtures, CID spectra can be acquired with the array detector while each peptide elutes from the column. In more complex cases, fractions are stored in sample loops attached to a multiposition trapping flow path valve, allowing the trapping of 16 or 23 fractions, respectively (13).

PROTEIN STRUCTURAL PROBLEMS, THE ROLE OF TANDEM MASS SPECTROMETRY
Donald F. Hunt, Jeffrey Shabanowitz, Patrick R. Griffin, Nian Zhou Zhu,
John R. Yates, III, and Paul A. Martino
Department of Chemistry, University of Virginia,
Charlottesville, Virginia 22903

Development of new methods and instrumentation for the structural characterization of proteins continues to be a major goal of our research. Two instruments, a TSQ-70 triple quadrupole and a quadrupole Fourier transform mass spectrometer are employed in this effort. Ten proteins have been sequenced to date and more than forty additional proteins or protein systems are currently under study.

Typical steps employed in the sequence analysis of a protein include digestion of the protein with site-specific reagents such as cyanogen bromide, or proteolytic enzymes, partial fractionation of the resulting mixture of oligopeptides by microbore, high-performance, liquid chromatography (HPLC) and direct analysis of peptides in each HPLC fraction by the process of particle-bombardment, collision-activated-dissociation, on the TSQ-70 triple-quadrupole mass spectrometer and by particle bombardment, laser photodissociation on the quadrupole Fourier transform instrument.

Molecular weight measurements on the quadrupole Fourier transform instrument are routinely conducted on sample at the 0.1-20 pmol level in the mass range up to 6 kDa. Photodissociation of peptide (M+H)⁺ ions with an argon fluoride excimer laser is readily accomplished at the 10-30 pmol but generates complete sequence information for less than 30% of the samples examined. Most samples, including insulin, fragment to small ions in the mass range below 700 Da. Accordingly, the resulting spectra afford only partial structural information.

Sample quantities required for sequence analysis by collision activated dissociation on the TSQ-70 instrument are generally in the 1-10 pmol range for molecules of mol wt below 1,000 Da, 5-50 pmol for molecules below mass 2,000, and 30-300 pmol for molecules whose mol wts fall between 2,000 and 2,600 Da. At these levels the probability of generating a complete amino acid sequence for any peptide sample is generally greater than 90%.

Samples are desorbed from a matrix of thioglycerol (0.5 ul) on a gold plated probe with a Cs⁺ ion gun operating at 6 keV. Source and manifold are kept at 50° C to minimize vaporization of the matrix. Collision experiments employ a 2/1 mixture of argon and xenon at a total pressure of 3 mtorr as the target. Optimal peptide fragmentation is observed when the offset potential on quadrupole II (collision energy) is set between 15-35 eV. Quadrupoles I and III are operated at less than unit resolution to maximize ion transmission. Shown in Figures 1-2 are collision activated dissociation spectra recorded on the (M+H)⁺ ions of renin tetradecapeptide (5 pmol) and the methyl ester of ACTH CLIP (20 pmol).

Shown in Fig. 3 is the primary structure of the rabbit sex steroid binding protein (rSBP) obtained by a combination of tandem mass spectrometry and Edman degradation. Peptides are labeled according to the method used to generate them and the technique used to sequence them. Proteolytic and chemical cleavage methods are designated as follows: K = endo Lys-C, Tr = trypsin, C = chymotrypsin, E = endo Glu-C, El = elastase, D = endo Asp-N, M = cyanogen bromide, A = acid cleavage at Asp. Peptides sequenced by Edman degradation are labeled, -Ed-. Unidentified residues are designated by blank spaces. Peptides sequenced by collision activated dissociation on the triple quadrupole mass spectrometer are labeled by the nominal monoisotopic mass of the corresponding (M+H)⁺ ion. Primary structures deduced from laser photodissociation spectra recorded on the Fourier transform instrument are designated by the label, --FTPD--, followed by the average mass value observed for the isotopic cluster corresponding to the (M+H)⁺ ion. Sequences confirmed by enzyme specificity and molecular mass measurement on the Fourier transform instrument are designated by dashed lines plus the label, --FT--, followed by the average mass value recorded for the isotopic cluster corresponding to the (M+H)⁺ ion. Mass measurements on (M+H)⁺ ions for the corresponding peptide methyl esters were used to support assignments made by this latter method. Predicted incremental mass shifts of 14 Da/carboxylic acid group were observed in all cases.

Edman degradation proved to be the method of choice for generating sequence information at the N-terminus of the molecule, largely because the procedure could be carried out directly on the intact protein. Advantages of the tandem mass spectrometry method include the ability to sequence peptides present in mixtures and the speed with which one can obtain sequence information over the entire length of the protein. Only 3-5 hours of instrument time is required to obtain both molecular mass and sequence data on all peptides generated in any particular digest. As a result, ca. 75% of the rSBP primary structure was assembled into large non-overlapping segments with only several weeks of effort. Location of disulfide bonds is also greatly facilitated by mass spectrometry. Mass measurements performed on peptides from a particular enzyme digest, before and after reduction of the sample on the probe of the mass spectrometer, identifies those sequences attached through a disulfide linkage. This experiment requires only minutes of instrument time.

The major limitation of the above sequencing approach is that it is presently impossible to distinguish Leu and Ile, two amino acids of identical mass, under the low energy collision conditions employed on the triple quadrupole instrument. All 57 Leu and Ile residues in rSBP were assigned from either amino acid composition or Edman degradation data.

The region within the rSBP structure that proved most difficult to sequence by tandem mass spectrometry included residues 260-280. This region contains a paucity of acidic and basic amino acids and a large number of small hydrophobic residues. As a result, proteolytic enzymes produced either one or two peptides whose $(M+H)^+$ ions fell outside the mass range of the triple quadrupole instrument or a large number of small peptides, 2-4 residues in length, the sequences of which could not be overlapped to generate a unique primary structure for this part of the molecule. Automated Edman degradation of a 59 residue Asp-N peptide provided the necessary data to sequence through residues 260-280.

Figure 2.

Figure 3.

now at the University of Hamburg.³ All of the peptides to date contain C-terminal amide functions and most contain a pyroglutamyl N-terminal unit. However, two unusual peptides have provided intriguing challenges. One of these is Pol-RFamide II, derived from *Polyorchis penicillatus* (a hydromedusa). The amino acids identified by hydrolysis were lysine, leucine, arginine, glycine, phenylalanine, and glutamic acid, but these did not add up to the molecular weight. High resolution, however, established the presence of tryptophan, and the CID-induced MS/MS fragmentation indicated the sequence shown (7). Synthesis of 7 indicated the synthetic peptide had slightly different chromatographic and mass spectrometric properties from the natural product. We now tentatively (pending synthesis) assign an ϵ -lysine peptide link.

The peptide Antho-RNamide from the sea anemone *Anthopleura elegantissima* has provided a different surprise. Subtraction of the amino acid units involved from the high-resolution molecular ion of Antho-RNamide leaves a $C_9H_9O_2$ unit (149 amu). Mass spectrometry alone allowed too many options for the N-terminal unit, and we turned to nuclear magnetic resonance to assign that structural unit. 1H NMR showed the presence of a benzene ring and a CH_3CH group. Combining these data with the FABMS/MS spectrum of the acetyl derivative of Antho-RNamide allows assignment of the tentative structure 8, again subject to the results of synthetic studies underway.

Cyanobacterial Hepatotoxins. Cyanobacteria produce a variety of toxins, often of significance to human health. The hepatotoxins which thus far have been found in *Microcystis* and *Nodularia* species are cyclic peptides containing the uniquely characteristic C_{20} amino acid Adda [(2S,3S,8S,9S)-3-amino-9-methoxy-2,6,8-trimethyl-10-phenyl-4,6-decadienoic acid]. We recently completed structural assignments of two of these compounds, microcystin-LR (9) and nodularin (10), including all stereochemical aspects of Adda.⁴ With these hepatotoxins, FAB fragmentation of the intact molecule and its hydrogenated counterpart did not occur, so that sequencing was not possible. Sequencing was, however, carried out on the partial hydrolysis product from dihydronodularin, and FABMS/MS analysis indicated it to be a mixture of at least three peptides. Successive application of FABMS/MS to successive fragment ions allowed partial assignment of the structures of the three peptides, which could then be combined to a partial structure for nodularin, the complete assignment resting at that stage on analogy to earlier assignments of microcystin structures. We have now developed what appears to be a useful general method for dealing with sequences of these cyclic peptides: this involves ozonolysis, followed by sodium borohydride treatment to give a linear protected peptide whose structure can be assigned by standard fragmentations, as shown in Scheme 1.

Scheme 1

Tryptic Digests of Aldose Reductases. In collaboration with Professor C. C. Doughty at the University of Illinois-Chicago and Dr. C. E. Grimshaw, Scripps Clinic and Research Foundation, La Jolla, we have recently been investigating the sequences of the aldose reductases from bovine lens and bovine kidney. Bovine lens aldose reductase was first cleaved with cyanogen bromide to give four large fragments. The C-terminal fragment was subsequently treated with trypsin, and the four isolated tryptic peptides were submitted to FABMS/MS sequencing. The three larger peptides indeed gave the fragmentations expected on the basis of earlier Edman degradation. More problematical was the N-terminal cyanogen bromide fragment, which was N-protected. While it was initially thought to contain 24 amino acids, this peptide gave mass spectral fragmentation consistent with half that molecular weight, that is, 12 amino acids, including the C-terminal homoserine lactone (protected as the dimethylaminoethylamine derivative). Partial sequencing was also successful (11), employing the B/E scan technique on our ZAB SE spectrometer. When a subsequent tryptic digest became available, FABMS/MS showed the N-terminal tryptic peptide to contain the expected 11 amino acids and confirmed the presence of lysine adjacent to the homoserine unit. Taking account of the amino acid composition of the undeca-peptide, we deduced the N-terminal group to be an acetyl and used the CID-induced fragmentation to assign the sequence shown (12). Initially the positions of leucine and isoleucine were regarded as interchangeable. Careful consideration of the FABMS/MS spectrum, however, and final comparison with two authentic synthetic samples containing the alternative locations of the leucine and isoleucine units established isoleucine at position 4 and leucine at position 6. With the N-terminal sequence in hand, the sequence of bovine lens aldose reductase was completed.

More recently, we turned our attention to the aldose reductase from bovine kidney. More specifically, we have compared the tryptic digests of bovine lens aldose reductase and bovine kidney aldose reductase with respect to the identifiable tryptic peptides present. No separation was attempted of the tryptic peptides, mass spectra instead being determined on the crude mixture. All peptides recognized were identified by their LRFAB mass spectra and most by their HRFAB spectra as well as FABMS/MS carried out on the 70 SE 4F spectrometer. These experiments are discussed in greater detail in another paper in this volume;⁵ it should be noted here, however, that approximately 27% of the sequence of bovine lens aldose reductase is found also in bovine kidney aldose reductase. More impressively, essentially all of the peptides found to date in the bovine kidney tryptic digest are also found in bovine lens digest. One major difference is the N-terminal peptide from bovine lens; it has not yet been found either in derivatized or underivatized form in bovine kidney.

**AN INTEGRATED APPROACH TO PEPTIDE AND PROTEIN STRUCTURE
ANALYSIS UTILIZING TANDEM HIGH PERFORMANCE MASS SPECTROMETRY**

Steven A. Carr, Mark F. Bean, Mark E. Hemling and Gerald D. Roberts
Smith Kline and French Laboratories, Department of Physical and Structural Chemistry, King of Prussia, PA

The availability of large amounts of purified recombinant proteins together with the ability to specifically alter the structures of these compounds promises to revolutionize both the treatment of diseases and our understanding of their molecular bases. Many of these proteins are being developed as potential therapeutic agents, while others are being made for diagnostic purposes and for structural studies directed at elucidating their mechanism of action.

While cloning and sequencing of the gene coding for virtually any desired protein can now be accomplished with tremendous speed and efficiency, structural characterization of the recombinant protein product is often a relatively slow step. Amino-terminal and carboxy-terminal sequencing of the protein product are required to establish identity and internal sequences must be verified to check the fidelity of translation. Difficulties frequently arise with application of conventional sequencing methodologies such as Edman degradation since the N-termini of recombinant proteins are often blocked preventing confirmation of this region. Many other native or induced protein modifications cannot be identified by Edman. Clearly fast, sensitive, and reliable procedures are necessary to bridge the analytical gap between protein chemistry and molecular genetics. Unfortunately, no one technique is sufficiently accurate or rapid. Successful structural characterization of macromolecules like peptides and glycoproteins requires a coordinated, rational approach and close collaboration among spectroscopists, biochemists and chemists. Having the right instrumentation is only part of the solution.

In our laboratories at SKF we use MS and, since early 1986, tandem MS (VG ZAB-SE 4F) together with conventional chemical and enzymatic sequencing techniques to solve structural problems that are not readily soluble by any single technique. In our experience, peptide molecular weight determination by FAB/MS coupled with analysis of specific peptides by tandem MS is an ideal complement to Edman degradation for structural characterization of peptides and proteins. Tandem MS has been particularly useful in defining the location and structure of posttranslational modifications in peptides and proteins and for sequencing synthetic peptides incorporating unusual amino acids or in cases where the synthesis has gone awry (1). We have used this integrated approach to characterize androgen-dependent proteins from prostate and seminal vesicles, neuromodulatory enzymes and lymphokines. In these studies tandem MS has been used to determine the sequence of N-terminally blocked peptides (2,3), locate and correct errors in DNA and cDNA-deduced protein sequences (4), obtain internal and C-terminal sequence information for verifying the fidelity and the end of translation (3,4,7), define the site of attachment and sequence of peptides labeled with suicide substrate inhibitors (5) and naturally-derived peptides with unusual side-chain modifications (6), and pinpoint sites of deamidation in proteins (7).

The principles of this combined approach are illustrated by our structural studies of tumor necrosis factor (TNF), a protein which induces hemorrhagic necrosis of various tumors in animals. We were asked to check the overall sequence fidelity of a sample of TNF which had been found to have altered activity in a bioassay relative to the reference standard. Ninety-two percent of the protein sequence was corroborated in this single experiment. However, two signals, at m/z 1241.6 and 1397.7, could not be mapped to the deduced sequence. Both of these signals are 1 Da more than predicted for two expected tryptic peptides. FAB/MS of the tryptic peptide mixture after one and two cycles of manual Edman degradation established that the shifted signals were derived from peptides Arg32-Arg44 and Ala33-Arg44, respectively. Tandem MS of the peptides of $(M+H)^+ = 1397.7$ and 1241.6 (Fig. 1) demonstrated that the single mass unit shift was the result of deamidation of Asn39 to Asp. The tandem mass spectrum of the $(M+H)^+ = 1241.6$ peptide illustrates the typical appearance of the daughter ion spectra of tryptic peptides using high energy (keV) collision induced dissociation. The C-terminal fragment ions observed have the expected masses up to Gly8 based on the predicted sequence, but are shifted upward by one mass as fragmentation proceeds toward the N-terminus through residue seven, indicating that Asn (in-chain mass = 114) at this position has converted to Asp (in-chain mass = 115). Pinpointing the site of deamidation in TNF was completed in approximately one day by MS/MS, and did not require separation or purification of individual peptides.

Deamidation of Asn proceeds via a cyclic succinimide that can reopen to Asp or β -Asp in which the methylene group is now in the peptide chain (Fig. 2). Dodecapeptides Ala33-Arg44 containing Asp and β -Asp at position 7 in the peptides were synthesized and analyzed by FAB tandem MS with high energy collisions. Specific side-chain fragments indicative of Asp vs. β -Asp were obtained by conversion of the peptides to the corresponding trimethyl esters (Fig. 3, top and middle frames, respectively). Methylation of the tryptic digest of TNF and tandem MS of the peptide of m/z 1283.7 (trimethylated 1241.6) indicated that a mixture of Asp and β -Asp had been formed at this location in the protein. Tandem MS using high energy collisions will be useful in distinguishing these residues since no other routine methods presently exist.

^{252}Cf -Plasma Desorption Mass Spectrometry of Metal Clusters

C.J. McNeal, R.E.P. Winpenny, J.P. Fackler and R.D. Macfarlane
Department of Chemistry, Texas A&M University, College Station, TX 77843

We have examined several classes of metal clusters including mixed transition metal-gold complexes, small gold phosphine complexes and large gold phosphine clusters by ^{252}Cf -PDMS. The mixed metal clusters are of interest because of their potential use as bimetallic catalysts and catalyst models (1). The smaller gold clusters are the building blocks of larger clusters which are at the transition between particles with single atom character and larger aggregates that function as bulk materials. There is also potential biological applications of these clusters in the area of imaging and as chemotherapeutic agents when the gold is radioactive. The molecular structures of the small metallic complexes have been determined by a combination of NMR, x-ray crystallography and FABMS. However, the structural characterization of large gold clusters is problematic because they are often too large and heterogeneous to be characterized by x-ray crystallography. Conversely, they are too small to be examined by electron microscopy.

Fast atom bombardment MS has been used to structurally characterize the mixed-metal and small gold clusters (2). The results obtained by ^{252}Cf -PDMS are very similar to the FAB spectra. A typical positive ion spectrum is shown in Fig. 1 for a gold-ruthenium hydride compound. In this spectrum, the molecular ion has been identified as $(\text{M} - \text{H})^+$. However, higher resolution data is needed to confirm this identity. Fragment ions are formed by losses of the organic ligands and/or metal atoms. In the lower mass range, the $(\text{Au} + 2\text{H})^+$ ion is observed as well as small gold-phosphine and ruthenium-phosphine ions. In some cases, negative molecular ions are observed of the type $\text{M}^+ \text{X}_2^-$ or $\text{M}^{2+} \text{X}_3^-$ where X is the associated anion, but very few significant fragment ions are present.

Figure 1.

In these mixed metal clusters, the d-orbitals of the transition metal atom stabilize the complex. As the ratio of gold atoms to transition metal atoms increases, we observe that the molecular ions become less abundant and there is far more fragmentation. In the positive ion spectrum of $[\text{Au}_6\text{Pt}(\text{PPh}_3)_7](\text{NO}_3)_3$ there is no clearly identifiable molecular ion. A series of low intensity ions that are formed by sequential loss of gold and triphenyl phosphine ligands is observed. The $\text{Au}_5\text{Pt}(\text{PPh}_3)_3^+$ ion is the most prominent in this mass range. Below this mass, ions are observed that can be attributed to further sequential losses of metal atoms and ligands as well as ions formed by partial losses of the ligands which add an increased complexity to the fragmentation pattern. The positive ion spectrum of $[\text{Au}_9(\text{PPh}_3)_8](\text{NO}_3)_3$ resembles this latter region of the Au_6Pt complex. Again, it is difficult to unambiguously assign a peak to the molecular ion. Peak intensities are greatly reduced in this region compared to ions in the mass range of $\text{Au}_9(\text{PPh}_3)_3$ to $\text{Au}_3(\text{PPh}_3)_2$. The negative ion spectrum contains a series of Au_n^- ions extending beyond Au_{19}^- . Although there is a general decline in intensities, the gold clusters having an odd number of gold atoms are more intense than the adjacent even-numbered cluster. Each cluster is part of a pentuplet of ions that are formed by the addition of 24, 31, 55 and 79 mass units. The identities of the ions have not been completely resolved.

There has been some controversy over the structure of a gold complex believed to be $\text{Au}_{55}(\text{PPh}_3)_{12}\text{Cl}_6$. The structure determination has eluded chemists because of the problems previously stated. One proposed structure is a two-layer cuboctahedron in which a Au_{13} cuboctahedra is surrounded

by 42 additional gold atoms in a cubic close packed array (3). Teo has proposed an alternate structure of vertex-sharing icosahedra building upon each unit to form a highly symmetric supra-cluster (4). The positive ion ^{252}Cf -PD mass spectrum of one supra-cluster (5) contains three broad but distinct distributions centered at m/z 8200, 12800 and 16600. None of these correspond to the 14193 D mass of a Au_{55} cluster. These zones do fit fairly well for a series of two, four and six icosahedra having stoichiometries of $\text{Au}_{25}(\text{PPH}_3)_{12}\text{Cl}_6$ (mw. 8284), $\text{Au}_{46}(\text{PPH}_3)_{12}\text{Cl}_6$ (mw. 12421) and $\text{Au}_{67}(\text{PPH}_3)_{14}\text{Cl}_8$ (mw. 17153) (6). In the lower mass range of this spectrum a series of ions corresponding to almost all possible combinations of $\text{Au}_x(\text{PPH}_3)_y^+$ (where $y \leq 12$) is observed. Usually the $\text{Au}_x(\text{PPH}_3)_3^+$ ion is the most intense for a particular Au_x value; there is no clear evidence for chlorine incorporation nor, was chlorine incorporation observed in the mass spectrum of the smaller gold-phosphine compounds. The broadness of the distributions is undoubtedly due in part to these types of ions. If it is assumed that the centers of the distributions are gold clusters containing three ligands, with no chlorine attached, these distributions may correspond to $\text{Au}_{37}(\text{PPH}_3)_3$ (mw. 8075), $\text{Au}_{57}(\text{PPH}_3)_3$ (mw. 12014) and $\text{Au}_{76}(\text{PPH}_3)_3$ (mw. 15757) each having one more icosahedron than the preceding structures. In an effort to determine if part of the broadness of these bands was due to the presence of a mixture of various gold clusters, a sample from a different source (7) was passed through a column of diatomaceous earth. Mass spectra were recorded before and after purification. The positive ion spectra are shown in Fig. 2. The mass spectrum obtained after purification resembles much more closely that of the Pignolet gold cluster with the exceptions that there are some higher mass peaks and the m/z 16,600 peak is shifted to a higher mass. This experiment clearly demonstrated that the samples are heterogeneous in nature and that part of the broadness of the different distributions is the result of impurities.

Figure 2.

In summary, ^{252}Cf -PDMS has been demonstrated to be useful in characterizing the structures of various metal clusters. This is also the first application of mass spectrometry to the analysis of supra-clusters and opens up an exciting new application for mass spectrometry as well as providing important new insights into the structure of these large complexes.

VG Analytical Ltd, Float Road, Wythenshawe,
Manchester ENGLAND M23 9LE

We have recently employed FABMS to characterize a variety of inorganic and organometallic compounds of synthetic and biological origins. The main focus of our studies has been the two classes of synthetic materials listed in Tables 1 and 2, and the esters of a nickel-containing porphyrinoid isolated from *Trididemnum solidum*, a Caribbean tunicate (compounds 1-7).

The polyoxoanion complexes (Table 1) are important analogues to metal oxide surfaces used in industrial scale oxidations. These soluble complexes are potential homogeneous catalysts. The heterometallic natures and difficulties in obtaining uniform crystals of these compounds prevented complete characterization by elemental analysis, NMR and X-ray crystallography. Both positive and negative ion FABMS experiments have shown useful structural information at 1000 and 6000 resolution. Analysis of the isotope envelopes of negative ion FABMS obtained at 6000 resolution on a VG ZAB-SE confirm that the cyclopentadienyl ligands are strongly retained and that fragmentation of the core anions is dominated by multiple losses of WO_3 and O moieties.¹

We have also employed FABMS/MS on a VG 70-SE-4F instrument to study the fragmentation of the core anions of several rhenium carbidocarbonyl compounds (Table 2). The overall objectives of the mass spectral analysis of these compounds is to better understand the properties of metal clusters. Daughter ion scans have shown sequential losses of carbonyl groups from molecular ions before any breakdown of the rhenium core. Negative ion FABMS/MS studies of more complex ions containing one or more organometallic ligands are currently underway.

FABMS and FABMS/MS have also played a key role in the structure elucidation of compounds 1-7 and related compounds² since only a few micrograms of the tunichlorin esters have been isolated from kilograms of the organism. A structure of the ester side chain was proposed after an acid catalyzed transesterification and analysis of the products by GC/EIMS on an HP 5970 MSD. The data suggests that the resulting alcohols have rearranged to straight-chain methyl esters. Comparison studies with the appropriate model methyl esters showed identical fragmentation pattern and retention times under the same GC/MS conditions. Coinjection experiments also show coelution of the cleaved natural product and these model compounds.³ Experiments to conclusively determine the structures are in preparation.

FTMS STUDY OF THE ELECTRON AFFINITY OF TRANSITION METAL TRIS-(ACETYLACETONATE) COORDINATION COMPOUNDS

Richardson, D.E., Sharpe, P., Ryan, M.F. and Eyler, J.R.
University of Florida, Gainesville, FL.

The thermodynamics of electron attachment to gas-phase ligated transition metal ions that have direct solution-phase counterparts have not been studied extensively. Such data are crucial to understanding the thermodynamic origins of electrode potentials in solution and the changes in bond energies that occur upon reduction of metal complexes in the absence of solvation. The compounds chosen for this study are the *tris*(acetylacetonate) and *tris*(hexafluoroacetylacetonate) complexes of the first transition metal series (Figure 1). The metal centers are formally in the +3 oxidation state and are coordinated by a pseudo-octahedral arrangement of 6 oxygen donor atoms. Each ligand has a negative charge, and the *tris* complexes are volatile neutral molecules.

At the experimental temperatures used in these studies, values of ΔG and ΔH for electron capture by gaseous molecules usually do not differ markedly and are close approximations to the true electron affinity. The data obtained in this study can therefore be used in thermochemical cycles that yield further important thermochemical information (Figure 2, where $D(M-L)_{avg}$ is the average heterolytic bond dissociation enthalpy).

Free energies of electron capture by the metal complexes were studied by using a Nicolet FT/MS 1000 ion cyclotron resonance mass spectrometer. Parent negative ions are made from a gas mixture containing a metal complex and an organic reference compound. The reference compound is taken from tables of organic acceptors for which the free energy of electron capture has been previously determined by pulsed high pressure mass spectrometry. Through a combination of free energy bracketing and observations of charge transfer equilibria, free energies

of electron attachment for each complex were determined. The results for the series of $M(acac)_3$ and $M(hfac)_3$ complexes are shown in Figure 3. In comparison to the values for electron capture by the free +3 metal ions, the values for the complexes are greatly lowered. This lowering of EA for the ligated metal ions reflects the higher average heterolytic M-L bond energies for the neutral complexes in comparison to the corresponding anions. The maximum occurring at manganese in both series results from the enhanced stability associated with the formation of the d^5 "half-filled shell" configuration, for which stabilization through electron exchange interactions is also a maximum. Other variations from a smooth increase in EA with increasing atomic number can be ascribed to splitting of the energy of the *d* orbitals in the complexes and can be more fully rationalized by a ligand field or molecular orbital analysis. The free energy of electron capture by the series of $M(hfac)_3$ complexes is approximately 50 kcal mol⁻¹ greater than for the $M(acac)_3$ analogs, but the relative order within the series is the same. The higher values for the $M(hfac)_3$ complexes are related to the lower polarizability of the fluorine containing ligand and the resulting lower value of $\Delta D(M-L)_{avg}$.

Acetylacetonate is close to H_2O in the spectrochemical series of *d*-orbital splitting. The ground state spin states for each member of the series of $M(H_2O)_6^{3+/2+}$ and $M(acac)_3^{3+/2+}$ couples are therefore the same. Comparison of the redox potentials for the $M(H_2O)_6^{3+/2+}$ couples to the free energy of electron attachment in the gas phase shows a similar trend across both series since electron attachment is to a metal center in a locally similar environment and differential solvation energies for the series of redox couples are roughly constant.

R	LIGAND
CH ₃	ACETYLACETONATO (ACAC)
CF ₃	HEXAFLUOROACETYLACETONATO (HFAC)

Figure 1

Included in this study was an estimation for the enthalpy of electron attachment to $\text{Ru}(\text{acac})_3$ at 298 K. This data as well as the reported reduction potential in water can be used to determine the differential enthalpy of hydration between $\text{Ru}(\text{acac})_3$ and its anion as shown in the lower part of the cycle in Figure 2. The absolute value for the hydration enthalpy of the neutral can be estimated from the reported values for the enthalpy of solution and the enthalpy of sublimation. This leads to a value for the enthalpy of solvation of the anion of $-60 \pm 5 \text{ kcal mol}^{-1}$. For anions of this type, the Born equation fails to predict accurate values from the crystal radii, and the large deviation can be partially accounted for by solvent penetration between the planar chelating ligands in solution. Similarly, in the upper part of the cycle in Figure 2, the difference between the electron affinities of a free metal ion and the corresponding metal complex yields the difference in the heterolytic bond enthalpies between the neutral complex and its anion. Absolute values for the neutral $\text{M}(\text{acac})_3$ complexes have been provided in the literature and so the values for the anions can be estimated. The trends in the bond energies are in accord with the crystal field model.

SOLIDS ANALYSIS VIA GLOW DISCHARGE MASS SPECTROMETRY

W. H. Christie
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831

Glow discharge mass spectrometry (GDMS) represents the newest instrumental concept for the bulk analysis of solids. That GDMS is an important new technique is attested to by its recent and rapid commercialization. The use of glow discharge sources in mass spectrometry is described in an excellent review by Coburn and Harrison (1), two of the pioneers in this field. Some of the features that make GDMS an attractive analytical technique are: Direct analysis of metals for major, minor, trace and ultra-trace components with minimal sample preparation, ability to obtain isotopic information and a stable, reproducible ion beam that facilitates quantitative analysis.

The GDMS studies in our laboratory were done on a VG 9000 instrument. This instrument was equipped with a gas purification system to remove trace reactive impurities from the 99.999% Ar used to support the glow discharge. To evaluate GDMS as a quantitative technique we have used empirical sensitivity factors (S.F.). The sensitivity factor method compares the relative sensitivity of the analytical method for each sample constituent to some constituent that is designated a reference (usually a matrix species). The SF's are determined from standards and are then applied in the analysis of unknown samples of similar matrix. Sensitivity factors are defined as

$$SF_i = \frac{I_{ij} / (C_i f_{ij})}{I_R / (C_R f_R)}$$

where SF = the sensitivity factor of element i; I_{ij} = the measured signal of isotope j of element i; and f_{ij} = the isotope fraction of isotope j of element i. Subscript R refers to the relevant property of the reference element.

Table 1 lists sensitivity factors derived from averaged data from multiple analysis of the NIST 600 series low alloy iron standards. NIST does not provide certified values for N and O in these standards.

Table 1. Derived Sensitivity Factors

Standard	661	662	663	664

Table 2 shows the results of analyzing NIST 665 as an unknown using the SF's reported in Table 1. In 665 the dopants are present at trace levels and below. GDMS analysis gives values for N, O, Zr, Nb, Sn, Ta, and W, elements that are not listed by NIST as being in the sample. With the exception of C, Al, Ti, and Mo, the observed ratios of GDMS/NIST values are significantly better than our lab does using spark source mass spectrometry on these same samples.

*Values via GDMS analysis; these elements not certified by NIST.

As a test of the ability of GDMS to accurately measure major components in a sample, we derived a suite of SF's from the analysis of NIST stainless steel standards 447 and 449 and applied them to the analysis of NIST 446 and a vendor analyzed sample of 308 stainless steel. These results are presented in Table 3. The two sets of GDMS analytical values for NIST 446 were determined one month apart using the same suite of SF's. The results in Table 3 indicate that if suitable standards are available GDMS can return analytical values for major components that are comparable in accuracy to established methods, such as optical emission and X-ray fluorescence.

ANALYTICAL COMPARISONS OF DIRECT CURRENT AND
RADIO FREQUENCY GENERATED GLOW DISCHARGE ION
SOURCES FOR DIRECT SOLIDS ANALYSIS

Douglas C. Duckworth and R. Kenneth Marcus
Department of Chemistry,
Howard L. Hunter Chemical Laboratories
Clemson University
Clemson, SC 29634-1905

Recent advances in the field of glow discharge mass spectrometry (GDMS) have primarily employed the more common d.c. sustained discharge. In our laboratory we have employed a radio frequency (rf) powered glow discharge source for the analysis of both conducting and nonconducting sample types. When high voltage pulses, 13.56 MHz in this case, are applied to insulators a d.c. offset voltage exists which results pseudo-continuous discharge which serves as both the atomization and ionization source. Because the need for the sample to be conducting has been eliminated, a wide range of sample types are amenable to analysis employing this source. This range of applicability is demonstrated and other analytical characteristics of interest are compared in the analysis of brass, steel, and glass samples by both rf and d.c. plasmas (mixing of the glass with a conducting metal powder is necessary with the latter).

EXPERIMENTAL

Comparison of the rf and d.c. sources were made under the optimum operating conditions for each as determined by the signal intensity of the matrix material. Optimum source parameters for the d.c. source are typically 1-3 torr with 0.5-3.0 mA discharge current using a pin sample geometry. The rf source, operating at 0.33 torr and typical powers of 25-30W, utilized a 1/2" diameter sample. Comparisons are made relative to the power density (W/cm^2) of each.

Figure 1 is a diagrammatic representation of the double-quadrupole instrument employed in this laboratory. Ions exiting the source region pass through a differential pumping stage and into the analyzer region. These ions are focussed into a collision cell by a three-element lens system. For purposes of this study the collision cell was operated with no collision gas. The collision cell and mass analyzer are equipped with Extrel 3/8" quadrupole assemblies powered by 1.2 MHz generators. Ions traversing the rf-only quadrupole are directed into the analyzer by a single-element lens. All of the spectrometer scan functions, ion lens/pole offsets potentials, and ion detection are controlled by an Extrel C-50 mainframe.

Figure 1. Double quadrupole glow discharge mass spectrometer system.

RESULTS AND DISCUSSION

Shown below are the d.c. and rf glow discharge mass spectra of NIST 1103 brass. These spectra illustrate the typical differences and similarities observed. The molecular interferences such as metal argides and dimers are common to each; however, the metal argide and dimer species are more prominent in the rf spectra. The absolute ion current observed from the ^{63}Cu ion in the rf source is sixteen times greater than that in the d.c.

Sputter rates were also determined for both sources and compared on the basis of power densities. Based on these power density considerations, the rf source appears to be a better atomization source with a sputtering rate twenty-one times that of the d.c. However, the ion currents per unit power density were only four times that of the d.c. indicating that the d.c. source is a more efficient ionizer.

Rf and d.c. powered glow discharges are comparable, with the rf having a distinct advantage in the ability to analyze both conductors and nonconductors. Future studies will involve the characterization and implementation of a dual rf/d.c. probe with subsequent evaluations of the parametric dependencies of the analyte signal intensity and spectral features. Following this, rigorous comparisons of the analytical figures of merit and fundamental studies of the atomization and ionization rates of the respective sources will be made.

PRECISE ATOMIC MASS MEASUREMENTS AND NEUTRINO PHYSICS: RECENT RESULTS AT THE UNIVERSITY OF MANITOBA*

K.S. Sharma, R.C. Barber, G.R. Dyck, M.S. Sidky, J.G. Hykawy, B.J. Hall, C.A. Lander and H.E. Duckworth, Department of Physics, University of Manitoba, Winnipeg, Manitoba, CANADA, R3T 2N2

1. INTRODUCTION Recently, we have used the high resolution double focusing mass spectrometer at the University of Manitoba (Manitoba II) to precisely determine the energy available for the β and double β decay of certain nuclides. The results of these measurements provide data for experiments aimed at determining some of the properties of the electron ν .

2. EXPERIMENTAL DETAILS The Manitoba II spectrometer has been described in detail elsewhere [1]. The instrument is based on a design suggested by Hintenberger and Konig : $R_m = 62.74$ cm, $\Phi_m = 90.00^\circ$, $R_s = 100.00$ cm and $\Phi_s = 94.65^\circ$. The ion optics are correct to second order in both energy and radial angle. Typically resolving powers of 200,000 are realized at 10% of peak height.

A mass peak is generated by sweeping the ion beam across the collector slit by means of a small, sawtoothed magnetic field located near the exit of the magnetic analyzer. The ions that pass through the slit are detected with a channel electron multiplier and a mass spectra is accumulated by a multi-channel scaler/signal averager whose sweep is synchronized to the sawtoothed magnetic field.

The mass difference between two ionic species is measured by some variation of the peak matching technique [2,3]. The technique is based on a theorem given by Bleakney [4] which states that two ions with masses M and M' will follow identical paths through the mass spectrometer if all magnetic fields are unchanged and all of the electrical potentials applied to the instrument are changed from V_i to V_i' such that

$$MV_i = M'V_i' \quad (1)$$

$$\text{or} \quad \Delta M/M = \Delta V/V_i \quad (2)$$

where $\Delta M = M - M'$ and $\Delta V_i = V_i' - V_i$

Thus, on alternate sweeps, the potentials applied to the instrument are changed so that both members of a doublet follow the same trajectory through the spectrometer in succession. The coincidence of these two ion paths may be detected either by the "visual null" [2] or by the "computer assisted peak matching" techniques [3]. Once the required changes for the applied potentials are established one can determine the mass doublet spacing by measuring the ratio $\Delta V_i/V_i$ and combining the result with the mass of one of the doublet members. In practice the potentials applied to the electrostatic analyzer are used to establish this ratio because the beam position is most sensitive to this parameter.

3. RESULTS AND DISCUSSION Two modes of $\beta\beta$ decay are possible. The first is similar to ordinary β decay in that 2 β particles and two anti- ν s are emitted. In this mode lepton number is conserved and the energy spectrum of the emitted β particles is very broad. In the second mode two β particles are emitted but the ν emitted with the first β is absorbed during the emission of the second. Therefore, two electrons are emitted with the simultaneous emission and re-absorption of a virtual ν . Lepton number is not conserved and the energy spectrum of the emitted electrons consists of a single narrow peak corresponding to the total energy available for the decay. This provides a clear, unambiguous signature for the detection of this decay mode. The detection of this process would imply that the ν and its corresponding anti-particle were the same and that a lower bound (greater than zero) exists for the mass of a ν . Accordingly, various groups around the world have been searching for evidence of neutrinoless

$\beta\beta$ decay [5,6].

The half-lives associated with $0\nu\beta\beta$ decay are usually on the order of 10^{22} years. This results in extremely low event rates (a few counts per year) in existing detectors. It is therefore important that the $\beta\beta$ Q-value be accurately and precisely known, enabling experimenters to distinguish between the numerous background peaks that appear in the spectra and the signature of the decay. In past work [7] we have measured a Q-value of 2040.71 ± 0.52 keV for the $\beta\beta$ decay of ^{76}Ge . This has served to identify as background some peaks occurring near the region of interest (approximately 1 keV away) [5,6].

We have also determined the spacing of 4 doublets among isotopes of Te and Xe [8]. These measurements when combined with other mass spectrometric measurements in this region over-determine the energies available for the $\beta\beta$ decay energies for ^{128}Te and ^{130}Te . The results of a least squares adjustment in this region yield $\beta\beta$ decay Q-values of 930.3 ± 1.3 keV for ^{128}Te and 2914.4 ± 1.6 keV for ^{130}Te . Earlier data underestimated the value for ^{130}Te by 6 keV, a serious discrepancy. In both of these cases our new data improve the precision of these Q-values opening the way for future searches for these rare decay modes.

The observed flux of neutrinos from the sun is approximately a factor of 4 lower than that predicted by theoretical models. It has been suggested that a detector with a lower energy threshold may be able to resolve this discrepancy. The inverse beta decay of ^{205}Tl to ^{205}Pb caused by ν capture may provide such a detector. Through this process ^{205}Tl in geological samples has been integrating the solar ν flux. Since the half life of ^{205}Pb (1.5×10^7 years) is much shorter than the age of the earth little primordial ^{205}Pb is expected to survive in geological samples. A determination of the abundance of ^{205}Pb in thallium ores would therefore reflect the effects of the solar ν flux averaged over approximately 10^7 years. The ν absorption cross section of ^{205}Tl is very sensitive to the mass difference $^{205}\text{Pb} - ^{205}\text{Tl}$ (this is essentially the Q-value for the electron capture decay of ^{205}Pb to ^{205}Tl , Q_{ec}). This mass difference has been deduced from the intensity ratios of the X-ray lines emitted following electron capture as 41.4 keV. This value disagrees with that calculated from other nuclear reaction data, 53.5 ± 1.6 keV. This 12 keV discrepancy is sufficient to change the ν absorption cross section by a factor of 2. To resolve this discrepancy we have determined 4 new doublet spacings in the mass spectra of lead and thallium chlorides. The average precision of these measurements was $2.5/10^4$. When combined with existing nuclear reaction data these new measurements provide up to 4 different ways of calculating Q_{ec} . A least squares adjustment of all available data (excluding the X-ray measurements) results in a value of 53.40 ± 0.4 keV for this energy[9].

A MASS-SELECTED REAGENT ION CHEMICAL IONISATION SOURCE

Gregory G Dolnikowski, Mark R A Falcini, Keith R Jennings
University of Warwick, Department of Chemistry, COVENTRY CV4 7AL, U.K.

A mass-selected reagent ion chemical ionisation (CI) source has been developed for producing novel reagent ions, for reducing chemical noise in the CI mass spectra and for studying the mechanism of the CI process. Reagent ions from a Balzers quadrupole mass filter (mass range = 255) enter the high pressure reaction chamber of a Kratos MS9 forward geometry double focussing mass spectrometer. The high pressure reaction chamber contains the sample and helium buffer gas. Ionic products are analysed by scanning the magnet as in ordinary CI. A diagram of the mass-select reagent ion CI source is shown in Figure 1.

The quadrupole mass spectrometer and its power supplies are floated at the accelerating voltage of the MS9 (in this case 6kV) using a specially designed insulating flange and an isolation transformer. Both the reaction chamber and the quadrupole housing are mounted on a PEEK insulator which has been inserted into a standard MS9 source flange. The quadrupole and the high pressure reaction chamber are differentially pumped so that there is little mixing of the sample gas and the reagent gas. The pressure in the reaction chamber is measured by a Baratron capacitance manometer and is variable from 0.1 to 1.0 torr.

The mass-selected reagent ions pass through a short rf-only quadrupole after the mass filter to collimate the ion beam. In order to inject the reagent ions into the reaction chamber, they are accelerated to 2 keV of kinetic energy through a lens system (designed using the SIMION program) and focussed on to a 0.5 mm diameter aperture in the high pressure reaction chamber. This technique overcomes the scattering caused by the jet of gas exiting through the aperture. After entering the high pressure region the reagent ions are decelerated to less than 5 eV by a voltage applied to a grid located 1.5 mm behind the aperture. Any ions formed due to collision-induced dissociation with the buffer gas necessarily have less kinetic energy than the reagent ions and cannot pass the grid into the reaction chamber.

When the reagent ions have passed into the reaction chamber they are rapidly thermalised by multiple collisions with the He buffer gas. Since the partial pressure of buffer gas exceeds that of the sample by at least a factor of 100, most of the thermalising collisions are with the buffer gas, not the sample. Using He as the buffer gas also has the effect of eliminating glow discharge ionisation in the reaction chamber. The thermalised reagent ions react with sample molecules by means of ion/molecule reactions and yield product ion spectra of the type shown in Figures 2 and 3.

GC SAMPLE INTRODUCTION INTO THE COLLISION CELL OF A TRIPLE QUADRUPOLE MASS SPECTROMETER FOR MASS-SELECTED REACTANT ION CI

M. E. Hail¹, D. W. Berberich¹, and R. A. Yost, University of Florida,
Department of Chemistry, Gainesville, FL 32611.

¹Current address: Finnigan MAT, San Jose, CA 95134.

A new gas chromatographic/tandem mass spectrometric technique has been investigated. This technique, gas chromatography/mass-selected reaction/mass spectrometry (GC/MSR/MS), involves mass-selection of reactant ions and reaction of these ions with the effluent from a GC column. This is accomplished by interfacing a gas chromatographic column directly to the collision cell of a triple quadrupole tandem mass spectrometer. Reactant ions are selected with the first quadrupole mass filter (Q1) and are allowed to react with neutral sample molecules which elute from a short (e.g., 2-3 m) open tubular GC column into the second quadrupole collision cell (Q2). The third quadrupole (Q3) is scanned for the products of the ion-molecule reactions.

Charge exchange (CE) and proton transfer chemical ionization (CI) reactions have been investigated. The selectivity of CE and proton transfer CI results from control of the energetics of the ion-molecule reactions between reactant ions and sample molecules. For example, a CE reaction may occur if the ionization energy (IE) of the sample molecule is less than the recombination energy (RE) of the reactant ion. Similarly, proton transfer CI reactions may occur if the proton affinity (PA) of the sample molecule is greater than the proton affinity of the conjugate base of the reactant ion. For both CE and proton transfer CI, the exothermicity of the ion-molecule reaction largely determines the extent of fragmentation of the molecular ion or pseudo-molecular ion. Since ion-molecule reactions can be performed with selection of a single m/z reactant ion, mixed-mode ionization, which is often observed when ion-molecule reactions are performed in the ion source, is avoided. Thus, mass-selection of reactant ions provides the highest possible selectivity for ion-molecule reactions.

One example of the intrinsic selectivity of ion-molecule reactions is demonstrated by the mass-selected CE chromatogram in Figure 1, where both argon and benzene were ionized in the source and the Ar^+ and C_6H_6^+ reactant ions were mass-selected with Q1 during alternating scans. As shown in the figure, the Ar^+ (RE = 15.8 eV) reactant ionizes all of the compounds in the mixture, while the C_6H_6^+ reactant (RE = 9.2 eV) ionizes only the aromatic components. Since the RE of the C_6H_6^+ reactant ion is less than the IE's of the aliphatic compounds, the aliphatic compounds are not ionized via benzene CE. The added selectivity of mass-selected reactions is particularly useful when combined with short-column GC to rapidly screen for specific classes of compounds. For example, C_6H_6^+ CE can be used to investigate the aromatic content of a jet fuel (a complex mixture containing aromatics and aliphatics) without interference from aliphatic constituents.

Another advantage of the GC/MSR/MS technique is that both structural information and molecular weight information can be obtained in the same chromatogram (i.e., a single GC injection) by alternating between reactants that have different recombination energies or proton affinities. Figure 2 shows a comparison of the spectra of 2,4 dimethylaniline obtained from Ar^+ and C_6H_6^+ CE from the chromatogram of Figure 1, as well as an EI spectrum acquired separately for comparison. Note that the Ar^+ CE spectrum resembles the EI spectrum (with more intense fragment ions), while the C_6H_6^+ CE spectrum exhibits an intense molecular ion with very little fragmentation. In addition, we have found that the mass-selected Ar^+ CE spectra provide reasonably consistent hits when searched against the NBS EI library. Thus, mass-selected CE spectra appear to be highly useful in providing both structural and molecular weight information for the classification of unknowns.

It was found that the detection limits obtainable with the GC/MSR/MS technique are comparable or better than those obtained with conventional GC/MS. Figure 3 shows mass-selected reaction chromatograms obtained with benzophenone as the analyte and C_6H_6^+ as the CE reactant ion. Figure 3a shows the mass chromatogram for the m/z 182 ion of 100 pg of benzophenone for a full scan of Q3 (80-240 amu in 0.5 seconds). Figure 3b shows the chromatogram obtained from 15 pg of benzophenone when Q3 was scanned from 181-183 amu in 0.5 seconds. The signal-to-noise ratios (S/Ns) for Figures 3a and 3b are approximately 9:1 and 30:1, respectively. For comparison, the specifications for the full scan sensitivity of the instrument used (Finnigan MAT TSQ70) with GC/MS are quoted as 200 pg for EI with a S/N of 10:1 and 100 pg with methane CI with a S/N of 25:1. The ability to obtain the molecular ion (or pseudo-molecular ion) with little or no fragmentation for an analyte provides the maximum sensitivity for trace analysis. Since such 'soft ionization' is easily performed with mass-selected reactions, the GC/MSR/MS approach provides the opportunity to control the ionization to obtain excellent limits of detection.

ONE QUADRUPOLE ANALYSER, MS^{n+1} , ZERO-ANGLE (SID)ⁿ

Claude Beaugrand and Gérard Devant,
Nermag, 49 quai du Malage, 92500 Rueil-Malmaison, France

Daniel Jaouen, Nicole Morin, Hélène Mestdagh and Christian Rolando,
Ecole Normale Supérieure, 24 rue Lhomond, 75231 Paris Cedex 05, France

The surface induced dissociation process (SID) has been shown by P. G. A. Cooks to be a particularly efficient way of breaking ions difficult to fragment by other processes, such as Poly Aromatic Hydrocarbons (PAH) (1) or isomeric ions (2). Various instruments have been designed by this group and others for performing SID : B (SID) Q (3), Q (SID) Q (3) or Q (SID) Q (CAD) Q (4); recently a new instrument working under Ultra High Vacuum and in a wide range of angle has been built up (5); furthermore they have designed a "on line" SID device (6) that can be used in a conventional tandem MS/MS triple quadrupole instrument with a linear geometry. Current work from our laboratory has demonstrated that a quadrupole filter can be successively used as an analyzer and as an ion-trap in the same experiment (7). This led us to the idea of a new configuration for an MS/MS instrument using a zero angle SID:

source	quadrupole	surface	detector
--------	------------	---------	----------

This configuration has potential advantages : (i) collision energy is maximum at zero angle, (ii) strong focussing properties of quadrupole field and good symmetry fit allow high collection efficiency. (iii) this configuration gives the virtual possibility of consecutive SID experiments allowing MS^n experiment with a single analyser.

A typical SID experiment follows this scheme : (i) filling of the trap (RF-only), (ii) parent ion selection (resolving quadrupole), (iii) SID (RF-only, and opening of the exit lens), (iv) daughter ion selection (resolving quadrupole), (v) ion detection (switching on the detector).

Preliminary experiments show that using this SID configuration daughter ions can be obtained; improvement of the overall sensitivity is under way.

The principal, distinguishing, optical characteristic of a focusing liquid metal ion (LMI) column is its very high brightness; in practical terms this means that a very large number of the emitted particles can be focused into a very small spot.¹ Because of this characteristic, we have suggested in the past² that an opportunity might exist for increasing the sensitivity of liquid matrix assisted organic SIMS by using a finely focusing LMI column to substantially reduce the absolute amount of analyte required for analysis, to increase the efficiency of ionizing the analyte molecules, and to increase the efficiency of collecting the analyte ions for transmission through the mass analyzer. Two years ago we attached a commercial, focusing LMI column (FEI Company) to a single focusing, magnetic sector mass spectrometer (Hitachi RMU-6E) and were able to obtain usable mass spectra from subnanogram amounts (~300 fmole) of several tripeptides.³

Although our earlier results demonstrated the potential for significantly greater sensitivity in liquid matrix SIMS, they were obtained with only small molecules on less than modern instrumentation. Consequently, we built a prototype LMI column for testing on a Kratos MS50TC-RF mass spectrometer. The LMI column delivers a positive ion beam of 1-5 nA into a spot on the target 3-10 μm diameter (1-70 mA cm^{-2}). The column is operable at accelerating voltages up to 25 kV. To prevent degradation of the LMI beam's optical properties as it approaches the sample target, the LMI column was built to float at the ion source potential of the mass spectrometer, and a small bore tube, also maintained at the ion source potential, was provided to guide the primary ions from the LMI column to the sample probe without interference from external electric fields. With the aid of a small electron multiplier located in the vicinity of the sample and a display monitor, the system could be operated in a scanning ion microscope or microprobe mode in which the sample could be alternately imaged and mass analyzed. This feature was used to tune the LMI column and to locate a sample and coarsely aim the beam onto it.

Samples, 10-100 nL, were introduced into the mass spectrometer on a small diameter wire either as a dried smear or as a small viscous droplet suspended on the wire like a bead. Secondary ion yield was maximized by accurately finding the optimum emission zone on the sample with the finely focused beam from the LMI column, and at the same time maximizing collection and transmission of the secondary ions by accurately positioning the sample within the acceptance zone of the mass analyzer. Tuning was monitored by observing the shapes and amplitudes of individual mass peaks on the instrument's oscillographic screen. Tuning proved to be difficult, but once achieved, was generally stable over an entire sample run requiring only minor adjustment to the LMI beam position to compensate for shrinkage of the sample ball. Even after a change of samples, little or no adjustment of the tuning was required. We were frequently able to exploit this feature when we attempted to analyze samples that had only short lifetimes in the mass spectrometer or that had such low concentrations that the analyte signal could not be observed in single scans.

Numerous mass spectra for each of the oligopeptides Met-Enkephalin (M,574), Bradykinin (M,1060), Bovine Insulin Chain B, Oxidized (M,3500), Glucagon (M,3550), Bovine Insulin (M,5735), Aprotinin (M,6510), and Ubiquitin (M,8560) and each of the oligonucleotides d(A)₄ (M,1190), dp(T)₄ (M,1234), dp(T)₆ (M,1842), dp(T)₈ (M,2449), d(GAT CGA TCG A) (M,3050), dp(T)₁₀ (M,3058), d(ATG CAT ATG CAT) (M,3642), d(GAT CCC TGC AGG) (M,3644), d(GTA AGG AGG TTT AC) (M,4340), d(TGA CCA TGA TTA CGA) (M,4573), d(CGG GAA AGG TTC CGT TC) (M,5223), d(GTA ACA ATT TTG TAA AAA) (M,5520) were recorded in both LMI and FAB modes for comparison. It was possible to obtain reasonably quantitative sensitivity data for most of the oligopeptides, but relatively little

quantitative data could be obtained for the oligonucleotides because of their low solubilities. A negative, integrated molecular ion profile, produced from 14 pmole (50 ng) of bovine insulin chain-B, oxidized, by bombardment with 25 keV Bi-ions is shown in Figure 1; this spectrum is typical of those produced from the other oligopeptides and the oligonucleotides. With respect to the relative sensitivities of the LMI and FAB modes on the MS50 for the two classes of biopolymers studied, it appears 1) that the two techniques have comparable sensitivities for either class of compounds up to 1,000 daltons, 2) that the LMI mode is roughly 5-10 times more sensitive than the FAB mode for oligopeptides over 1,000 daltons (bovine insulin being a notable exception that must be retested), and 3) that the FAB mode is slightly more sensitive than the LMI mode for oligonucleotides up to about 4,500 daltons and significantly more sensitive beyond that mass. The sensitivity using a focused LMI primary beam is not as great as anticipated due to what appears to be a radiation damage limit. Our results to date suggest that with technical improvements realistic liquid matrix, secondary ionization detection limits for biopolymers in the mass range of 1,000-10,000 daltons can be reduced to around 0.1 pmole for oligopeptides and 10 pmole for oligonucleotides. Of course, these are best case values and many compounds would be expected to have higher detection limits.

EXACT MASS DETERMINATION BY HIGH RESOLUTION TIME-OF-FLIGHT SIMS

E. Niehuis, T. Heller, U. Jürgens and A. Benninghoven,
Physikalisches Institut, Universität Münster, Wilhelm-Klemm-Str. 10,
D-4400 Münster, FRG

In many applications of static SIMS an exact mass determination is required to derive or confirm the composition of a molecular ion. This is true not only for the analysis of large biomolecules, but also for surface analysis of complex materials like polymers. In combination with a high mass resolution accurate mass determination eases the peak assignment and the interpretation of the spectra considerably.

First time-of-flight SIMS instruments (TOF-SIMS) had a rather poor mass resolution of a few hundred, but during the last years the resolution was increased considerably. With the high resolution TOF-SIMS, developed at the university of Münster, we achieved a resolution of 13000 /1/. The instrument is equipped with a mass separating pulsed primary ion gun (pulse width 800 ps), a reflectron-type TOF-analyzer, a postacceleration detector and a multistop time-to-digital converter (800 MHz resolution).

In this paper the precision of mass determination presently achievable by TOF-SIMS will be discussed.

1. Mass calibration

For an electrostatic TOF-analyzer there is a strict and simple relation between mass and flight time:

$$m = c (t - t_0)^2$$

In TOF-SIMS deviations from the exact masses are mainly determined by the energy distribution of the secondary ions. The corresponding flight time deviations are quite large in a linear instrument, but they are reduced significantly by energy focusing. A precision in the ppm-range can be expected for a reflectron TOF-analyzer.

Due to the parallel detection of all masses well known peaks in the low mass range can be used for mass calibration. The two parameters c and t_0 were determined by a least square fit for up to 10 peaks in the mass range up to 500, which are present in almost any positive SIMS spectrum:

Therefore the calibration procedure is simple and no special calibration standards and peak matching methods are necessary.

Typical deviations of the calibration peaks from the fitted curve are less than 0.1 mmu for the masses 1 - 3 amu and less than 1 mmu for the higher masses.

2. Results

2.1. Low mass range (1 - 500 amu)

A large number of spectra were evaluated in the low mass range including fingerprint spectra of polymers like PMMA etc. /2/. Typical errors in this mass range are about 1 mmu or below (10 - 20 ppm).

2.2. High mass range (> 1000 amu)

The accuracy of mass determination in the high mass range was investigated with several spectra of the polymer Polydimethylsiloxane (PDMS) prepared on Ag. The spectra show high intensities of intact oligomers cationized by Ag in the mass range from 1157 up to several thousand amu. The calibration was performed by using the peaks given above. Then the masses of the oligomers and their deviations from the calculated masses were determined. Table 1 summarizes the relative mass deviations $m/\Delta m$ for four different spectra. A precision better than 10 ppm was achieved. From the measured masses of the oligomers the mass of the repeat unit of the polymer and the masses of the terminal groups could be determined with an accuracy of 1 - 2 mmu.

Table 1

sample	average deviation	standard deviation
1	0.5 ppm	2.9 ppm
2	5.1 ppm	3.9 ppm
3	-6.4 ppm	4.2 ppm
4	5.2 ppm	2.9 ppm

In addition the precision of mass determination was investigated for some peptides like Met-Enkephalin (MW 573.226), Bradykinin (MW 1059.561) and Substance P (MW 1346.727). The results are listed in table 2.

Table 2

sample	composition	average deviation
Met-Enkephalin	$C_{27}H_{35}N_5O_7S$	7.5 ppm
Bradykinin	$C_{50}H_{74}N_{15}O_{11}$	10.0 ppm
Substance P	$C_{63}H_{99}N_{18}O_{13}S$	19.5 ppm

HIGH PRECISION CARBON $^{13}/^{12}$ RATIOS BY
GC / COMBUSTION / MASS SPECTROMETRY

W. A. Brand, M. Rautenschlein, K. Habfast, Finnigan MAT GmbH, Barkhausenstr. 2, D-2800 Bremen 14, F.R.Germany

M. Ricci, K. L. Freeman, J. Hayes, Biogeochemistry Laboratories, Indiana University, Bloomington, IN 47405, USA

Although the method of combusting organic compounds eluting from a Gas Chromatograph and subsequently determine the $^{13}/^{12}$ Carbon isotope ratio with a dedicated multiple collector mass spectrometer has been reported as early as 1976 [1], considerable progress leading to commercially available products has arisen only recently [2,3].

Figure 1: Combustion interface layout

In our system (fig.1) the GC eluate passes through a micro combustion furnace. Its quartz tube is 200 mm in length and has an i.d. of 0.6 mm. Filled with cupric oxide, organic compounds passing the furnace are oxidized quantitatively to CO_2 and water at 750 C. The water is removed continuously using a permeable membrane separator. A conventional open split assembly serves to introduce 0.6 ml/min gas into the ion source of the mass spectrometer. The combustion interface can be backflushed for peak cutting and for solvent peak suppression.

The mass spectrometer records the CO_2 masses 44, 45 and 46 (the latter for 17-O correction on 45) simultaneously in a triple Faraday cup arrangement. Fast data acquisition using a dedicated microprocessor board ensures continuous data integration without interruption.

Figure 2 shows the intensity of the 44 ion current as a function of time. Here, the separation of C-17 and C-18 n-alkanes from the saturated isoprenoids phytane and pristane in a crude oil extract is demonstrated. The upper trace monitors the evolution of the 45/44 isotope ratio over time. In all cases we have observed, the 45 ion current always precedes its 44 counterpart by several tens of milliseconds, resulting in an apparent "differential" peak shape. This is due to isotopic separation inside the capillary column. The exact amount of separation in time depends on a number of parameters like column type, flow rate, compound, temperature. However, in cases where the $^{13}/^{12}$ ratio is off the naturally occurring range, the trace will exhibit a "normal" peak shape (i.e. only positive or only negative), thus enabling a very sensitive detection of $^{13}\text{-C}$ labeled material down to the picogram range.

Figure 2: GC/C/MS traces

Figure 3: Crude oil ^{13}C record

Figure 4: Crude oil extract

Finally, a complete carbon isotopic record has been obtained for a crude oil extract (Fig. 3 and 4) ranging from C-10 to C-35. The points were obtained by checking and correcting manually the automatic background and peak boundary assignments. In the lower carbon number region, corrections up to 2 permil were necessary due to peak overlap whereas for the higher carbon numbers corrections were negligible. From the isotopic record conclusions can be drawn to the history of the oil and the origin of the compounds. E.g. the C-30 to C-34 n-alkanes show an admixture from terrestrial higher plants which derive their carbon from atmospheric CO_2 by the Calvin photosynthesis cycle.

AROMATIC SUBSTITUTION REACTIONS OF RADICAL CATIONS

H.-F. GRUTZMACHER and D. THÜLMANN

FAKULTÄT FÜR CHEMIE, UNIVERSITÄT BIELEFELD
FRG-4800 BIELEFELD 1, WEST GERMANY

The aromatic substitution is one of the most important organic reactions in solution, both by electrophiles and by nucleophiles. Usually these reactions proceed by a two electron transfer to and from the aromatic system to form a Meisenheimer und a Wheland intermediate, respectively. Besides these classical aromatic substitution reactions, other mechanisms involving a single electron transfer and hence radical cations and radical anions are discussed in the literature, in particular for photochemically and electrochemically induced reactions.

Aromatic substitution reactions in the gas phase were observed for certain benzene derivatives under $\text{Cl}(\text{NH}_3)$ conditions. Although radical cations participate very likely in this reaction, the mechanism is not very well known. The present paper gives the results of a detailed ICR study of the reaction between halogenated benzenes and NH_3 after electron impact ionisation, using an external ion source.

The isomeric dichlorobenzenes give rise to chloroanilinium ions in a $\text{Cl}(\text{CH}_3)$ plasma. The comparison of the CA spectra of these product ions with those of authentic reference ions reveals an ipso-substitution of the chloro substituent by NH_3 . The transfer of NH_3 radical cations into the ICR cell and reaction with mono- and dichlorobenzenes results only in an efficient charge transfer. However, the reaction of externally generated radical cations of halogenobenzenes with neutral NH_3 gives rise to nucleophilic substitution products.

The following reaction rates have been determined:

compound	$k_{\text{exp}} \times 10^{-10} [\text{cm}^3 \text{s}^{-1}]$	eff = $k_{\text{exp}}/k_{\text{AOC}} \times 100$
<chem>C6H5Cl</chem>	3.2	19 %
<chem>C6H5Br</chem>	3.2	20 %
<chem>o-C6H4Cl2</chem>	2.6	16 %
<chem>m-C6H4Cl2</chem>	1.4	8 %
<chem>p-C6H4Cl2</chem>	0.1	0.6 %
<chem>2-BrC6H4Cl2</chem>	4.0	25 %
<chem>3-BrC6H4Cl2</chem>	1.7	10 %
<chem>4-BrC6H4Cl2</chem>	0.4	2.4 %

The reactions proceed with an efficiency between 25% and 0.6%, and the rates decrease with the kinetic energy of the aromatic radical cations. The radical cations of chlorobenzene and bromobenzene exhibit identical reactivities, but for the dihalogenobenzene radical cations the rate depends strongly on the position of the second substituent and decreases in the series ortho > meta >> para.

Furthermore, in the case of the bromo-chlorobenzenes a positional substituent effect on the reaction selectivity is observed. The 2-bromo-chlorobenzene radical cations substitute the Cl- and Br-substituent nearly at a ratio of 1:1 while substitution of Br is preferred in the radical cations of 4-bromo-chlorobenzene by a factor of 14.

These results indicate a multi-reaction step mechanism for the nucleophilic substitution of the radical cations of halogenated benzenes and a change of the rate determining step with the type of substitution of the benzene derivative.

SOLVOLYSIS AND PROTONATION: POSITIVE ION FORMATION IN THE GAS PHASE AND SOLUTION

Thomas Hellman Morton, University of California, Riverside CA 92521

Bond heterolysis of a gaseous ion to form an ion-molecule complex can be described as a gas phase analogue of solvolysis, where a covalent bond (which is directional in nature) is converted to an ionic bond (where the ion is virtually free to rotate about its center of mass and to undergo structural rearrangements). In the gas phase the ionic bond consists of ion-dipole and ion-induced dipole components, rather than ion pairing. Otherwise the chemistry of ion-molecule complexes is very much similar to the chemistry of ion pairs in solution when they undergo E1 elimination reactions.

We have investigated a model for the formation of ion-molecule complexes from covalent precursors. Our model does not assume that there is any potential energy barrier separating the ion-molecule complex from a covalent isomer. (In practice, ion-molecule complexes can be reliably inferred only when the cationic fragment undergoes a rearrangement, such as the conversion of n-propyl phenyl ether molecular ion to the complex of isopropyl cation with phenyloxy radical, depicted above.) Although there is, in general, a barrier between the precursor and the complex, there is no potential energy barrier preventing the complex from returning to a rearranged covalent molecule (e.g. the collapse of the complex above to the molecular ion of phenyl isopropyl ether).

We consider the number of vibrational states that lead to simple bond fission, $G_{3N-7}(E^*-E_0)$, when the precursor molecule has internal energy E^* and a thermodynamic dissociation barrier E_0 . We compare $G_{3N-7}(E^*-E_0)$ for the simple fission transition state with the number of vibrational states corresponding to the ion-molecule complex. To get this latter number we compute the density of states of the ion-molecule complex, $\rho'_{3N-6}(E^*-E_1)$, where E_1 is the energy of the ion-molecule complex relative to its covalent precursor. The internal degrees of freedom for the ion-molecule complex are the 3 degrees of freedom of a point dipole in the central field (not necessarily symmetric) of the ion represented by r , ψ , and ω , the two librations of the dipole represented by θ and ϕ , the relative rotation about the axis connecting the centers of mass, and the internal degrees of freedom of the two fragments. When we compute $\Delta E \rho'$ (where ΔE corresponds to uncertainty broadening) and G_{3N-7} for phenoxy radical + isopropyl cation, we find that for ion-molecule complexes in the range $r = 7\text{\AA}$ to $15\text{\AA}$, complex formation is approximately as probable as complete fission ($r=\infty$) even when the total energy content corresponds to $E^*-E_0 = 0.5\text{ eV}$. This is taken to account for the predominance of ion-molecule complex products over simple fission in R2PI/Photodissociation expts.

SOLVENT AND STRUCTURAL EFFECTS ON GASEOUS ION ENERGETICS AND REACTIONS

T.B.MCMAHON
DEPARTMENT OF CHEMISTRY
UNIVERSITY OF WATERLOO
WATERLOO, ONTARIO, CANADA
N2L 3G1

A number of gas phase ion molecule reactions have been investigated, using the techniques of Fourier transform ion cyclotron resonance spectrometry and high pressure mass spectrometry, which illustrate both the similarities and differences between reactions of ions in the gas phase and in solution. The considerable power of ion cyclotron resonance techniques to probe mechanistic details of ion molecule reactions has been exploited to examine an isoelectronic analogue of the Wittig reaction. Both fluorosilyl and methylsilyl substituted carbanions can be regarded as isoelectronic with a phosphorous ylid which serves as the key reagent in the Wittig reaction. For example, if $\text{F}_3\text{SiCH}_2^-$ is allowed to react with formaldehyde a Wittig style reaction occurs, presumably by a 4-centered intermediate, to yield F_3SiO^- and ethylene (eqn 1).

This reaction appears to be general for any combination of methyl and fluorine substitution on silicon in the silyl carbanion. However when exothermic proton transfer can occur it usually proceeds to the exclusion of the Wittig like reaction.

A second mechanistic investigation with a solution phase analogue involves the gas phase derivatization of carbonyl compounds. In solution carbonyl compounds are frequently characterized by the melting point of oximes which are generated in the reaction of the carbonyl with hydroxylamine in acidic solution. We have examined an analogous process in the reaction of protonated methoxyamine with carbonyl compounds. As in solution the reaction observed is elimination of water from an intermediate complex to yield a protonated oxime as, for example, in eqn (2).

High pressure mass spectrometry has proven itself to be an outstanding method for the determination of energetics of both exchange and clustering ion molecule equilibria. We have made use of this technique to examine the clustering of acetone and dimethyl ether onto methylated acetone. The adducts of both ether and acetone with methylated acetone are strongly covalently bound with binding enthalpies of 26 kcal/mol and 22 kcal/mol respectively. The principles of stereoelectronic control predict that the most strongly bound conformer will be that one in which a maximum amount of steric interference will arise. This prediction is borne out in the measured entropy changes for these two clustering reactions of -58 cal/mol-K and -42 cal/mol-K respectively (see Table 1). Construction of space filling models serves to verify that the ether adduct is indeed more sterically congested than the acetone adduct. In order to confirm that these anomalously large negative entropy changes are due to the restriction of rotations in the adducts we have also examined various deuterated analogues of these adducts. In each case the expected behaviour is observed with the magnitude of the negative entropy change increasing with increasing deuterium substitution. This study has thus permitted a quantification of the magnitude of steric effects in congested species. At higher temperatures it is observed that a marked change in the clustering energetics occurs with a shift to lower binding enthalpies but also to more normal less, unfavorable entropies. This change is associated with an isomerization to a more weakly bonded methyl cation bound dimer species with minimal restriction of internal rotations.

The advantages of FTICR and high pressure mass spectrometry have been combined in a new instrument which we have recently constructed at the University of Waterloo. An external high pressure ion source has been mated to our Spectrospin CMS-47 FTICR spectrometer to allow the production of cluster ions in the high pressure environment and to then transfer them to the ICR cell where they can be trapped for long periods of time and their subsequent ion molecule reactions with selected substrates examined. This facility allows us to probe the transition from gas phase to solution phase behaviour by generating ions with a specific extent of solvation and observing the change in reactivity as this extent of solvation is varied. For example we have recently examined the bimolecular reactions of protonated water clusters with a variety of substrates. If the $(\text{H}_2\text{O})_3\text{H}^+$ ion is allowed to react with acetone in the ICR cell the reactions observed are the addition of acetone followed by elimination of either one or two molecules of water. The new species formed then react in the same fashion until all of the water has been removed from the cluster ion. Interestingly the ion formed at m/z 117 is found by CID experiments to have a structure different than the proton bound dimer (I) which is produced in the direct association of protonated acetone with acetone. This ion most likely has the structure of a dimethyl-alkoxy carbocation (II). This is then a good example of how solvent can modify

ionic reactivity. Since the reactant ion is a protonated acetone coordinated to one or two water molecules the second acetone molecule cannot add at the proton since a water molecule already blocks this site. Instead, the acetone approaches the carbonyl carbon, the site thought of in solution as the more reactive centre. This reaction can be thought of as the reaction of acetone with a 12 M acid droplet in the gas phase.

TABLE 1

Methyl cation transfer and clustering reactions and associated thermochemical data derived

BIMOLECULAR REACTIONS AND STRUCTURES OF IONS IN THE GAS PHASE

Nico M.M. Nibbering
Institute of Mass Spectrometry, University of Amsterdam,
Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Bimolecular reactions and structures of ions in the gas phase constitute an important part of chemistry. Studies in that particular area can reveal similarities with and differences from corresponding reactions and species in solution, thereby providing a better insight into the role of solvent molecules and intrinsic properties of the species involved.

This will be exemplified by results to be presented below, which have been obtained via application of the elegant and powerful low pressure method of Fourier transform ion cyclotron resonance (FT-ICR).¹⁻⁴ A few years ago the reaction of naked hydroxide ions with formaldehyde has been found to lead to hydride solvated water molecules⁵ as shown in equation (1):

In this case the solvation energy gained upon formation of the collision complex, which is not carried off because of the absence of third-body collisions under the low pressure conditions of FT-ICR, fuels a proton transfer from formaldehyde being less acidic than water in the gas phase. A subsequent hydride transfer from the formyl anion to the water molecule in the correspondingly generated complex eventually leads to the products of H_3O^- and CO. These H_3O^- ions, which have also been prepared independently in an ion-beam experiment,⁶ contain exclusively the oxygen atom of the hydroxide ion as shown by ^{18}O -labelling experiments, while ^2H -labelling has indicated that the hydrogen atoms in H_3O^- are not equivalent.⁵

It is also possible to prepare under FT-ICR conditions hydroxide ions solvated by a single water molecule via the reaction sequence (2a) to (2b), where reaction (2a) resembles the well-known Riveros reaction.⁷

If the water solvated hydroxide ions are allowed to react with formaldehyde, long-lived complexes containing the elements of the hydroxide ion and water are generated. ^{18}O -labelling in combination with collision induced dissociation (CID) and chemical reactivity experiments on these long-lived complexes⁸ now show in contrast with the observations made via reaction (1) that the oxygen atoms have exchanged which can be explained on the basis of the reaction steps summarized in equation (3):

These observations demonstrate two things:

- (i) Upon reducing the internal energy of the collision complex between OH^- and formaldehyde, the chemistry shifts from a relatively simple initial proton abstraction by OH^- to an attack of OH^- upon the carbonyl carbon atom to form a tetrahedral species which is well known to play a role during the hydrolysis of esters in solution.⁹
- (ii) The proton shift required to interconvert the tetrahedral structures **a** and **b** in equation (3) means that they are intermediates and, therefore, correspond to potential energy minima.

Another result, which is thought to be relevant to solution chemistry, concerns the generation of the long-lived spiro [2,5] octadienyl anion **c** in the gas phase.¹⁰

This species has received considerable interest in the condensed phase, but its detection has been thwarted by counterion and solvation effects in addition to the possibility that it may be the radical rather than the ion.¹¹ Three routes have been explored to generate the desired $C_8H_9^-$ ion in the FT-ICR cell:¹⁰

- (i) Proton abstraction from spiro [2,5] octa-4,5-diene.
- (ii) Phenyl ring assisted expulsion of trimethylsilyl fluoride following F^- attack upon the Si-centre of 2-phenylethyltrimethylsilane, a route advanced by DePuy et al.¹² for the generation of a variety of stable carbanions.
- (iii) CO_2 loss by CID of the carboxylate anion of 3-phenylpropanoic acid, a reaction type which has been applied successfully by Squires et al.¹³ for the generation of carbanions whose corresponding radicals have a vanishingly small electron affinity.

All three routes have been found to be effective to generate $C_8H_9^-$ ions, whose structures have been probed and identified by specific ion/molecule reactions with hexafluorobenzene through comparison with reference $C_8H_9^-$ ions.

In this way it has been established that the $C_8H_9^-$ ions generated via routes (i) and (ii) are α -methyl benzyl and ortho-ethylphenyl anions, respectively, while those generated via route (iii) react similar to the structurally related 1,1-dimethylcyclohexadienyl anions.¹⁰ Moreover, the $C_8H_9^-$ ions generated via route (iii) react quite differently from those generated via routes (i) and (ii) with hexafluorobenzene in that the former react under expulsion of one molecule of HF, containing exclusively an original phenyl ring hydrogen as shown by 2H -labelling, whereas the latter two react under expulsion of two molecules of HF.¹⁰

In addition, the $C_8H_9^-$ ions generated via route (iii) have appeared not to be capable of transferring a hydride to suitable hydride acceptors.¹⁰

On the basis of all these observations it is therefore quite likely that the spiro [2,5] octadienyl anion 2 is formed by CID decarboxylation of the 3-phenylpropanoic acid carboxylate anion and that it can be a long-lived and stable species in the gas phase.

It is hoped that the few results presented are sufficiently convincing to state that gas phase ion chemistry studies can provide data which are of interest, if not essential, for the field itself and for the chemistry in the condensed phase as well.

DRUG METABOLISM MADE EASY (SOMETIMES): THE USE OF TANDEM MS TECHNIQUES
FOR RAPID STRUCTURE ELUCIDATION
Kenneth Straub, Syntex Research, Palo Alto, CA, 94304

Drugs and other xenobiotics typically undergo a series of biotransformation reactions that result in the formation of metabolites. These metabolites may have reduced, enhanced, or unexpected types of pharmacological activities, and the rate or extent of biotransformation can vary between individuals. A thorough understanding of metabolism is therefore essential to designing studies that can define the pharmacokinetics, pharmacodynamics, and toxicological profile of a given drug. It is for these reasons that the study of drug metabolism is an integral part of the process for drug discovery and development.

Traditionally, drug metabolism is considered a part of the development process rather than as a part of the drug discovery or design process. This is in part due to the comparatively long lead time required to fully characterize the metabolism of a drug. Conventional approaches to the study of drug metabolism typically involve the use of radiolabelled analogues to assist in distinguishing drug-related materials from endogenous compounds, and require the purification and isolation of individual metabolites prior to characterization by techniques such as NMR spectroscopy, mass spectrometry, and chemical synthesis.

The utility of MS/MS as a technique for rapidly determining the structures of drug metabolites was first proposed by Yost and co-workers in 1982 (1). In this paper, the authors pointed out that since metabolites usually retain some of the substructural features present in the parent drug, MS/MS scans that are specific for these substructures could be used to search for drug-related components present in crude sample extracts. The authors made use of a conventional direct insertion probe and CI conditions for sample introduction and ionization; conjugates were hydrolyzed enzymatically or chemically prior to MS/MS analysis. In subsequent papers by other investigators (2-4), it was demonstrated that when desorption ionization techniques such as FAB or thermospray were used, MS/MS scan sequences could be designed that were specific for the various types of conjugation products (eg., glucuronides, sulfate esters, glutathione conjugates, etc.). Thus, a combination of MS/MS scans specific for either the drug or for expected conjugation products could in principle be used to screen a sample extract for all of the possible metabolites of a given drug. Note that MS/MS is being used here as a method for enhancing the specificity of the mass spectrometer so that only drug-related components will be observed. This emphasis differs somewhat from the more ordinary use of MS/MS as a means for increasing the amount of structural information present in a mass spectrum. It is relatively straightforward to obtain structurally significant fragmentation on a given compound, but it can be very difficult or even impossible to devise a scan that has the requisite selectivity and sensitivity for screening purposes.

This approach, coupled with the fact that biotransformation is usually restricted to a limited number of metabolic pathways, was shown to be capable of providing useful data on metabolism in a few experiments, without the need for lengthy isolation procedures. The potential for a significant savings in time over more traditional approaches to metabolite identification attracted widespread attention, both by academic researchers and by the pharmaceutical industry.

The ideal case for the use of MS/MS techniques in drug metabolism occurs when the drug of interest is a low molecular weight (<500 d.) compound containing several distinct structural moieties, which will yield a CAD spectrum with fragment ions corresponding to each of the substructures. An example of such an ideal case is provided by the structure shown in figure 1. CAD of the protonated molecular ion ($M+H$)⁺ formed by FAB or TSP ionization yields fragment ions characteristic of the (N,N)-di-n-propylamino side chain (m/z 114) and of the indolone (m/z 160, 132). Precursor ion scans for these features (eg., parents of m/z 114 or 160) are an efficient means of detecting drug-related materials present in a urine or plasma extract. Conjugates such as O-glucuronides or sulfate esters can be detected by appropriate MS/MS scans (eg., neutral loss of 176 d. for glucuronides, neutral loss of 80 d. in negative ion mode for aromatic O-sulfates, etc.), and a fairly comprehensive understanding of the metabolism of this drug can indeed be obtained from a very limited number of experiments (5).

Over the past several years numerous examples of the successful use of MS/MS techniques for metabolite structure elucidation have appeared, but it has also become apparent that there are instances where the methodology provides ambiguous or even incorrect answers. For example, a structure that has a CAD spectrum that is dominated by loss of an acetate or other common substituent may not yield fragment ions that can be used to adequately distinguish drug metabolites from endogenous components (non-specific or trivial fragmentation). Another commonly encountered problem is that of overly complex CAD fragmentation, an example of which is shown in figure 2. Selection of a useful set of precursor ion scans for detection of metabolites of this structure would be difficult, although scans specific for conjugating moieties might still provide some useful information. Perhaps the most commonly encountered problem is that of a CAD fragmentation process that is not well understood. An example of the latter is shown in figure 3, where the apparently simple loss of MeOH from a methylbenzazepine N-oxide was shown by isotopic labelling to actually involve loss of benzylic carbons in a 1:1 ratio by a complex rearrangement reaction. This fragmentation appears to be unique to this particular structure, and MS/MS scans based on it (eg., neutral loss of 32 or parents of 180) are of no value for the detection of other metabolites of the parent drug.

While most of the early publications on the use of MS/MS for metabolite identification tended to stress the ability to examine crude mixtures directly (*ie.*, MS/MS as a substitute for a chromatographic separation), the tremendous complexity of biological samples dictates the use of some sample cleanup or extraction steps. Combined chromatography-MS techniques would seem to be an ideal method for dealing with this complexity, and most recent publications have taken this approach. HPLC-MS/MS systems using either thermospray, continuous flow FAB, or one of the variants of electrospray appear to offer the most flexibility for metabolism studies. These ionization methods can be successfully applied to most types of drug metabolites, especially polar, thermally labile conjugation products. A variety of additional techniques previously developed for MS studies of complex mixtures can be fruitfully applied to MS/MS studies on metabolism. One particularly useful technique is the use of "isotope twinning", where a 1:1 mixture of the drug and a stable isotope analogue is used. The unique isotope pattern that results can simplify the task of distinguishing drug-related components from endogenous compounds.

Techniques to improve the specificity of MS/MS scans for different classes of metabolites are also under active development. These include the use of reactive collision gases and the use of combinations of MS/MS scans. One interesting example is shown in figure 4. The bottom trace shows a total ionization chromatogram of a thermospray LCMS analysis, while the middle trace shows the TIC obtained for a neutral loss of 176 d. This MS/MS scan is highly specific for glucuronides (loss of $C_6H_8O_6$ via cleavage of the glycosidic bond), but is not absolutely specific. The minor peaks apparent at 25 and 29 min are in fact not glucuronides, but result from fragmentation of a heterocyclic compound (composition $C_{10}H_{16}N_2O_4$) that also happens to have a nominal mass of 176 d. Under the conditions of thermospray ionization with an ammonium acetate buffer, O-glucuronides form an NH_4^+ adduct with the carbohydrate moiety, yielding an ion of m/z 192. This species undergoes CAD to yield NH_4^+ at m/z 18. The top trace of figure 4 shows the enhanced specificity for glucuronides that is obtained by plotting both the RIC for m/z 18 in conjunction with the TIC for the neutral loss of 176 d.; the coincidence of both peaks provides additional evidence for the presence of a glucuronide. Improved specificity in this example could in theory be obtained by the use of high resolution MS/MS, but such experiments have not been reported as yet.

Extension to "Biotechnology" Drugs:

Drugs derived from biotechnology are just beginning to find their way into common use. These types of drugs are characterized by higher molecular weights (>1000 d.), low therapeutic doses, and complex structures encompassing many different types of functional groups. Examples include peptides, oligosaccharides, and lipopolysaccharides. Are the possible biotransformation products from these types of structures amenable to MS/MS screening techniques?

A good model for a complex polyfunctional compound is the immunosuppressant drug Cyclosporin-A. This is a cyclic undecapeptide incorporating a number of N-methylated amino acids plus a unique residue at position 1 ((4R)-4-((E)-2-butenyl)-4,N-dimethyl-L-threonine). This structure undergoes metabolism in a variety of species to give a series of mono- and dihydroxylated and/or N-demethylated derivatives (6).

Analysis by either FAB or thermospray ionization in the positive ion mode gives a prominent signal corresponding to $(M+H)^+$ at m/z 1202.8. MS/MS analysis of $(M+H)^+$ yields a variety of fragments which provide information about both the identity and sequence of the modified amino acids (figure 5). However, none of these ions appears to be specific enough for the Cs-A structure to serve as the basis for an MS/MS scan to selectively identify metabolites present in a crude bile or urine sample. The negative ion MS/MS spectrum of Cs-A derivatives, in contrast, is dominated by a single fragment corresponding to cleavage of the C7 side chain of residue 1. An example of this is shown in figure 6, for a typical (monohydroxylated) metabolite of Cs-A. A neutral loss scan for this fragment (112 d.) provides a highly selective MS/MS scan for metabolites that retain the butenyl-di-methyl threonine residue. In a similar fashion, metabolites formed by hydroxylation of this residue can be successfully detected by carrying out a neutral loss scan for 128d. in negative ion mode.

Conclusions:

It is perhaps most useful to consider MS/MS as a powerful adjunct to existing methods for characterizing the structures of metabolites, rather than as a replacement for those techniques. In favorable situations, MS/MS experiments can be used to selectively identify metabolites with minimal sample cleanup or isolation. However, there are numerous examples where significant or unexpected metabolites may be overlooked. Specificity is always a problem, and some form of sample cleanup will continue to be required in most cases. In addition, certain types of essential information are still difficult to obtain from MS/MS experiments. Quantitative data, for example, is usually only obtainable if isotopically labelled internal standards are used. Finally, the application of MS/MS screening techniques to the study of endogenous biologically active compounds such as steroids and eicosanoids is an area of emerging interest as MS/MS instruments become more generally available to researchers.

ULTRAVIOLET LASER DESORPTION/IONIZATION OF BIOMOLECULES
IN THE HIGH MASS RANGE

Franz Hillenkamp and Michael Karas

Institut fuer Medizinische Physik, Universitaet Muenster
Huefferstr. 68, D-4400 Muenster, Fed. Rep. Germany

INTRODUCTION

There is obviously a high interest in mass spectrometric techniques for the analysis of biomolecules up to masses of several hundredthousand Dalton. The problem for such applications lies with the generation of such large ions and several approaches have been taken over the last decade or so to develop suitable desorption techniques for ion generation. So far Fast Atomic Bombardment FAB with an upper mass limit of app. 10,000 Dalton and Plasma Desorption PD with an upper limit of app. 35,000 Dalton have been the most successful ones. Most recently Tanaka et al. and the authors group have extended the mass range to several 100,000 Dalton using matrix assisted UV-laser desorption with different matrices <1,2>. This report summarizes some of the most important features of laser desorption of proteins with a nicotinic acid matrix and nanosecond pulses of a quadrupled ND-YAG laser at a wavelength of 266 nm.

EXPERIMENTAL

The LAMMA 1000 instrument, used for these analyses has been described elsewhere <see e.g. 3>. In contrast to the intended operation of this instrument as a microprobe with a laser focus of app. 3 μm diameter, the laser was usually defocused to about 10 - 30 μm for best results in these experiments. Samples were mostly used as supplied by the manufacturer (Serva or Sigma) or by colleagues from different laboratories. Generally results are the better, both in ion yield and spectral resolution, the more salt free the samples are (compare e. g. the spectra of β -D-galactosidase in ref. <3> and <4>. 10^{-5} - 10^{-6} mol/l aqueous solutions were mixed with 10^{-2} mol/l aqueous solutions of nicotinic acid. Ca. 1 μl of this mixture was dripped onto a silver substrate followed by evaporation of the solvent either in air or in the vacuum to yield a reasonably homogeneous substance layer. Preparation of the samples and analysis in the mass spectrometer take typically 15 minutes.

RESULTS

Typically for molecules with masses below app. 100,000 Dalton, but in some cases even for larger molecules like Glucoseisomerase (MW 174,000 Dalton), molecular ions are so abundant that single shot spectra can be recorded with good signal to noise ratio. In other cases 10 to 100 spectra have been added. Spectra usually contain signals of the parent ion as well as those of oligomer - and multiply charged ions. Structural information on non-covalently bound subunits is frequently contained in the spectra; in some cases it appears, as if selected other structural information can also be attained (see e. g. Urease below). No unspecific fragmentation has ever been observed to any measurable degree; all signals below 500 Dalton can unambiguously be assigned to the matrix. The mass resolution is so far limited to typically 50; still the centroids of the peaks permit a determination of the parent molecular mass to typically 0.2%. The sensitivity of the technique was tested for a number of molecules in the range between 14,000 and 170,000 Dalton <5>. For lysozyme and trypsin the total amount of material used for the preparation could be minimized to 50 fmol without substantially sacrificing the quality of the spectra. For glucoseisomerase 200 fmol were needed. It was estimated that in all these cases the total amount of material actually used for the spectra was no more than about 10^{-17} mol.

The following three examples demonstrate the power of the technique. Fig. 1 shows the spectrum of a monoclonal antibody (IgG of the mouse against a specific human lymphokine). It is a typical example of spectra obtained from highly purified, carefully prepared samples. The spectrum contains exclusively signals of the singly and multiply charged parent molecule and its oligomers. From the spectrum the mass has been determined to 149,190 Dalton.

A spectrum of jack bean urease (Sigma) is shown in Fig. 2. This protein consists of 6

Figure 1. Laser desorption/ionization mass spectrum of a monoclonal antibody. Sum of 25 single spectra. For explanation see text.

Figure 2. Laser desorption/ionization mass spectrum of jack bean urease. Sum of 100 single spectra. For explanation see text.

Figure 3. Laser desorption/ionization mass spectrum of violet phosphatase. Sum of 25 single spectra. For explanation see text.

equal subunit and supposedly has a total mass of ca. 545,000 Dalton <G>. The largest ion detected at mass 274,800 is the fragment containing 3 of the subunits; this fragment is known to be relatively stable. The decay into these fragments occurred possibly already during preparation rather having been induced by the laser during the desorption process. Several peaks in the low mass region cannot be assigned to multiply charged ions of the subunit or its oligomers. Though it cannot, at this time be excluded that these signals, tentatively assigned to proteins P1 and P2 represent contaminations of the samples, they reasonably match a pattern of active domains of the subunit chain as found by limited proteolytic cleavage. This would then represent the first demonstration of structural information in laser desorption/ionization spectra obtained through cleavage of presumably exposed covalent bonds.

Glycoproteins are accessible by the technique as well as is demonstrated in Fig. 3. Base peak in the top spectrum is the parent molecular ion of violet phosphatase at mass 35,050 Dalton. The bottom spectrum was obtained from the same sample after cleavage of the carbohydrate fraction of app. 2400 Dalton with endoglycosidase H.

RECENT DEVELOPMENTS IN ISOTOPE ABUNDANCE MEASUREMENTS

J.R. DE LAETER
Department of Applied Physics
Curtin University of Technology
Perth, Western Australia, 6001

Sector field mass spectrometers have been revolutionised by improvements in ion optical design, vacuum technology, multicollector detector systems and microelectronics, whilst computers now play an essential role, not only in data collection and reduction, but also in controlling the spectrometer operation itself.

Ion optical design improvements include the use of non-normal beam incidence and curved pole pieces which enable the effective radius of curvature of the mass spectrometer to be extended whilst the physical size of the instrument remains unaltered. This increased dispersion improves the abundance sensitivity of the spectrometer and provides higher transmission efficiency without a deterioration in resolving power.

The ionisation efficiency of solid source mass spectrometers has been improved by the use of activators [1], resin bead techniques [2] and micro-electrodeposition [3]. These techniques have enabled sample sizes to be reduced without sacrificing accuracy and precision. In the nuclear industry, this reduction in sample size has been driven to some extent by safety requirements, but it has also provided the opportunity to tackle a range of previously inaccessible problems not only in nuclear science, but in fields as diverse as cosmochemistry and lunar science [4].

One of the most recent enhancements in mass spectrometer design has been the advent of multicollection. This enables simultaneous measurements to be made of a number of ion beams, thus removing errors caused by fluctuations of beam intensity in the peak jumping mode. Small samples can therefore be measured with greater precision than is the case for single collector instruments. Modern mass spectrometers can be equipped with a computer controlled, fully automated collector system which allows the analysis of a variety of elements with minimal operator intervention. The collector system can also be fitted with an electron multiplier or Daly Collector system for ion beams that are too small to be measured with Faraday Cup collectors.

Mass fractionation represents a fundamental limitation to the accuracy of isotopic ratio measurements in mass spectrometry. Mass fractionation can arise from a variety of sources - from evaporation processes in thermal ionisation sources, in sputtering processes in ion microprobe spectrometers and in some collector systems. Furthermore, the measured isotopic ratios change progressively with time during an analysis. It is also important to distinguish between instrumental-induced mass fractionation, and fractionation caused by natural processes [5]. The double spike technique can be used to eliminate machine-induced fractionation and enables physiochemical isotopic effects to be measured [6]. Light elements are particularly prone to mass fractionation. This can be overcome in large measure by measuring a heavy molecular species containing the light element.

The advent of modern computer-controlled mass spectrometers, which apparently provide excellent data with little operator involvement, require a comprehensive calibration regime to ensure that the output information is of optimum quality. Thus the linearity of the instrument should be periodically calibrated over a wide range of isotopic ratios. Synthetic mixtures of highly enriched uranium isotopes are now available to enable the mass spectrometry community to test the accuracy of their instruments [7]. Multi-collector detector systems also require the frequent calibration of the gain of each measuring channel to ensure that the isotopic ratios are measured accurately. The US National Institute of Standards and Technology

provide calibrated samples for a number of elements to enable the mass spectrometer performance to be checked against internationally approved standards.

The stable isotope dilution technique enables the abundance of over 70 elements to be determined in a wide range of samples. Its accuracy and sensitivity is approached only by neutron activation analysis. The abundance of an element is determined from the change produced in its isotopic composition by the addition of a known amount of a tracer of that element whose isotopic composition is different from that of the naturally occurring element. The technique has been widely used in nuclear science and in geochronology. It has also been used extensively in determining the amount of trace elements in geochemical reference samples. It is now being adopted in medical applications as an alternative to radioactive tracer techniques.

Negative thermal ionisation can be used as an alternative to the more commonly used positive ion technique. Negative thermal ionisation can produce high ionisation efficiencies for certain elements, and has the added advantage that organic impurities are reduced. The interaction of solar neutrinos with molybdenum produces extremely small quantities of technetium. This has prompted the development of a highly sensitive isotopic technique for measuring technetium using negative thermal ionisation [8]. Technetium samples of approximate size 1 pg can be analysed with high ionisation efficiency.

Concurrent with these developments in instrumentation has been the necessity to improve chemical processing procedures. This has been essential in order to reduce chemical blanks and to improve the purity of the extracted samples, so that the enhanced sensitivity in mass spectrometry can be fully utilized. Improved clean-room facilities and reagent purity are mandatory.

An alternative approach is to omit any form of chemical processing by analysing the sample in situ. The ion probe mass spectrometer has been successfully used to measure the isotopic composition of a number of elements in a variety of materials. A schematic representation of the Sensitive High Resolution Ion Microprobe (SHRIMP) at the Australian National University is shown in Figure 1. It has been successfully used to examine isotopic anomalies in titanium and magnesium from hibonite grains in carbonaceous chondrites [9], and has revolutionised zircon geochronology [10]. The technique offers great possibilities in deciphering the nucleosynthetic processes that are responsible for isotopic anomalies in meteorites. Apart from the minimisation of contamination, the ion microprobe technique also has the advantage that it does not extensively damage the samples and enables the isotopic composition of elements in mineral phases to be analysed.

FIGURE 1

FIGURE 2

Mass spectrometry has progressively adopted technological advances developed in other scientific areas to improve the sensitivity and precision with

which isotopic ratios can be measured. The use of particle accelerators as ultrasensitive mass spectrometers has enabled isotope ratios below 10^{-12} to be measured. The basic concept in accelerator mass spectrometry is to discriminate between atomic species in the ion source by using negative ions to destroy interfering molecular species, and then to count identified individual accelerated ions. The ion beam transport system of the Rochester University tandem accelerator mass spectrometer is shown schematically in Figure 2 in which ion beam defining apertures are designated by AP, and Faraday cups for ion beam current measurements as FC.

One of the most important applications of accelerator mass spectrometry is carbon-14 dating, since it has sufficient sensitivity to make it superior to conventional counting techniques. Accelerator mass spectrometer systems can now measure the ^{14}C content of samples containing approximately a milligram of carbon in which the mass ratio $^{14}\text{C}/^{12}\text{C}$ is 10^{-13} . Satisfactory agreement between ages calculated from accelerator mass spectrometry and conventional ^{14}C dating techniques has now been demonstrated. The most celebrated use of accelerator mass spectrometry is the radiocarbon dating of the Shroud of Turin. Very small samples from the shroud have been dated in laboratories in Arizona, Oxford and Zurich. The results from the three laboratories are in good agreement, and showed that the age of the shroud is AD 1260-1390 at the 95% confidence level [12]. The results therefore conclusively prove that the linen in the Shroud of Turin is of mediaeval age.

A number of new mass spectrometers have been developed in recent years. Inductively coupled plasma source mass spectrometry (ICP-MS) offers a direct method of determining trace elemental and isotopic analyses on samples in solution. The technique has now been adapted to solid samples using a laser ablation system which carries the ablated particles into the ICP source. Resonance ionization mass spectrometry (RIMS) uses a pulsed laser to remove the electrons from a selected atomic species by tuning it to a discrete resonant electronic transition. The probability of ionisation increases enormously because of the step-wise absorption of photons. A laser microprobe mass spectrometer (LAMMA) utilises a laser pulse to vaporize and ionize trace amounts of an element which is then analysed in a time-of-flight spectrometer. The primary advantage of a laser microprobe is its ability to analyse organic and inorganic species with high precision.

RECENT COMPUTER APPLICATIONS IN MASS SPECTROMETRY

Charles L. Wilkins
Department of Chemistry
University of California, Riverside
Riverside, California 92521

A rapidly-developing area of interest in analytical mass spectrometry involves the use of combined analysis systems (e.g. GC-FTIR-MS) to improve the reliability of mixture component identification. There are, at present, two such commercial instrument systems. One employs an infrared lightpipe GC interface and a high performance Fourier transform infrared spectrometer, designed for maximum sensitivity. The other is based on use of a matrix-isolation GC-FTIR interface, also for the purpose of enhancing infrared spectral sensitivity. Both systems utilize a simple quadrupole mass spectrometer (the Hewlett Packard mass selective detector) as the mass spectrometer component. An advantage conferred by use of two or more independent detectors for GC mixture analysis is that the performance constraints for the individual elements can be relaxed (i.e. lower spectral performance can be compensated by the increased information available). Thus, four wavenumber infrared spectral resolution and unit mass resolution are adequate for combined GC-FTIR-MS analysis. With the availability of such linked systems, capable of providing even more information than GC-MS alone produces, the challenge of developing computer interpretation algorithms is an even more important issue. In research to date, the primary approach to interpreting such data was to search independent computer-readable infrared and mass spectral libraries and to compare the results, looking for coincidences and (by inference) increased identification reliability when this occurred. Isenhour and coworkers have explored use of concatenated infrared and mass spectral libraries, analyzed by factor analysis and eigenvector projection (1) and, more recently, we have examined use of pre-search algorithms with a combined library (2). Applications of our new search strategies to complex mixtures, including environmental samples, have shown that such an approach can be highly reliable for both identifying mixture components or suggesting chemical class in cases where the unknowns are not represented in the spectral libraries. In the most recent studies, sample quantities between 10 and 80 nanograms in a thirty component model mixture were sufficient for a joint analysis which correctly identified 28 of the 30 components. An environmental soil steam distillate sample with unknown components present at similar levels also was successfully analyzed.

Efforts to combine computer-aided spectral analysis methods drawing on diverse spectral sources are not limited to directly-linked systems. An example of

another new approach to the interpretation of mass spectral data involves combining carbon-13 nuclear magnetic resonance data from an **unseparated mixture** with GC-MS data to develop algorithms which make topological inferences from the CNMR data and use those inferences to screen the results from GC-MS library searches(3). In this way, the rich information content available from NMR can be brought to bear on GC-MS interpretation. Due to the limited sensitivity of CNMR, this method is not suitable for trace analysis applications, but is a highly reliable adjunct to conventional library search techniques in applications which are not sample-limited. Thus, for a variety of test mixtures, it was found that false positive GC/MS library search identifications of mixture components were completely eliminated, when subjected to screening based upon quantitative carbon nuclear magnetic resonance spectra (3).

In summary, a promising new direction in computer-assisted mass spectral analysis is synergistic combination of additional types of information to improve reliability and efficiency.

**FABMS and FABMS/MS of Proteolytic Digests
of Bovine Aldose Reductase**

Anthony G. Thompson, Lu-shan Rong, Richard Milberg, Furong Sun,
and Kenneth L. Rinehart
Mass Spectrometry Center, School of Chemical Sciences,
University of Illinois, Urbana, IL 61801 USA

The sequencing of peptides has become a routine analytical procedure in our laboratory employing a VG-70-SE-4F four-sector mass spectrometer. The complex mixture of a tryptic digest of an aldose reductase enzyme isolated from bovine kidney has been exhaustively analyzed by FABMS and FABMS/MS. Aldose reductases are members of the aldehyde reductase superfamily of enzymes which show non-linear kinetic behavior and a large degree of homology in their structures¹. These enzymes show a broad substrate specificity, and have been implicated as a central cause of kidney dysfunction and cataracts in diabetic and galactosemic animals². The main objective of this study is to show that mass spectrometry can be used as a primary sequencing method without chromatographic separations which often consume precious sample.

The determination of the complete sequence of bovine lens aldose reductase (BLAR)¹ was recently completed. The sequencing of a blocked N-terminal tryptic peptide of BLAR by FABMS/MS was conducted in our laboratory. Our studies have concentrated on showing homology in the sequences of BLAR and bovine kidney aldose reductase (BKAR).

Equal quantities of BLAR and BKAR were treated under the same trypsin digest conditions and the resulting mixtures were analyzed. Comparison of LRFABMS in the regions of 100 to 2500 daltons showed that 16 peaks corresponding to known tryptic peptides of BLAR were also present in BKAR. High resolution peak matching experiments were conducted on a VG ZAB-SE. The HRFABMS data showed excellent agreement with the predicted compositions, as shown in Table 1. Sequencing of the tryptic peptides was conducted using VG 70-SE-4F tandem mass spectrometer, with either argon or xenon used as CID reagents. A complete fragmentation analysis produced the unambiguous sequences shown in Figure 1.

With greater than 25 percent homology already demonstrated, an investigation of the tryptic peptide mixtures using off- and on-line LC/FABMS are in progress. Many of the higher molecular weight and the more hydrophobic tryptic peptides of BLAR were not observed in the LRFABMS of the mixtures. It is hoped that with LC/FABMS these peptides will be observed and additional homology will be demonstrated. Studies using other proteolytic digests will also be necessary to complete the sequencing of bovine kidney aldose reductase.

**MOLECULAR WEIGHT DETERMINATION OF RECOMBINANT HUMAN GROWTH
HORMONE WITH AN ATMOSPHERIC PRESSURE ION SOURCE QUADRUPOLE
MASS SPECTROMETER**

John Chakel, GENENTECH, Inc., 460 Point San Bruno Blvd., South San Francisco, CA 94080

Thomas Covey, Bori Shushan and George Scott, SCIEX, Inc., 55 Glen Cameron Rd.,
Thornhill, Ontario, Canada L3T 1P2

The use of living organisms for the manufacture of pharmaceutical products and the complexity of the resulting products require the development of specific analytical methods for quality control. In this paper we describe the use of ion evaporation ionization on an API quadrupole mass spectrometer to provide a rapid and accurate means of determining molecular weights of biologically active proteins produced in the biotechnology industry. In addition, further information may be obtained by molecular weight determination of proteolytic fragments of the desired protein.

For mass measurements of recombinant proteins, a Sciex Taga 6000E triple quadrupole mass spectrometer equipped with a standard atmospheric pressure ion source was used. An ion spray Liquid Chromatography/Mass Spectrometry interface was used to effect ion evaporation ionization from a continuous solution of analyte. Purified samples were typically dissolved in dilute aqueous solutions containing acetic, formic and/or trifluoroacetic acid from 0.1 to 1.0% concentrations. Typical sample concentrations were 1 to 100 picomoles/ μ L. Samples were infused with a medical syringe pump at 1-5 μ L/min with one minute full scan acquisition times. Molecular weight determinations over a limited scan range required only subpicomole quantities of sample.

Methionyl-human growth hormone (met-hGH, Protropin® and recombinant hGH (r-hGH)) can be distinguished by tryptic mapping techniques involving the use of enzymatic digestion and gradient HPLC methods. They can also be unequivocally distinguished via their ion spray mass spectrum. By infusing 2-4 μ L of aqueous buffered solutions (ca. 25 picomoles/ μ L) of these proteins to an ion spray LC/MS interface, intense ion evaporation spectra were obtained on 50-100 picomoles of material. Based on amino acid composition, met-hGH (Protropin) should have an average M.W. of 22,256.2. Molecular weight measurements on this instrument indicated a mass of $22,256.32 \pm 0.44$ d, derived from the multiply charged protonated molecular ions having 13-19 charges (Figure 1). Mass measurements of r-hGH showed a similar accuracy and precision. A synthetic mixture of met-hGH and r-hGH also yielded an intense spectrum and accurate molecular weights of both species could easily be determined (Figure 2).

A tryptic digest of met-hGH was run over a reverse phase HPLC column (5 μ L injected of 50 picomoles/ μ L, 1 mm x 10 cm C8 column, 40 μ L/min gradient of 5% to 70% CH₃CN:H₂O with 0.5% TFA in 60 min) resulting in the total ion chromatogram shown in Figure 3. The mass spectrum of the peak at scan 158 (Figure 4) is of the T11 fragment and is representative of the quality of data obtainable. As tryptic fragments generally possess two basic sites (the N-terminus and the C-terminal Lys or Arg residue with the noted additions of any His residues, Lys-Pro or Arg-Pro bonds or subtraction for the C-terminal fragment), the doubly charged ions are of greater intensity than the singly charged (M+H)⁺ species and should yield excellent MS/MS spectra.

Several observations may be made in conclusion. The generation of multiply charged ions at atmospheric pressure and their mass spectrometric detection is an extremely useful technique for the determination of protein molecular weights. The technique is rapid, requires minimal sample handling and is amenable to high sample throughput. Low picomole amounts of material are typically required for analysis. Components in a mixture may be distinguished. The ultimate mass range obtainable depends on the number of charges which a protein can accommodate (total number of basic sites) and on the resolution of the mass analyzer. With this particular instrument it should be possible to attain accurate molecular weight information on 200-300 Kd proteins.

QUANTIFICATION BY GC/MS OF SEPARATED ENANTIOMERS OF ARABINITOL TO AID THE DIFFERENTIAL DIAGNOSIS OF DISSEMINATED CANDIDIASIS.

John Roboz, Edward Nieves and J.F. Holland
Mount Sinai School of Medicine, New York, NY 10029

The use of serum total (D + L optical isomers) arabinitol concentrations to diagnose and monitor disseminated candidiasis in immunosuppressed patients has been limited because of the inability to differentiate between increased arabinitol of fungal and non-fungal (i.e., due to renal dysfunction) origin (1). There is evidence that fungal arabinitol is all D (2) and endogenous arabinitol is a mixture of D and L isomers (3). Our objective was to develop a GC-MS technique for the separation and quantification of the D and L optical isomers of arabinitol in serum and urine.

SAMPLE PREPARATION. Serum: 200 μ L serum + 100 μ L I.S. (5 ng/ μ L) + 500 μ L hexane, vortex, centrifuge 10 min, 3000 g; to aqueous layer add 1.8 mL acetone, vortex, centrifuge 10 min, 3000 g, dry supernatant with nitrogen, waterbath 35 C°. Urine: filter 500 μ L urine through 10,000 dalton cutoff Centricon 10 (Amicon Co.) filter; 50 μ L filtrate + 100 μ L I.S. (5 ng/ μ L), dry with nitrogen. Derivatization: dried samples + 200 μ L methylene chloride + 100 μ L TFA, heat 75 C° for 20 min, cool to 25 C°, dry with nitrogen, add 50 μ L toluene, vortex, inject 1 or 1.5 μ L.

GC-MS CONDITIONS. Perpentylated α -cyclodextrin glass capillary (4), 0.25 mm ID, isothermal 100 C°, 7 min (20 m column) or 18 min (40 m column), increase to 150 C° at 20 C°/min, hold 4 min. Carrier: helium. Injection: splitless, 200 C°; transfer line 220 C°. Mass spectrometer: Model Trio-3 (VG Masslab); CI: isobutane; multiplier 650-950 V. Full spectra: scan 100-650 amu in 1 s. Selected ion monitoring of base peaks: m/z $\approx$ 519 and m/z = 526 (int. std.) ions corresponding to the loss of an OCF₃CO group from the acetylated compounds (fully deuterated arabinitol, int. std.).

CHROMATOGRAPHIC SEPARATION. Fig. 1 illustrates the separation of 1 ng each of D- and L-arabinitol, adonitol and xylitol, using a 20 m long column. The retention times of D- and L-arabinitol were between 4 and 5 min and the separation was nearly at baseline. Using 50 m long columns, retention times increased to 16-18 min as illustrated in Fig. 2 (see below). The longer columns offered no advantages, thus most experiments were carried out using 20 m columns. As the columns aged, chromatographic resolution decreased, and often the separation was poorer than shown in Fig. 1 (e.g., compare Fig. 4A and 4B).

D-ARABINITOL IN CANDIDA. The D/L ratio in normal serum (Fig. 2A) changed drastically after inoculating and incubating with *Candida albicans* (Fig. 2B) showing that D-arabinitol is the major metabolic product; Fig. 2C shows the addition of L-arabinitol.

D/L IN NORMAL SERUM AND URINE. In normal serum (Fig. 3) from the blood bank (n=16), the mean $\pm$ s.d. of D/L ratio was (based on peak heights) 1.5 ± 0.4 (range: 0.9 - 2.2). The mean for cancer patients without candidiasis (n=10) was 1.6 ± 0.4 (range: 1.0 - 2.2). Defining the upper limit of normal as the mean + 2 s.d., D/L ratios > 2.3 are considered abnormal. In normal urine (n=14) the mean $\pm$ s.d. of D/L ratio was 1.6 ± 0.3 (range: 1.1 - 2.1). Defining the upper limit of normal as the mean + 2 s.d., D/L ratios > 2.2 are considered abnormal.

D/L PROFILES (Fig. 4). A = confirmed candidiasis, increased creatinine, B = confirmed candidiasis, normal creatinine, C = no candidiasis, high creatinine (dialysis), D = no candidiasis, high creatinine (renal dysfunction). In 12 confirmed candidiasis samples, D/L was > 2.3 in 10 cases (range 2.4-14.1), there was one false negative, and one was borderline.

Ion Evaporation ionization is a process which has the capability to generate quasi-molecular singly and multiply charged ions from molecules in the tens of kilodaltons mass range(1,2). Pure Ion Evaporation spectra can be obtained from an Electrospray interface, an Ion Evaporation interface, or an Ion Spray interface. An Ion Spray interface was used with a Sciex TAGA 6000E MS/MS equipped with an Atmospheric Pressure Ion source to obtain the following data.

The spectra of several multiply charged high mass ions will be shown to provide considerable information about the nature of the molecular composition and structure of the molecules. Molecular weights of cyclic and linear proteins and peptides can be determined to within one dalton of the average mass with a simple calculation. The number of positive charges and the charge distribution provide information about the basicity of the molecule. Globular proteins generally have a subunit structure, the subunits being either identical or of different composition and bound together by hydrogen bonding, ionic interactions, and Van Der Waals forces. The spectra of subunit containing proteins provide the mass of the individual subunits. It appears that the molecules denature in the gas phase as a result of their highly charged state. Examples include hemoglobin of MW 61,983 composed of two pairs of identical chains (15,126 and 15,865 daltons) and a heme (616 daltons), and jacalin (a peanut agglutinin) composed of a 14,660 dalton protein and a 2058 dalton peptide. Under the correct conditions, co-factor and metal binding proteins also tend to release the ligand to allow for independent mass measurements of the protein backbone and the ligand. This can be observed in the spectra of hemoglobin when acquired in solvents containing a high content of organic modifier.

Influence of the Ratio of Glycerol to Analyte on FAB-MS Analyses

C.E. Heine*, J.F. Holland⁺, and J.T. Watson*⁺, Departments of Chemistry* and Biochemistry⁺,
Michigan State University, East Lansing, MI 48824.

Sample preparation is a critical factor in determining the quality of FAB-MS results. The mass spectrometrists would prefer to maximize the signal from the analyte and minimize the interfering spectrum from the liquid matrix. Various strategies have evolved to accomplish these goals. Many workers add acidic or cationic modifiers to their samples to enhance the analyte ion abundance in the positive ion mode; unfortunately, this method also increases the abundance or complexity of the matrix spectrum in many cases (1). Some laboratories apply the matrix from a solution of a particular concentration (e.g., 50% aqueous glycerol), while others deposit a neat portion of matrix on the sample pedestal. The present fundamental study documents the effects of the relative proportions of analyte, glycerol, and water upon the FAB-MS results for 5 different peptides and presents a model to explain these results.

This investigation was spurred by the following observation. 4 nmoles of the nonapeptide bradykinin provided significantly improved spectra when sampled from a mixture containing 0.10 mg glycerol and 1.92 mg water (a 2 μ l aliquot of 5% glycerol) over that sampled from a mixture containing 1.3 mg glycerol and 1.0 mg water (a 2 μ l aliquot of 56% glycerol). Both these compositions pertain to the sample prior to its exposure to the vacuum. The spectral improvement was pronounced in terms of increased visibility of analyte peaks with respect to matrix peaks. To characterize this effect, 2 μ l samples containing 4 nmoles of bradykinin in 56%, 21%, 5%, 2%, and 1% glycerol (prior to exposure to the vacuum) were analyzed repetitively. The first 10-second scan was evaluated in each case. Plots of peak intensity vs. weight % glycerol were constructed for both analyte and matrix ions. These plots illustrate a distinct increase in bradykinin peak intensities coupled with a significant decrease in glycerol peak intensities as the proportion of glycerol in the sample declined.

Because the spectral improvement coincided with a decrease in glycerol proportion and an increase in water proportion of the initial sample, experiments were conducted to identify the critical sample component. Samples containing the optimal portion of glycerol (0.10 mg) but widely varying quantities of water (along with the 4 nmoles of bradykinin) yielded indistinguishable results by FAB-MS. Gravimetric measurements of the optimal sample composition taken before and after exposure to the fore vacuum indicated that the vast majority of the aqueous component had been pumped away before the beginning of the analysis by FAB-MS. These results suggested that appreciable quantities of water played no direct role in the enhancement mechanism.

Calibration curves were constructed for several bradykinin ions from samples containing 1-12 nmoles of bradykinin in 1.3 mg of glycerol. These plots showed an approximately linear relationship between peak intensity and quantity of bradykinin. Another set of calibration curves was prepared from experiments employing a similar range of bradykinin quantities sampled from 0.10 mg of glycerol; this set showed a distinct tendency for bradykinin peak intensity to "level off" or to "plateau" for the larger amounts of analyte. Such curves have been observed by others involved in quantitation by FAB-MS (2); the plateau of the curves has been attributed to an optimum surface concentration of the analyte in the matrix. Response curves for the glycerol ions also were constructed from these experiments. The bradykinin samples containing 1.3 mg glycerol showed little change in matrix ion response for all the quantities of analyte employed. Analogous curves corresponding to the bradykinin samples containing only 0.10 mg glycerol showed a dramatic diminution of glycerol peak intensities with the increased portions of bradykinin. This observation also is interpreted as a surface effect, in which strong matrix signal suppression results from increasing analyte surface concentration.

The following model is proposed to explain the spectral enhancement. The molar ratio of glycerol to bradykinin in the 1.3 mg glycerol/4 nmol bradykinin samples is approximately 4,000:1. In the 0.10 mg glycerol/4 nmol bradykinin samples, this ratio reduces to 300:1. Depositing a constant amount of bradykinin into smaller portions of glycerol may be an effective means of forcing the analyte to the surface of the matrix.

Because this model emphasizes surface effects, one might expect differences in the enhancement behavior for molecules possessing different surface activities. Table 1 lists 5 peptides, the masses of their protonated molecules, and the Bull and Breese hydrophobicity index associated with each (3). Figure 1 illustrates the mass spectral enhancement for the protonated molecule of the most hydrophobic peptide, the most hydrophilic peptide, and the peptide of intermediate hydrophobicity when 4 nmoles of analyte are analyzed in the indicated amount of glycerol. The peak intensities correspond to the absolute intensity divided by the full scale value of the detector output. The trend illustrated in Figure 1 is consistent with the proposed model in that the peak intensities of the most hydrophobic peptide are maximized in larger portions of glycerol, while smaller portions of glycerol are necessary to observe the enhancement for the most hydrophilic peptide. Figure 2 documents the behavior of the protonated glycerol molecule for samples

containing each of these peptides. Interestingly, the region of the curves in which this matrix peak is significantly diminished coincides with the region in which the analyte peaks are significantly enhanced. This behavior also is consistent with the model which emphasizes the competition between analyte and matrix at the surface of the sample. Data from the experiments involving proenkephalin and fibronectin related peptide fit into the illustrated trend.

Differentiation of Leafy Spurge (*Euphorbia esula* L.) Accessions Based on Chemical Constitution Using Curie Point Pyrolysis-Mass Spectrometry-Pattern Recognition.

Ron V. Valcarce and Grant Gill Smith

Department of Chemistry and Biochemistry, Utah State University, Logan, Utah 84322-0300

James M. Torell and John O. Evans

Department of Plant Science, Utah State University, Logan, Utah 84322-4800

Curie point pyrolysis-mass spectrometry, in combination with multivariate pattern recognition methodology (py-ms-pr), is shown to be an effective method for differentiating accessions of leafy spurge (*Euphorbia esula* L.) based on the chemical constitution of plant latex. Three multivariate statistical programs--hierarchical cluster analysis, factor analysis, and principal component analysis--correctly classified pyrolysis-mass spectra as to either *E. esula* or *E. cyparissias*. In addition, different accessions of *E. esula* corresponding to three different populations (Mandan, North Dakota; Cambridge, Idaho; and Baker, Oregon), were classified by this method. The features (m/z) responsible for each differentiation/classification were identified using Fuzzy c-Varieties Pattern Recognition (FCV). The results of this study were compared to results obtained in an earlier study using Curie point pyrolysis-gas chromatography-pattern recognition (py-gc-pr) to differentiate/classify the same set of leafy spurge plants.¹ Results from both techniques (py-ms-pr and py-gc-pr) elucidated various biotypes of leafy spurge, demonstrating the applicability of both methods for differentiating/classifying this troublesome weed.

Leafy spurge (*Euphorbia esula* L.) was introduced into North America from Europe in the 1800s, and has since spread throughout southern Canada and the northern United States.² Leafy spurge inflicts large economic losses for livestock producers because it reduces forage utilization and yield.³ Because leafy spurge is not indigenous to North America, natural enemies that would normally keep its population in check, are not present. Currently, a concerted effort is being made by American and Canadian researchers to develop effective biological controls using natural enemies such as phytophagous insects from native European spurge. Prerequisite to implementing successful biological control programs is understanding the biochemical similarities and/or differences among leafy spurge biotypes. Once relationships between biochemistry and host specificity are determined, success of a given biocontrol agent at a given site may be predicted.

Results Mass spectra from *E. esula* accessions were visually discernable from those of *E. cyparissias* spectra as shown in Figures 1 and 2. Pyrolysis-mass spectra from *E. cyparissias* plants could not be distinguished from one another by visual inspection. Mass spectra from four accessions of *E. esula* type spurge were less discernable from each other than from *E. cyparissias* spectra, but were more discernable from each other than were pyrograms resulting from py-gc analysis, which were indistinguishable from one another by visual inspection.¹ The results from hierarchical cluster analyses using UPGMA clustering and Euclidean distance measure, and Principal component analysis of the resulting data are shown in Figs 3-5. As can be seen in Figs 3 and 4, the pyrolysis-mass spectra from *E. esula* and *E. cyparissias* spurge were grouped into two major clusters by HCA and PCA, which is consistent with morphological evidence and is in agreement with previous results for the same samples using py-gc.¹ Subclustering the *E. esula* spectra (Figs 3 and 5) resulted in four distinct groups, corresponding to the different accessions of *E. esula*.

MATRIX ASSISTED UV LASER DESORPTION OF BIOLOGICALLY INTERESTING MOLECULES.

Ronald C. Beavis and Brian T. Chait
The Rockefeller University, New York, NY, USA 10021.

Recent developments in the volatilization of large molecules using matrix assisted ultraviolet (UV) laser desorption have made it possible to produce intact quasimolecular ions from materials with molecular weights in excess of 100,000 using nicotinic acid matrices [1]. We have constructed a linear time-of-flight (TOF) mass spectrometer to be used for both basic research and rapid mass determinations of high mass molecules. Our results demonstrate that mass resolutions of $m/\Delta m \approx 500$ (FWHM definition) can be obtained for small proteins ($m/z < 20,000$), with sensitivities better than 1 picomole and mass range in excess of 100,000 u. Our results also indicate that the actual dimensions of the laser focus are not a critical factor in producing high mass ions. Our irradiation area of 0.1 mm x 0.3 mm produced sufficient numbers of ions so that detector saturation (tandem multichannel plates, 25 mm dia.) was a significant problem.

A survey of possible matrix materials has shown that several different types of compounds produce very similar results to those obtained from the original matrix material 3-pyridinecarboxylic acid (nicotinic acid). Materials were selected for trial on the following criteria: 1) strong UV absorption at 266 nm (the wavelength of our frequency quadrupled Nd-YAG laser); 2) water solubility (so that they could be co-dissolved with proteins); and 3) volatility (volatile/sublimable solids were chosen). Four matrix materials (in addition to nicotinic acid) were found to be useful. These were: 2-pyrazinecarboxylic acid (pyrazinoic acid); 3-methoxy, 4-hydroxybenzoic acid (vanillic acid); thymine; and thiourea. Surprisingly, the nicotinic acid isomers picolinic acid and isonicotinic acid did not work well as matrices, even though their UV absorption properties were very similar to nicotinic acid. Presumably the detailed interaction of the matrix molecules with the protein molecules and with each other is changed by the changing the position of the carboxylic acid group with respect to the nitrogen in the pyridine ring. The much less volatile and relatively insoluble dicarboxylic acid analogues of nicotinic acid did not work as matrices. Analogues of thiourea that did not have strong UV absorptions at 266 nm, urea and guanidine hydrochloride, were also ineffective as matrices.

Another important finding is that matrix assisted UV laser desorption produces both positive and negative quasimolecular ions, with the preferred intact species being singly charged. Figure 1 shows the complete positive and negative TOF mass spectra of insulin (MW = 5733.5 u). Both singly and doubly charged species are seen in both spectra, but the singly charged species is more abundant. This pattern has held true for all of the proteins and peptides so far examined (in excess of twenty different compounds).

Figure 2 is a detail of Fig. 1 (a), showing the positive, singly charged quasimolecular ion region. Fig. 2 clearly demonstrates the presence of several different adduct species. The most intense peak is the protonated insulin molecular ion. The second most intense peak is an adduct with a mass 80 u higher than the molecular weight. This ion can be explained by the addition of the matrix molecule's ring system (pyrazine, MW = 80 u) to the protein molecule. Pyrazine is an expected decarboxylation photochemical product formed by UV irradiation of the matrix (pyrazinoic acid, MW = 124 u). This type of adduct ion (i.e. the matrix molecule minus CO₂) is a feature common to all of the acidic matrices used. It is most significantly a major contribution to peak broadening for high mass proteins, where the resolution is not sufficient to separate the protonated and matrix adduct ion peaks.

The sensitivity of the technique is typically 1 picomole or less. Figure 3 shows the positive ion mass spectrum of *E. coli* β -galactosidase (MW = 116,336) showing the singly, doubly and triply charged quasimolecular ion species, obtained from 0.7 picomoles of protein using pyrazinoic acid as the matrix. The area of the sample probe is 3 mm² and less than 5% of this area was irradiated to produce this spectrum. Total sample probe loadings of 0.1 picomoles of insulin produce spectra with the protonated molecular ion as the base peak. More than 20 peptides, proteins and lipoproteins were examined, and each one produced strong quasimolecular ion signals from ≈ 1 picomole of applied protein.

Conditions: 0.5 μ l of protein/matrix solution loaded onto the probe (0.7 picomoles protein + 5 μ g pyrazinoic acid); total acceleration voltage (w.r.t. the detector) = + 22 kV; 200 shots accumulated; data recorded in 5 ns channels and displayed in 250 ns bins.

STRUCTURAL ANALYSIS OF COMPLEX BACTERIAL OLIGOSACCHARIDES BY TWO- AND FOUR-SECTOR LSIMS

Constance M. John, Michael A. Apicella*, J. McLeod Griffiss & Bradford W. Gibson

Departments of Pharmaceutical Chemistry and Laboratory Medicine, University of California, San Francisco, California 94143-0446 and *Department of Microbiology, SUNY Buffalo, Buffalo, New York

Complete structural determination of the oligosaccharide components of the bacterial lipooligosaccharides (LOS) from *Neisseria gonorrhoeae* will further understanding of the role of the LOS in the pathogenicity and immunochemistry of the disease. LOS from different strains of *N. gonorrhoeae* have been shown to be highly variable in size and immunochemistry.¹ Therefore we are elucidating the structures of the oligosaccharides from several strains. Furthermore, five pyocin-resistant mutants of *N. gonorrhoeae* strain 1291, with altered LOS structures were produced by exposure to pyocin, a bacteriocin from *Pseudomonas aeruginosa*. LOS from these mutant strains have been suggested to contain progressive saccharide deletions.² Determination of the structures and properties of the altered LOS produced by the mutants should greatly aid the development of physical and immunochemical models of these complex and structurally variant LOS.

In general, relatively small quantities of material are available and thus sensitive and efficient procedures are needed for the analysis of LOS structures. Our strategy employs traditional methylation analysis, derivatization with 4-hydrazino-benzoic acid ethyl ester (HBEE),³ reverse phase HPLC purification, two- and four-sector LSIMS with high energy collision-induced-dissociation (CID). The HBEE derivatives are formed using 20 to 300 µg of oligosaccharide in 40 µl of methanol and 10 µl of H₂O with 1 µl of glacial acetic acid, and 1.5 equivalents of HBEE. The reaction condition typically used is 80°C for 30 min and no extraction is necessary due to the small amount of HBEE reagent used. The reaction mixture is dried and injected directly onto a C₁₈ reversed phase HPLC column with UV detection and eluted with an acetonitrile/H₂O gradient.

Figure 1 shows the two-sector negative ion LSIMS spectrum of HBEE derivatives of oligosaccharides from the LOS of 1291A, B, and C mutant strains. These oligosaccharides have so far all been found to contain phosphoethanolamine and O-acetate, which can be removed with aqueous HF treatment, and a common triantennary structure containing 3-deoxy-manno-2-keto-octulosonic acid (KDO) at the reducing terminus attached to a heptose disaccharide and a single N-acetylhexosamine.

Figure 1. Negative ion two-sector LSIMS spectra of HF-treated oligosaccharide from mutant strains 1291 A,B, and C derivatized with HBEE. The 1291-A oligosaccharide is present as the anhydro derivative that is sometimes formed under the HBEE reaction conditions

Figure 2. Negative ion four-sector spectrum with CID LSIMS of HF-treated oligosaccharide from mutant strain 1291B derivatized with HBEE.

A four sector MS (Kratos Concept II HH) with an optically-coupled diode array detector on MSII was used to acquire the MS/MS data. LSIMS spectra were obtained in MS-I in negative ion mode using a Cs⁺ beam and CID was performed in a He collision cell. Figure 2 is a negative ion MS/MS spectrum of HF-treated 1291B oligosaccharide derivatized with HBEE. A systematic nomenclature for the observed fragmentation has been recently described.⁴ Under CID conditions, fragments were observed resulting from glycosidic bond cleavage at every possible linkage including the Hep-Hep bond which was not found in the conventional two-sector LSIMS spectrum (see Figure 1). Valuable branching and sequence information is contained in this MS/MS spectrum as supported by methylation analysis and work on known standard oligosaccharides.

In conclusion, by derivatization of the reducing terminal KDO with HBEE increased sensitivity and fragmentation in LSIMS can be obtained. This fragmentation is mainly directed with charge retention on the derivatized reducing terminus containing the HBEE moiety. More complete fragmentation of the molecule can be obtained by four-sector LSIMS with CID than two-sector LSIMS. Non-reducing terminal fragments perhaps obscured by matrix ions or altogether absent in the two-sector spectrum can be observed in the MS/MS spectrum. The sequence and branching of the molecule can be determined from the fragments formed to some extent in two-sector LSIMS and completely in four-sector LSIMS with CID.

HIGH ENERGY CID (TANDEM MS) OF OLIGOSACCHARIDES USING MULTICHANNEL ARRAY DETECTION

Beth L. Gillece-Castro and A. L. Burlingame, Dept. of Pharmaceutical Chemistry and the Mass Spectrometry
Facility, University of California, San Francisco, CA 94143-0446

Identification of oligosaccharides, whether attached to lipids or proteins, is central to the interpretation of the function of glycoconjugates. In order to elucidate the structures of glycans and conjugates we have enhanced the information content available from pmol amounts of oligosaccharides by enhancing the sputtering yield and fragmentation of glycans. This is accomplished by derivatization and tandem mass spectrometry.

In their native state oligosaccharides can be protonated or deprotonated in MS1 and their high energy CID spectra obtained. The sputtering yield for underivatized materials is low (1-10 nmol required), particularly for positive ions. Fragmentation of deprotonated species in the negative mode is dominated by ring cleavages of the type $1,5A,1$. Increasing the hydrophobicity of glycans by derivatization improves sputtering yields and directs the fragmentation by providing preferred sites of protonation, deprotonation and charge retention. All hydroxyls may be capped by permethylation or peracetylation, increasing the sensitivity by a factor of ten. Alternatively, free reducing termini may be coupled to a lipid-like tail. If tetradecylaniline is used the sensitivity has been shown to increase by a factor of 50. The positive ion CID spectra of these derivatives are dominated by $1,5X, Y, Y+2$, and Z fragments. The masses of the Y ions are shown in Figure 1 while the $1,5X, Y+2$ and Z ions are designated $+$, $!$ and $*$ respectively. The $Y+2$ fragmentation pathway involves glycosidic bond cleavage with a hydrogen rearrangement onto the nonreducing terminal neutral fragment. Ten picomoles of the p -tetradecylaniline produced fragments in the tandem spectrum of sufficient intensity to allow structural assignment.

The coupling to aniline derivatives may be combined with peracetylation. For example, the ethyl p -aminobenzoate derivative of a high mannose oligosaccharide underwent partial acetolysis and the positive ion CID spectrum, of a $Man_6GlcNAc$ cleavage product is shown in figure 2. B fragments (oxonium ions) for 1, 2 or 3 hexose residues were the only abundant fragments in the spectrum demonstrating the directing effect of permethylation and peracetylation. The fragments are consistent with the predicted longest hex sequence in the structure containing three mannose residues.

The sputtering yield of glycolipids may be enhanced by permethylation since no reducing terminus is available. We have analyzed a novel ganglioside whose molecular weight is approximately 2500u. The CID spectrum of an abundant fragment m/z 1087 contained B and Z ions which identified a Hex-(Fuc-3)HexNAc terminus.

Chromatographic Separation of High Mannose Oligosaccharide Isomers and
Their Characterization by Collision Induced Dissociation

Johnson, R.S., Costello, C.E.^Ψ, and Reinhold, V.N.
^ΨHarvard University School of Public Health, Boston, MA 02115.
^ΨMassachusetts Institute of Technology, Cambridge, MA 02139.

Tandem mass spectrometers have been shown to be effective instruments for resolving mixtures of peptides. Moreover, sequence for these linear biomolecules can be directly deduced from their CID spectra. Comparable approaches, unfortunately, are not applicable to oligosaccharides, which frequently consist of isomeric monomers with branched sequence arrays. Thus, for the analysis of glycoconjugates there is a greater reliance on chromatographic methods to resolve the structural details inherent in these biopolymers. Collision (or FAB) spectra in the absence of data on isomeric purity should not be considered as an appropriate answer to questions on chain branching. To address this branching-CID relationship, we have utilized a two-dimensional chromatographic approach (1) employing an amino column, and a reverse phase C₁₈ column for the isolation of N-linked high mannose isomers. The samples were obtained from Endo H treatment of a soybean lectin, and from the urine of sheep suffering from mannosidosis. For sensitive HPLC detection, the mixtures were prepared with either pyridinylamine (PA) or aminobenzyl ethylester (ABEE) labels on the reducing-end. The purified fractions were salt-free and used directly for MS studies.

In this study, an aminopropyl column was used for size fractionation. These fractions were then injected onto a uBondapak C₁₈ column, (Waters Assoc, Milford, MA) using a gradient of 6-12% acetonitrile in 30 minutes. It was found that for high mannose oligosaccharides the resolution provided by the ABEE derivative on an amino column was as good or marginally better than either the reduced PA or the unreduced PA glycosyl amine. The reduced PA derivative is suitable for C₁₈ separations of isomers containing the more hydrophobic chitobiose reducing end (GlcNAc-GlcNAc); however, PA labeled oligosaccharides with single GlcNAc reducing ends are not retained on the column (using isocratic water) for a sufficient period of time to affect separation. With the more hydrophobic ABEE label this is not a problem. The alpha and beta anomers of the unreduced PA glycosylamine complicate the C₁₈ chromatograms; only the reduced derivatives are therefore recommended in this procedure.

There is little difference between the mass spectra of the two sugar derivatives. Both PA and ABEE labeled oligosaccharides gave abundant (M+H)⁺ or (M+Na)⁺ ions with little fragmentation in the positive mode. The negative FAB spectra exhibit (M-H)⁻ ions as well as abundant fragment ions for both derivatives. The fragment ions in the negative FAB spectra are of the same mass as (M-H)⁻ ions of lower molecular weight oligomers, so positive FABMS is best for determining molecular weight heterogeneity.

ABEE derivatized soybean lectin oligomers were fractionated on an amino column. The fraction containing two Man₇GlcNAc-ABEE derivatives was collected and separated on a C₁₈ column. The negative ion CID spectra, (EB-CID-EB), of these two fractions were recorded on a four-sector mass spectrometer, (HX-110), (Fig. 1). Both terminal end (A) and reducing end (Y) fragments are observed (2). Figure 1a, (C₁₈ fraction 1), clearly shows the losses of one (m/z 1341), two (m/z 1179), and four (m/z 855)

hexoses, but no fragment for a loss of three hexoses (m/z 1017). Similarly, terminal end fragment ions are found containing one (m/z 221), two (m/z 383), and four (m/z 707) hexoses, but nothing corresponding to a terminal fragment containing three hexoses (m/z 545). Comparison with Figure 1b, (C₁₈ fraction 2), reveals that these two fractions contain different isomers; the known structures are easily matched with the spectra as shown. Of significance is the observation that the so-called "double cleavage" ions, i.e., ions resulting from the rupture of more than one bond, are apparently absent. It remains an open question as to whether the absence of "double cleavages" is due only to obtaining samples that are free of isomeric contaminants, or if, in addition, the reducing end label suppresses the detection of multiple cleavages.

LDI-FT-ICR MASS SPECTROMETRY OF OLIGOSACCHARIDES.

³Nicolet Analytical Instruments, 5225-1 Verona Road, Madison, WI 53711-0508, USA.

Our research effort has been directed towards LDI-FT-ICR of bacterial capsular polysaccharides (CPS) by hydrolysis using viral enzymes^{1,2}. The oligosaccharides obtained by this procedure correspond to the repeating units of CPS³. Such oligomers are commonly tri- to hepta-saccharides, substituted with labile non-carbohydrate moieties, such as, O- and N-acetate, pyruvic acid acetal, which determines the antigenicity of the CPS. The structural elucidation of these carbohydrate biomolecules involves mostly wet chemical techniques, with FAB and DCI coming into prominence for their role in sequencing. FAB spectra usually show only glycosidic bond cleavages, and the oligosaccharide has to be reduced prior to mass spectrometric analysis for unambiguous sequencing. Furthermore, derivatization (permethylation or peracetylation) is normally required. Unfortunately, both methods may remove base- or acid-labile substituents that may be present in the oligosaccharide⁴.

The LDI-FT-ICR fragmentation patterns seen in oligosaccharides¹⁻² appear to be characteristic of carbohydrates in that these patterns can be used⁵ to assign structural features to fingerprint mass spectra of polysaccharides⁶.

The following examples illustrate the use of positive and negative ion LDI-FT-ICR for the sequencing of underivatized oligosaccharides derived from bacteriophage degradation of *Klebsiella* serotype K3 and *E. coli* serotype K9 bacterial CPS^{7,8}. LDI-FT-ICR spectra of the oligosaccharides showed intense fragmentation resulting from glycosidic bond cleavage and ring rupture. The presence of both ring cleavage ions and glycosidic bond cleavage ions allows, without the necessity of a prior reduction step, unambiguous sequencing of oligosaccharides.

The low resolution mass spectral data of the positive ion LDI-FT-ICR of *Klebsiella* K3 repeating oligosaccharide indicated that i) the CPS is made up of a pentasaccharide repeating unit, consisting of four hexoses, one hexuronic acid and one pyruvic acid acetal; ii) three hexose units are linked together; iii) the hexuronic acid is linked to the three hexose unit; iv) the pyruvate is not linked to the three hexose unit. Thus, the low resolution glycosidic bond cleavage data suggested two possible sequences for the oligosaccharide: Hex-HexA-Hex-Hex-Hex or Hex-Hex-Hex-HexA-Hex. The high resolution ring cleavage data indicated that i) the pyruvate is linked to the terminal single hexose unit; ii) the reducing end terminal hexose is linked via either position 3 or 4; iii) a two hexose unit is sandwiched between two ring cleavage fragments (m/z 553.1760: $[(2\text{Hex})+\text{C}_4\text{H}_7\text{O}_4+\text{C}_4\text{H}_7\text{O}_3+\text{Na}]^+$). The fragment $-\text{C}_4\text{H}_7\text{O}_3$ can only be derived from a hexose unit, thus, the sequence of this m/z 553.1760 fragment is $\text{C}_4\text{H}_7\text{O}_4-(2\text{Hex})-\text{C}_4\text{H}_7\text{O}_3$. The reverse of this sequence will imply a four hexose unit, which is ruled out by the low resolution glycosidic bond data. Therefore the sequence of the pentasaccharide is Hex(pyr)(1→?)HexA(1→?)Hex(1→?)Hex(1→3/4)Hex.

The low resolution mass spectral data of the negative ion LDI-FT-ICR of *E. coli* K9 repeating oligosaccharide indicated that i) the CPS is made up of a repeating tetrasaccharide, consisting of two hexoses, one acetyl hexosamine and one acetyl neuraminic acid; ii) the two hexoses are not linked to each other; iii) the hexosamine unit is sandwiched between the two hexoses; iv) the neuraminic acid is linked to a hexose unit. Thus, the low resolution glycosidic bond cleavage data suggested two possible sequences for the oligosaccharide: Hex-HexNAc-Hex-NeuNAc or NeuNAc-Hex-HexNAc-Hex. The high resolution ring cleavage data indicated that i) one hexose residue is either 3- or 4- linked to the hexosamine (m/z 170.0448: $[(C_3H_4O_2N + C_4H_7O_3) - H_2O - H]^-$); ii) the neuraminic acid gave five fragmentation products, indicating that it is 4- linked to the HexNAc-Hex unit. Therefore the sequence of the tetrasaccharide is Hex(1→?)HexNAc(1→3/4)Hex(1→4)NeuNAc.

In conclusion, high resolution LDI-FT-ICR mass spectrometry can unambiguously sequence underivatized oligosaccharides, including location of an acid-labile pyruvic acid acetal. Tentative position-of-linkage information can also be obtained from both the positive and negative ion spectra. Our earlier work indicated that negative ion LDI-FT-ICR may be able to distinguish the anomeric stereochemistry of carbohydrate molecules, however, this does not seem to be a general phenomena and further work is being carried out to establish the analytical aspect of this empirical observation.

**FAST ATOM BOMBARDMENT MASS SPECTRAL BEHAVIOR OF SACCHARIDES
AND NUCLEOSIDES: MATRIX EFFECT.**

E. Y. Osei-Twum and O. A. Mamer, The Biomedical Mass Spectrometry
Unit, McGill University, Montreal, Quebec H3A 1A3.

The positive ion fast atom bombardment mass spectral behavior of five sugars and five nucleosides was investigated using glycerol, diethanolamine, and propanolamine as the matrix compounds.

Saccharides. In glycerol, the monosaccharides give very weak or no quasi-molecular ion. The predominant process is dehydration for fructose; adduct formation for glucose.

The disaccharides show abundant dehydrated quasi-molecular ions as well as adduct ions between glycerol and the quasi-molecular ions. Sucrose gives abundant ion at m/z 163 which is also the most abundant ion in fructose. The efficient dehydration of fructose is well known and it is attributed to the presence of two CH_2OH groups in the furanose ring.

In propanolamine all the saccharides show extensive dehydration which leads to the adduct ion from propanolamine and the dehydrated quasi-molecular ions.

All five saccharides show no dehydration in diethanolamine. Rather they give the adduct ions formed between the quasi-molecular ion and the matrix.

Nucleosides. Dehydration of the nucleosides is absent. They give abundant $[M+H]^+$ and $[B+H]^+$ ions in glycerol. In addition to these adduct ions resulting from addition of one or more glycerol molecules to $[M+H]^+$ are observed.

Propanolamine has one major influence on the compounds; they are fragmented to give $[B+H]^+$ as the major ion. No adduct ions are observed in this matrix.

There is a graded behavior of the compounds in diethanolamine. With adenosine which has the amino group as the only function in the base, $[M+H]^+$ is the most abundant ion. Guanosine and cytidine have similar spectral features. Both have an amino and an oxo functions in the base and they give more abundant adduct ion formed from the quasi-molecular ion and the matrix. Uridine and 5-methyluridine which have two oxo groups in the base do not give any $[M+H]^+$ ions. The adduct ion becomes the only predominant ion. The matrix and the nucleobases appear to play important roles in the stability of the compounds.

CHEMISTRY OF IONS DERIVED FROM METAL CARBONYLS

Ying H. Pan and D. P. Ridge
Department of Chemistry and Center for Catalytic Science
and Technology, University of Delaware
Newark, DE 19716

Electron impact on metal carbonyls produce a variety of species including atomic metal ions, bare metal clusters and coordinatively unsaturated metal carbonyl ions. These species have been found to have a rich and varied chemistry. The study of this chemistry has grown into a substantial activity yielding both technological and scientific returns. We give attention here to two types of ions. First we discuss the chemistry of 17 electron radical anions with organic molecules of varying electron affinity. The variation of reactivity with ligand electron affinity suggests that charge transfer plays a role in the mechanism for ligand substitution. Then we consider the chemistry of clusters of 4 metal atoms with cyclohexane. The reactivity of these clusters depends on the number of carbonyl ligands they have. This variation in reactivity suggests a specific electronic requirement for cluster reactivity.

The total rate constants for reactions of $\text{Cr}(\text{CO})_5^{-(1)}$, $\text{Fe}(\text{CO})_4^{-(1)}$ and $\text{Ni}(\text{CO})_3^{-(1)}$ with a series of organic ligands were measured using FTICR techniques on a Nicolet FTMS-2000 instrument. The anion reactants were formed by electron attachment to $\text{Cr}(\text{CO})_6$, $\text{Fe}(\text{CO})_5$ and $\text{Ni}(\text{CO})_4$. The reactant neutral was introduced to a pressure between 2×10^{-8} Torr and 2×10^{-7} Torr. Mass spectra of the trapped ions were obtained at varying delay times following an initial ionizing electron beam pulse. Decays of the reactant ion signal were exponential over at least 3 half-lives for reactive ligands suggesting that the results are unaffected by hot ions. With few exceptions the observed products corresponded to ligand substitution. Total rate constants are plotted vs. EA in Figure 1.

The reactions of species with large electron affinities proceed with near unit efficiency. At an electron affinity near 1 eV but slightly different for each metal reaction efficiency drops sharply with decreasing electron affinity. At larger electron affinities there is a tendency to replace more than one CO ligand. The products of these multiple substitutions tend to react further producing species with two or three reactant ligands bound to the metal. All exothermic charge transfer reactions of $\text{Ni}(\text{CO})_3^{-(1)}$ are observed. Only tetracyanoethylene accepted charge from $\text{Fe}(\text{CO})_4^{-(1)}$ and $\text{Cr}(\text{CO})_4^{-(1)}$. The failure of 2,3,5,6-tetrachloroquinone to react by charge transfer from those two ions suggests the corresponding neutrals have electron affinities greater than 2.78 eV or that there is a kinetic barrier to charge transfer.

The reactions are interpreted in terms of a potential surface represented schematically as a double well in Figure 2. The first well represents an electrostatically bound complex stable by ΔE_1 relative to reactants. At the top of the barrier between the wells (up $\Delta E'$ from the electrostatic well) is a transition state in which the electron is shared between the metal and the ligand. Whereas the radical anion reactant is a 17 electron species, transfer of charge to the ligand leaves a 16 electron species which might be expected to form a strong bond the ligand anion (bond strength = $\Delta E'$) resulting in the second well. This assumes that both the ligand and the ligand anion serve as a two electron donors. The complex in the second well might be called an inner sphere complex. If the bond between the metal and a CO ($\Delta E''$) in this complex is such that CO displacement is overall exothermic then that process will be the observed. If the electron affinity of the ligand is such that ΔE^0 is negative then charge transfer should complete with ligand substitution.

According to this model two quantities are critical in determining reactivities. If ΔE^0 decreases (dashed line in figure) the product surface and its intersection with the reactant surface, i. e. the transition state, drop. Conversely, if ΔE^0 is sufficiently large the energy of the transition state will exceed that of the reactants and reaction will not proceed efficiently. This is consistent with the observed correlation between ligand electron affinity and reactivity. Changes in $\Delta E'$ also effect the energy of the transition state. Stronger bonding between $\text{M}(\text{CO})_n$ and L^- will tend to lower the energy of the transition state. This may account

FIGURE 1

for the differences between the metals. For Ni ligand substitution occurs only if ΔE^0 is zero or negative while for Cr and Fe ligand substitution occurs when ΔE^0 is as large as 1 eV. This suggests that $\text{Ni}(\text{CO})_3$ binds L^- more weakly than do $\text{Cr}(\text{CO})_5$ and $\text{Fe}(\text{CO})_5$. The Ni complex is d^{10} and should be a relatively weak electrophile.

$\text{M}_4(\text{CO})_n$ complexes where M is Re can be prepared by ion molecule reactions in $\text{Re}_2(\text{CO})_{10}$ and by electron impact tetrametal dodecacarbonyls for M = Ir or Co. The chemistry of the Re and Ir clusters with cyclohexane have been described in the literature(2). Clusters of both metals dehydrogenate cyclohexane for sufficiently small n. For Re the n must be 11 or less, and for Ir n must be 6 or less. This was rationalized in terms of the electronic structure of a four atom cluster. Such a cluster will have 20 MOs derived from metal d orbitals and 4 MOs derived from metal s orbitals. It requires 48 electrons to fill these 24 orbitals in a low spin configuration. Since $\text{Ir}_4(\text{CO})_6^+$ has 47 electrons and $\text{Re}_4(\text{CO})_{11}^+$ has 49 electrons, it is suggested that a vacancy in the "s band" of orbitals much enhances the reactivity of the clusters. This is consistent with a

FIGURE 2

mechanism in which the metal acts as an electrophile towards the electron pair in a C-H bond.

The following reactions are observed for cobalt clusters:

This suggests an effect similar to that observed in Ir and Re for $n = 5-7$ since $\text{Co}_4(\text{CO})_7^+$ has 49 valence electrons. For $n = 2-4$, however, the results pose something of a puzzle. This puzzle can be solved using our orbital occupancy picture by supposing that the least substituted Co clusters have high spin ground states. This can lead to occupied s band orbitals for more than one CO substituent. With enough CO substituents a low spin configuration becomes favorable. This leaves more vacancies in the s and d bands so that electrophilic attack again becomes possible. Possible occupations of the s and d bands are indicated below (Scheme I).

"DAMAGE CONTROL" IN CHARACTERIZING COMPLEXES

Kelsey D. Cook and Johnny D. Reynolds, Department of Chemistry,
University of Tennessee, Knoxville, TN 37996-1600.

There are several means whereby artifacts can be introduced into the desorption ionization mass spectrum of an organometallic. Particularly pernicious are the possibilities of reduction and/or ligand exchange, which may arise from intrinsic sample chemistry in the DI matrix, or may be induced by the desorption ionization/sampling process. In the analysis of true "unknowns," such artifacts may complicate spectral interpretation or, worse yet, may lead to erroneous conclusions.

Electrohydrodynamic (EH) MS can provide valuable insight into potential problems specifically associated with the DI matrix, because non-invasive field evaporation is the only means of sampling in EH MS. For example, the EH mass spectrum of $\text{Ru}(\text{bpy})_3^{3+}$ sampled from glycerol is identical to that obtained from the $\text{Ru}(\text{II})$ analog, comprising only the $\text{Ru}(\text{bpy})_3^{2+}$ ion [1]. It can be shown by optical spectroscopy that the reduction of $\text{Ru}(\text{III})$ to $\text{Ru}(\text{II})$ is promoted by glycerol, independent of any mass spectrometric perturbations. By contrast, the further reduction of $\text{Ru}(\text{II})$ to $\text{Ru}(\text{I})$, and the fragmentation observed in the corresponding FAB mass spectrum are entirely bombardment-induced, and may be mitigated to varying extents by reducing the primary atom flux, by increasing the primary atom energy, and/or by resorting to a less reductive matrix solvent (e.g., m-nitrobenzyl alcohol, MNBA) [2]. The appearance of the ion pair $[\text{Ru}(\text{bpy})_3\text{ClO}_4]^+$ in the FAB spectrum may arise from the uncertain and varying analyte concentration at the bombardment site. The low abundance of M^{2+} in even the best FAB spectra of the $\text{Ru}(\text{II})$ complex may reflect the need for high fields in the region of desorption [3] for good sampling; M^{2+} is sampled with excellent sensitivity in EH MS [4].

Strong interactions with the extracting field do not always ensure good sampling efficiency in EH MS; when charge is "exposed" to strong solvent interactions, rather than surrounded by relatively non-polar ligands (as in the $\text{Ru}(\text{II})$ complex), sampling efficiency can drop precipitously [4]. Even 18-crown-6 does not appear able to protect coordinated metals from interactions with counterions and solvent [5]; sampling efficiencies therefore vary markedly depending on the metal's solvation and propensity to pair with counterions.

Other aspects of analyte chemistry may also affect the appearance of spectra. Labile complexes may exchange ligands for solvent or other anions, as was observed in EH spectra of $\text{Cr}(\text{bpy})_3^{2+}$ [6]. Condensation reactions with solvent are even possible in the presence of strong Lewis acids, like the Fe^{3+} -catalyzed esterification of EDTA with glycerol [7].

Despite these potential pitfalls, MS can provide substantial information useful for the characterization of organometallic complexes. In the most ambitious such undertaking in our laboratory to date, we have examined a family of three bridged dirhodium A-frame complexes, including M^{2+} , shown below, and two analogs with all phosphorus- or all arsenic-containing bridging ligands:

These complexes (MW 1605-1781) exceed the mass range of our EH-equipped mass spectrometer (a MS-902). Although the m/z of their molecular dications (657-745) would be accessible to the MS-902, the experiment has yet to be attempted. However, the FAB mass spectra (obtained with a ZAB-EQ) have been quite informative, as have been MIKES spectra obtained with the same instrument. (While the better resolution attainable with Q-scans on our hybrid instrument would relieve some uncertainty from spectral interpretation, the instrument is as yet incapable of performing effective linked E-Q scans over a broad mass range, as needed in this application. Simple Q-scans cannot accommodate the high collision energies necessary for effective CID of these large, stable molecules).

Although the FAB spectra of M^{2+} and its homologs are quite complex (e.g., Figure 1), several features stand out, especially with clarification from the MIKES spectra. Even under "optimized" bombardment conditions (low flux and high bombardment energy, with MNBA matrix), the prominent analyte ion in each case is the product of one-electron reduction, M^+ . Since this is the starting material from which M^{2+} is synthesized, its abundance could lead to an erroneous conclusion that the synthesis had failed; EH MS of this complex (with its freedom from beam-induced reduction) will be a valuable adjunct. Fortunately, the intact dication can be detected in the FAB spectrum (e.g., Figure 2), with the half-mass isotope spacing representative of doubly charged ions, and with isotope cluster intensities in good agreement with expectations. An ion pair (containing M^{2+} and one PF_6^- counterion) is also detected, confirming that at least some of the analyte is in the expected oxidation state.

The MIKES spectra of the dirhodium complexes are especially suggestive of the strength of the various ligand-metal interactions. CID of the ion pairs yields only one prominent ion, corresponding in each case to the loss of PF_6^- plus one *t*-butyl group. This surprising result may indicate localization of the counterion, at least in the gas phase; further study will be needed to confirm this speculation. CID spectra of the reduced material (M^+) (e.g., Figure 3) are richer in fragmentation. Whereas phenyl-containing moieties are detected only in the MIKES spectra of As-containing ions, the Br-containing ligand is lost only from the complex containing four phosphorus atoms. Both of these observations are consistent with the otherwise unconfirmed expectation that the P-Rh interactions should be stronger than the corresponding As-Rh interactions. They have even prompted speculation that the Br-containing (anionic) ligand may transfer an electron to Rh in the complex containing no As, generating a more easily detached neutral (radical) ligand.

Much more study (including MS/MS of the M^{2+} cation) will be needed before these and similar speculations can be confirmed or refuted. However, they serve to illustrate both the potential and the pitfalls of organometallic DI MS. As instrumentation and experience improve, this will clearly provide a powerful characterization tool.

STRUCTURE AND CHEMISTRY REVEALED BY THE MS AND MS/MS
SPECTRA OF INORGANICS AND ORGANOMETALLICS.

C. E. Costello

Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

LSIMS and FDMS have significantly widened the range of mass spectral analyses for inorganic, organometallic and polymer chemists, just as they have done for organic and biochemists. Usually, one or both ionization methods produce molecular ions for the analytes. However, LSIMS spectra of inorganics and organometallics are often complicated by the presence of ions that arise by reactions with the matrix. Positive and negative ion MS and MS/MS spectra are useful for structure determination, and for the insight they provide about the chemistry of the compounds and the nature of impurities. In general, the mass spectral sensitivities of these materials are excellent, and the product ion yields upon collision higher than those observed for large organic molecules.

We have obtained positive and negative FD and LSIMS spectra of neutral and ionic complexes of Tc and similar metals, and metastable and collision induced decomposition MS/MS spectra to determine effects of varying the ligand, the metal atom and the oxidation state of the metal. Relationships between mass spectral and chemical behavior have been demonstrated.

FD mass spectra of metallocene polymers (avg MW 2000-6000) show distributions of M^+ , and sometimes M^{2+} and/or M^{3+} as well. The combination of MS and MS/MS information facilitates the identification of synthetic byproducts. Fig. 1A-C show the m/z 50-1000 region of the FD MS/MS spectra obtained for molecular ions representative of three different series of components present in a metallocene polymer mixture: Components A, the intended product, and Components B and C, polymeric species in which the end group is incorrect.

FDMS and LSIMS and CID MS/MS spectra of large inorganic compounds with molecular weights in the 1500-5000 dalton range have been obtained, and include product ions due to both ligand and metal atom losses. Since these compounds contain numerous atoms with multiple isotopes, the isotope patterns of molecular, fragment and product ions can be interpreted to give compositional information. The two ionization methods are often complementary. For example, although for a very concentrated solution, the molecular ion cluster had extremely low abundance in the LSIMS spectrum of the bicyclic compound Sn_nR_nBu ($R = 2,6$ -diethylphenyl, $Bu = n$ -butyl), M , 1968 daltons, a unit resolution FD mass spectrum (which showed only molecular ions, no fragments) could be obtained from a dilute solution. Fig. 2 shows the LSIMS/MS spectrum obtained for the fragment ion at m/z 1198 in the cluster Sn_nR_nBu of the LSIMS spectrum of this compound. It can be noted in this spectrum that the cluster distribution of product ions is related to the number of multi-isotopic atoms lost from the precursor.

LSIMS mass spectra of heteropolytungstates vary greatly depending on the structures of the clusters. For some, the spectra are simple, containing only singly and doubly-charged molecular ions and few fragments. For others, facile losses of structural units are observed in both the normal and CID spectra. The spectrum of a new fluorine-containing compound is shown in Fig. 3A and the upper mass region of the CID spectrum of its major high-mass peak is shown in Fig. 3B. These illustrate that some types of large inorganic clusters undergo extensive, stepwise fragmentation and that CID can be quite informative even for compounds of this size.

Experimental. All spectra were obtained with a JEOL HX110/HX110 tandem mass spectrometer, operated at ± 10 kV accelerating voltage. Collisions took place in a cell in the field free region between MS-1 and MS-2. Helium or xenon was used as the collision gas, at a pressure sufficient to reduce the precursor ion abundance to 20% of its initial value. The collision cell was maintained at ± 3 kV from ground potential, so that collision energy was 7 kV. For LSIMS, the 6 keV primary beam was either Xe^+ or Cs^+ . For FDMS, sample solutions were applied to the activated carbon emitters with a syringe. The extraction potential was ~ 2.5 kV.

MASS SPECTROMETRY OF METAL-LINKED DIMERS AND COVALENT HEME PRODUCTS

Robert J. Cotter and Ling Chen
The Johns Hopkins University
Baltimore, MD 21205

The mass spectral analysis of organometallic complexes has been an interest of this laboratory for some years. Laser desorption (LD), fast atom bombardment (FAB) and plasma desorption mass spectrometry (PDMS) have all been employed for such studies.

In 1983 we reported the construction of a unique laser desorption mass spectrometer based upon a Tachisto (Needham, MA) 215G pulsed carbon dioxide laser and a CVC Products (Rochester, NY) model 2000 time-of-flight (1). The instrument had two interesting properties. First, the sample ions were formed in a field-free region and could be extracted up to 100 microseconds later to enable time-resolved studies. Second, an electron beam could be pulsed on just prior to ion extraction as a means of observing the desorbed neutrals. Spectra were generally obtained at about 20 us, where the major ions observed were cationized species. With this instrument we were able to obtain mass spectra of porphyrin dimers with and without Co atoms (2). In both cases the molecular ions observed were MK⁺ ions, when KCl was added to the sample.

The time delay feature was then used to study the metastable decomposition of chlorophyll-a from 5 to 30 us after the laser pulse (3)). These studies clearly revealed a two step fragmentation process involving loss of the phytol chain followed by extensive fragmentation of the ring structure. We also studied two derivatives: methylchlorophyllide-a (in which the phytol chain is replaced by a methyl group) and pyrochlorophyll (in which the carbomethoxy group is replaced with a proton). Interestingly, the absence of the phytol group resulted in the formation of molecular ions that were stable to further fragmentation, while the absence of the carbomethoxy group produced mass spectra showing prompt loss of the phytol group.

Fast atom bombardment mass spectrometry has been used for the study of reactions between myoglobin and BrCCl₃ as a model system for the production of radical-mediated heme-adducts of cytochrome P-450 (4). The analyses were carried out on a Kratos (Manchester, UK) MS-50 double focussing mass spectrometer with a high-field magnet and an Ion Tech (Teddington, UK) saddle field fast atom gun. HPLC separation of the products (Figure 1) revealed several modified hemes (peaks 2, 3 and 6) which were analyzed by FAB mass spectrometry. Isotopic patterns (Figure 2) were used to determine the number of Cl atoms incorporated into each of the modified hemes and to elucidate the structures shown in Figure 3. A final product (peak 5 in Figure 1) has been shown to be the result of covalent attachment of a modified heme to the peptide. The elastase digest of this product was separated by reversed phase HPLC, and the FAB mass spectrum indicated that it is attached to the elastase peptide with the sequence: AQSHAT. The structure of the modified heme forming the adduct was determined by comparison of the measured and theoretical isotopic distributions of the modified heme

Fig. 1

fragment ion as shown in Figure 4. Further digestion of the elastase peptide fragment with carboxypeptidase A and aminopeptidase-M resulted in isolation of a heme product bound to histidine.

Plasma desorption mass spectrometry was used to study the dimerization of the tat protein from human immunodeficiency virus (HIV) shown in Figure 5 (5). The analyses were

STRUCTURES OF
MODIFIED HEMES ISOLATED
BY REVERSE PHASE HPLC

carried out on a BIO-ION (Uppsala, Sweden) BIN-10K mass spectrometer. The 18-amino acid that contains the cysteine-rich region of the tat protein was synthesized. The plasma desorption mass spectrum of this peptide revealed (almost exclusively) molecular ions corresponding to the monomer. However, when the peptide solution was mixed stoichiometrically with two Cd^{+2} ions per monomer, the plasma desorption mass spectrum (Figure 6) revealed extensive dimerization involving four Cd^{+2} ions (Figure 7).

**ADVANCED FEATURES OF A FAST BUFFER BOARD FT-ICR
INTERFACE TO A PERSONAL COMPUTER**

Shenheng Guan and Patrick R. Jones
*University of the Pacific
Chemistry Department
Stockton, CA 95211*

The basic operations of the interface circuits of a personal-computer based broadband FT-ICR have been illustrated [1]. The advantages of using a personal computer to host the FT-ICR instrument include: (1) very low cost of the computer; (2) extensive graphic and mathematic capabilities; (3) easy performance alteration or expansion; (4) an abundance of application software; and, (5) support for a wide range of output devices. Real-time ICR operations also require high speed and accurate timing control. A dedicated digital hardware interface has been designed and constructed to solve the timing problems. The digital circuits of the spectrometer were assembled on an IBM PC AT extension board. The extension board, or "fast buffer board," is used to replace the frequency synthesizers and waveform recorders normally used for arbitrary waveform generation and data acquisition operating at a speed of several mega Hertz. This design has not only led to great reduction in construction cost but has increased the flexibility of the instrument to perform complex experiments as well.

The digital hardware design focused on meeting critical timing requirements and all the other signals are left to be generated by software. This strategy reduces the complexity of the hardware design and allows one to utilize more of the capabilities of the computer.

Design features:

1. Common memory for both excitation and data acquisition. Since ion excitation and ion-transient signal acquisition always take place sequentially, it is possible to use a common buffer memory to store the excitation waveform and ion transient data. Using common memory reduces the memory requirement for both excitation and data acquisition by half. This memory-stored-ion-excitation method also gives the operator great freedom in choosing from a variety of excitation signals. Because the excitation waveform is transmitted by clocking out the data stored in the buffer memory, the control circuit design is simplified. In this instrument, twelve 16k X 1 bit static RAM is used. This means that 16K 12 bit-words of data can be stored in the buffer memory. However, the word length can be easily expanded to 16 bits.

2. Control logic for critical timing steps. In the chemical cycle of FT-ICR experiments, the timing events can be divided into segments. There are only a few segments in which absolute timing controls are required (Figure 1). For this configuration, the control logic of the buffer interface is only active during these crucial time periods. The control logic consists of three 8-to-1 multiplexers, three flip-flops, and a 3-to-8 decoder. The control inputs are provided by software through a COMMAND register. The supported functions include: (1) basic ICR operations (transmitting an ion-excitation waveform, waiting a time period, and recording the corresponding ion transient); (2) two-dimensional excitation operation (transmitting an ion excitation waveform, waiting for a time period, and transmitting the same waveform again); (3) excitation only mode (transmitting a waveform or repeating the transmission of the waveform); and, (4) data acquisition (storing a digitized signal

in the buffer memory). The combination of these functions allows one to perform almost all FT-ICR experiments.

3. Counters and latches for address counting. During excitation-data transmission and data acquisition, the address of the data is provided by address counters. The address counters also control the length of time for delay periods. In this instrument, four 4-bit binary counters are synchronously connected for 16K data counting. However, the counters can be cascaded for many more stages for larger counting data. This means that the buffer memory size is not limited by the overall design.

4. Address mapping for fast data transfer. For some FT-ICR experiments, i.e. tandem MS, several excitation waveforms have to be transmitted and at least one ion transient has to be recorded in a single chemical cycle. Since only a single bank of memory is used for storing all the waveforms and ion transient, the data transfer rate between the buffer memory and the computer's system memory has great influence on the time efficiency of buffer interface. The problem is minimized by mapping the buffer memory directly into the computer's system-memory space. For a typical 80286 based personal computer, the best block data transfer rate can be obtained by the "repeat following" string operations provided by the processor's instruction set. It takes less than 10 ms to transfer all the 16K words of data to or from the buffer memory. The data transfer rate is several times faster than the direct memory access (DMA) operations provided by the computer's hardware.

5. Multi-board operations. For some ICR experiments, signal generation and data acquisition have to operate at the same time, as in heterodyne-mode operation. These types of experiments can be realized by using more than one buffer board. The only modification needed is to change the address decoding. For multiple-cell instruments, the use of parallel buffer boards could allow monitoring ions in more than one cell simultaneously.

**ENHANCED MASS RESOLUTION OF BROADBAND FT-ICR MASS SPECTRA
BY THE MAXIMUM ENTROPY METHOD (MEM)**

Shenheng Guan and Patrick R. Jones
University of the Pacific
Chemistry Department
Stockton, CA 95211

The maximum entropy method [1] has been demonstrated to be an attractive spectral analysis tool for improving mass resolution of narrow band FT-ICR mass spectra. We have found that more data points must be used to extend the method for broad-band spectral analysis. In our laboratory, the method has been adapted for use on our home-built FT-ICR mass spectrometer [2] which is based on an IBM PC AT compatible computer. The computer has a 6 MHz 80287 math coprocessor and 640 kByte of system RAM. The program, written in Microsoft Fortran, can produce 16384 error filter coefficients (EFCOF) and output the resulting spectral data into AutoCAD binary interchange files which can be further processed by AutoCAD programs to produce hard copies of publication quality spectra.

The subroutine which calculates error filter coefficients using Burg's algorithm was adapted from the literature [3]. When more time-domain data are analyzed, the data cannot be considered as stationary. The signal decay effect on the spectral analysis method is examined first with synthetic signals. The peak width of a single frequency signal continuously decreases to approach the theoretical line width with an increase in the number of data points used. When more data points are used, the spectral shape is found less sensitive to the initial phase.

The program has been used to calculate a propiophenone spectrum. The MEM and FFT spectra are shown in Figure (1) and Figure (2) respectively. The results of the two methods are summarized in Table (1). A resolution improvement of 40 times for most ion signals between 50 kHz to 250 kHz is achieved by using 4000 time-domain data and 2000 error-filter coefficients. In this case, there is no peak splitting found and difference of peak frequencies between FFT and MEM spectra is within the frequency interval of the FFT procedure.

The large computation time required for the method is well-known. However, this inconvenience will be relieved by the continued rapid development of powerful computers. The computation time for each calculation reported in this work is listed in Table (2). The computation time for the error-filter coefficient calculations increases quadratically with the number of data points when the ratio of data points and EFCOF is kept at the value 1/2. For comparison, a time domain ion transient signal with 120 data points and 90 EFCOF has been analyzed. It takes only 3.2 seconds for EFCOF calculation which is almost ten times faster than that cited for the previous work [1].

AN ADVANCED DATA SYSTEM FOR FT/ICR

J.T. Meek, W.G. Millen, G.W. Stockton, and R.S. Wayne
American Cyanamid Company
Princeton, New Jersey 08540

Introduction – The Cyanamid external ion source FT/ICR mass spectrometer¹ was designed to provide high mass accuracy over a wide mass range², and to be compatible with a wide range of sample inlet and ionization techniques, especially Thermospray LC/MS³. In all modes of operation the goal is to obtain unambiguous elemental composition information. In order to meet this goal we have constructed a data system which enables routine acquisition, processing and storage of 512k point transients. The system also controls our spectrometer and performs complete off-line analysis of data.

Primary Objective – To build a flexible open architecture data system capable of: 1. Acquiring a large number (524,288+) of data points. 2. Acquisition rates to 4 million samples per second. 3. Real-time storage of raw data on disk. 4. On-line signal processing for display and decision making. 5. Obtaining accurate mass information from raw data. 6. Using accurate mass data to determine elemental compositions.

Hardware – The primary components include a VME bus host computer, a high speed floating point array processor with a private bus, several disk drives, and a variety of standard and special interfaces to the outside world.

A Motorola MVME147 board is the host processor for the system. This board includes a 20 MHz 68030 microprocessor with a 68882 floating point co-processor, 4 MB of memory, four RS-232 serial ports, a parallel printer port, a SCSI bus interface for disk and tape, and an Ethernet port. A pair of Fujitsu M2361 ESMD 689 MB, 2.5 MB/s transfer rate disk drives are used for on-line storage of transient data. Because of software limitations these drives have a formatted capacity of 480 MB and an actual transfer rate of about 500 kB/s. Control of ion optics and RF quadrupole electronics is through an Opto-22 Optomux industrial control system. This system provides multiple channel, optically isolated, analog outputs using a RS-422 data link from the host computer.

For fast data acquisition and vector processing a Mercury Computer Systems ZIP 3232+ array processor with 10 MB of memory is used. The array processor is capable of operating at 10 or 20 MFLOPS and is user programmable via a "C like" language. A Burr-Brown ADC600 12 bit analog-to-digital converter is interfaced to the array processor through a Cyanamid built interface. Acquisition rates of up to 4 million samples per second are currently supported by the hardware. The number of data points that can be acquired is limited only by the total memory installed and the number of buffers required for the desired signal processing algorithms. One million point data acquisition and processing has been demonstrated, but the largest data record in routine use is 524,288 points.

Table 1 lists Fourier Transform times for several data table lengths. Due to hardware limitations in the array processor, 32k and larger Fourier transforms can use only one of the two arithmetic pipelines. Consequently, these functions operate at only 10 MFLOPS.

Table 1. ZIP3232 Real FFT Time, Single Pipeline (10 MFLOPS)

Points	Time, ms
32,768	194
65,536	304
131,072	831
262,144	1704
524,288	3540
1,048,576	7272

Data Acquisition Software – The host computer uses Motorola's VERSAdos real-time, multi-tasking operating system. This full service operating system provides a range of utilities and software development tools.

The acquisition and control software consists of six separate tasks which communicate with each other through shared memory and inter-task message passing. This multi-tasking scheme allows separation of high priority real-time tasks from those which must interact with the operator. The host computer programs are written in Pascal and assembly language and the array processor programs are written in Zip-C and microcode. Most of the signal processing routines are part of the standard algorithm library supplied with the array processor. The data acquisition microcode and several supplementary array processor programs were written specifically for this project.

All user interaction with the data system is done through two programs. CyAcq handles data acquisition and reduction and CnOp handles the user interface to the ion optics control system. These two programs communicate with several real-time tasks which run at a higher priority.

Table 2 outlines a typical LC/MS data acquisition sequence. From the table it is apparent that the most time consuming steps are the 128k Fourier transform and the transfer of 16 bit integer data to disk.

Table 2. Acquire and store 524,288 points, process 131,072 points on-line

Flush ions from cyclotron cell, Inject and trap ions in cell	
Acceleration Sweep	1-5 ms
Delay for pre-amp recovery	1 ms
Acquire 524,288 points, 12 bit integer data, 4 MHz	131 ms
Process 131,072 points for display/decision making	
Convert 16 bit integer to 32 bit floating point	26 ms
Real Fourier Transform	831 ms
Scale	34 ms
Power Spectrum	24 ms
Square Root (dual pipeline, 20 MFLOPS)	46 ms
Put Spectrum into increasing mass order	21 ms
Upload spectrum to host (256 kB)	73 ms
Display spectrum	90 ms
Check chromatographic window for peak (5k points)	8 ms
If peak is above threshold then	
Upload transient data to host for disk dump (1 MB)	288 ms
Dump 524,288 raw data points to disk	2014 ms
Total for Acquisition Sequence	3587 ms

Off Line Analysis – Peak centroids are normally obtained by CyAcq using a frequency interpolation technique². The peak centroid data is then analyzed by CyMass, a separate accurate mass program. CyMass provides calibration, elemental composition searches, chromatogram generation, pattern searching, stick plots and other services. It is possible for the entire set of acquisition, control, and analysis software to run on the data system simultaneously so that data quality can be quickly checked to the elemental composition level in a tune-up mode. CyMass and the mass spectrometry tool programs also run on MS-DOS computers and are being ported to Sun workstations.

The use of this data system has been an important factor in our ability to obtain high mass accuracy over a wide mass range^{2,3}.

A COMPARISON OF SEVERAL APODIZATION FUNCTIONS FOR SWIFT WAVEFORMS

B.A. Hearn and J.R. Eyler,
Department of Chemistry
University of Florida, Gainesville, FL 32611

Stored Waveform Inverse Fourier Transform (SWIFT)¹ has been used to improve the selectivity of the excitation process in FT ICR mass spectrometry. In FT ICR mass spectrometry, apodization of the received signal before calculation of the mass spectrum reduces the sidelobe height at the expense of resolution. A similar tradeoff exists in the excitation process of FT ICR when using SWIFT excitation. The finite duration of an excitation waveform causes masses outside the defined mass windows to be excited in addition to masses of interest. A reduction in the power input into these sidelobes through apodization of a SWIFT time domain waveform is accompanied by broadening of the originally defined mass windows.

For applications requiring the highest selectivity of the excitation waveform, a rectangular window (no apodization) is suggested. This window has the disadvantage of producing rather large sidelobes. For most applications, ultimate mass selectivity is not needed, so an apodization function such as the Blackman-Harris 3-term window² is suggested, which has slightly lower mass selectivity than the rectangular window but has much lower sidelobes. Due to the smooth response provided by the Blackman-Harris window, it provides an excitation waveform more insensitive to frequency changes such as due to changes in pressure, trapping voltage, or magnetic field drift. This is in contrast to a SWIFT waveform with no apodization, which may have a large difference in the excitation response with a small change in frequency.

Calculation of the expected response of a SWIFT excitation waveform allows one to determine if the excitation conditions can provide the selectivity needed. Due to the discrete nature of the sampling and the inverse dependence of mass on frequency, the desired mass windows never fall exactly at an array point in the frequency domain, so roundoff errors are present in defining the original frequency domain spectrum for the excitation. Evaluation of the expected response gives one an idea of how well the excitation deviates from that desired, which can be significant at high masses. Finally, plotting the expected response linear in mass (rather than linear in frequency, as is usually shown), presents the data in a manner more useful to the mass spectrometrists.

Figure 1 shows the initial mass windows defined for a SWIFT waveform. Figures 2 and 3 are the expected response calculated using no apodization and a Blackman-Harris window, respectively. Note the greatly reduced sidelobe height for the Blackman-Harris window at the expense of slightly lower mass selectivity along the edges of the excitation window.

A NEW METHOD FOR GENERATING SWIFT WAVEFORMS FOR FTMS

S. D. Goodman, Nicolet Analytical Instruments, 6416 Schroeder Rd., Madison, WI 53711;
D. A. Hanna, Masstron, Inc., 2545 Central Ave., Boulder, CO 80301

Control of ion excitation in Fourier transform mass spectrometers has been greatly enhanced by the stored-waveform inverse Fourier transform (SWIFT) technique. The goal of the SWIFT technique is to achieve excitation selectivity superior to the detection selectivity of FTMS and to excite selected ions to known radii or kinetic energy. Here, we present a signal processing technique that overcomes some inherent problems and produces the desired excitation spectra.

In the original SWIFT technique^{1,2}, we convert the desired ion excitation profile into an excite amplitude spectrum, take the inverse Fourier transform, then apply the resulting waveform to a DAC which produces an analog voltage for the excite power amplifier. This produces waveforms with much higher selectivity than burst or chirp excitation, but can result in waveforms that require thousands of volts to produce ion excitation over a wide mass range. Phase scrambling has been proposed to reduce the peak excitation voltage. This causes distortion that results in poor control of ion radii, particularly in the case of broad band excite spectra that require large amounts of phase scrambling.

To simultaneously excite an ion to a chosen radius while leaving a neighboring ion with an arbitrarily low kinetic energy, that is, to maintain high selectivity, it is essential to window (apodize) the SWIFT waveform. This is necessary to remove the Gibb's oscillation that occur whenever a continuous spectrum is represented with a finite length waveform. However, windowing a SWIFT waveform that has been phase scrambled results in very severe distortion.

The distortion problem of phase scrambling followed by windowing is caused by time shifts introduced by the phase scrambling function. The group delay (time shift) of the phase function shifts the energy at each frequency past the end of the data set at one end. Windowing the result takes more energy away from some frequencies than others, depending on the amount of their time shift, and makes the distortion worse. We propose "expanded windowing" to achieve distortionless phase scrambling: window, adding enough zeros to each end of the window function to accommodate the maximum group delay of the phase function, then phase scramble. The resulting actual excite spectrum is shown in Figure 1. Note that the absence of Gibb's oscillations and the well-behaved band edges. Just as in the FTMS detection case, the side lobe ripples can be made arbitrarily low and the resolution arbitrarily high by the choice of window function and number of data points.

We can derive an optimal phase function for any arbitrary excite amplitude spectrum by using this knowledge. Starting with the definition of group delay as the negative of the derivative of phase with respect to frequency, and spreading the excite power uniformly in the time domain, we arrive at the following relation, which is general for any excite amplitude spectrum.

where $\theta(n\omega_s/N) = \text{phase (radians)}$

$$\text{Equation 1. } \theta(n\omega_s/N) = \frac{\pi}{N} \sum_{k=0}^{N-1} \frac{\omega_k}{\omega_s} \frac{d}{d\omega_k} \left(\frac{1}{\omega_k} \right) - \frac{\pi}{N} \sum_{k=0}^{N-1} \frac{d}{d\omega_k} \left(\frac{1}{\omega_k} \right)$$

$n = \text{integer frequency index}$

$\omega_s = \text{sampling frequency (radians/sec)}$

$N = \text{total number of data points}$

$n_d = \text{number of group delay points each end}$

$$S_d(X) = |F_d(jkX)|^2$$

$F_d(jkX) = \text{discrete excite voltage spectral density (V/Hz)}$

An excite amplitude spectrum phase-scrambled with this function approaches a sweep (chirp) function in its ability to deliver excite energy efficiently. Note that for a single rectangular excite band, the optimal phase function is a quadratic, confirming empirical results. The center (non-zero) part of the expanded window function consists of any standard window scaled to the appropriate length. We choose the length of this center section as the minimum length required to achieve the desired excite resolution. Figure 2 shows the SWIFT waveform resulting from the use of the optimal phase function Equation 1 on the spectrum of Figure 1 after expanded windowing. Note the extremely even power distribution across the waveform.

Two more problems remain: how do we scale a SWIFT waveform to excite ions to a given radius, and how do we know how much phase scrambling to use to reduce the peak voltage required to a given level? Since the SWIFT waveform is a voltage waveform, the excite amplitude spectrum is a voltage spectral density (Volts/Hz). We derive the relation between voltage spectral density and radius by analogy with the fixed frequency sine wave (burst) excite case. The result is,

Equation 2. $F_d(jk\Omega) = \frac{rBd}{-2T}$ where $F_d(jk\Omega)$ = discrete excite voltage spectral density (V/Hz)

$j = (-1)^{1/2}$
 k = integer index value
 Ω = frequency point spacing (rad/sec)
 r = orbital radius (meters)
 B = magnetic field flux density (Webers/meter²)
 d = distance between excite plates (meters)
 T = time point spacing (sec)

The effect of the optimal phase function (Eqn. 1) on the peak voltage of the resulting SWIFT waveform may be derived by assuming that energy is conserved during phase scrambling and nearly conserved during expanded windowing. Using Parseval's energy relation, we achieve a very good approximation of the amount of phase scrambling for a given amount of peak voltage reduction. Putting this all together, we arrive at the following process for producing a SWIFT waveform conforming to any arbitrary requested excite spectrum.

1. Specify the requested excite spectrum in terms of mass, radius (or kinetic energy) and resolution
2. Convert mass to frequency, convert radius (energy) to voltage spectral density
3. Inverse Fourier transform
4. Estimate phase scrambling required and window end segment length for distortionless phase scrambling; calculate window center segment length to achieve requested resolution; perform expanded windowing
5. Forward Fourier transform
6. Calculate optimal phase function, apply to spectrum
7. Inverse Fourier transform

CONCLUSIONS: Using the above process, we can produce SWIFT waveforms that satisfy arbitrary requested excite spectra. Any amount of peak voltage reduction can be achieved while maintaining any desired resolution. The only limitation is the number of data points and the total excite time required. The method works equally well for heterodyne and direct mode SWIFT excite.

THEORY OF IMPULSE EXCITATION FOR FOURIER TRANSFORM MASS SPECTROMETRY

G. Baykut*, R. T. McIver, Jr. and R. L. Hunter

IonSpec Corporation, 17951 Skypark Circle, Ste. K, Irvine, California 92714, U.S.A.

Most Fourier transform mass spectrometers utilize a rapid radiofrequency sweep (chirp) to accelerate ions for detection. A mass spectrum is then obtained by monitoring the image current signals that are produced by the coherent motion of the ions. In impulse excitation Fourier transform mass spectrometry, ions are accelerated simultaneously by a sub-microsecond high voltage pulse. Unlike the rf-burst and the rf-chirp methods used previously, impulse excitation is not a resonance method, because all ions receive the same nonselective jolt from the high voltage pulse.

The equation of motion for a charged particle of mass m and charge q in electric (E) and magnetic (B) fields

$$m (d\mathbf{v}/dt) = q \mathbf{E} + q \mathbf{v} \times \mathbf{B}$$

can be solved using the impulse electric field in x -direction

$$E^{on} = (2U/L)(1 - e^{-at}) \quad (0 < t < T)$$

$$E^{off} = (2U/L)(1 - e^{-aT}) e^{-a(t-T)} \quad (t > 0)$$

Fig. 1

for the turn-on and turn-off period of the pulse (Fig. 1) respectively. Here is U the potential applied to one transmitter plate, L the distance between the transmitter plates, a the risetime constant of the impulse and T the pulse width. Solutions of the differential equations of motion can be obtained using the continuity of the ion motion at the time of the turn-off ($t=T$) and the initial condition $v=0$ at the time $t=0$. Velocities and position coordinates of the ions for turn-on and turn-off times are calculated to be

$$v_x^{on}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w) \sin wt - \cos wt + e^{-at} \}$$

$$v_y^{on}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w) \cos wt + \sin wt + (w/a) e^{-at} - 2qU/(mLw) \}$$

$$x^{on}(t) = 2qUa/[mL(a^2 + w^2)] \{ -(a/w^2) \cos wt - (1/w) \sin wt - (1/a) e^{-at} + 2qU/(mLw^2) \}$$

$$y^{on}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w^2) \sin wt - (1/w) \cos wt - (w/a^2) e^{-at} - 2qU/(mLw) + 2qU/(mLwa) \}$$

for $0 \leq t \leq T$, and

$$v_x^{off}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w) [\sin wt - \sin w(t-T)] - \cos wt + \cos w(t-T) + e^{-at} - e^{-a(t-T)} \}$$

$$v_y^{off}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w) [\cos wt - \cos w(t-T)] + \sin wt - \sin w(t-T) + (w/a) [e^{-at} - e^{-a(t-T)}] \}$$

$$x^{off}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w^2) [\cos w(t-T) - \cos wt] - (1/w) [\sin wt - \sin w(t-T)] - (1/a) [e^{-at} - e^{-a(t-T)}] \}$$

$$y^{off}(t) = 2qUa/[mL(a^2 + w^2)] \{ (a/w^2) [\sin wt - \sin w(t-T)] - (1/w) [\cos wt - \cos w(t-T)] - (w/a^2) [e^{-at} - e^{-a(t-T)}] - 2qU/(mLw) \}$$

for $t > T$.

* Present address: Bruker-Franzen Analytik GmbH, Kattenturmer Heerstr. 122, D-2800 Bremen 61, Federal Republic of Germany

The cyclotron radius of the ion after the impulse excitation can be obtained from the turn-off time velocities using the equation $r^{off}(t) = [(v_x^{off})^2 + (v_y^{off})^2]^{1/2} / w$ and the final radius of gyration can be calculated from its limit value for $t \rightarrow \infty$:

$$r_{final} = 2qUa/[mLw^2] \{(2 - 2\cos wT)/(a^2 + w^2)\}^{1/2}$$

The radius of gyration depends on the mass m , the cyclotron frequency w of the ion, the impulse peak potential U , risetime of the impulse signal $1/a$, its pulse width T and the distance L between the transmitter plates. If the period of the cyclotron motion is shorter than the pulse width of the impulse waveform, the ion will be first accelerated but then decelerated as it starts moving against the field. This can cause a collapse of the cyclotron motion, which can easily be seen from the final radius equation. The radius becomes zero if the term $2 - 2\cos wT = 0$, that is:

$$m_n = qBT/2n\pi \quad (n=1,2,3,\dots)$$

Fig. 2 is a diagram of the final radius of gyration versus the mass at $B = 1T$, $U = 120V$ and $a = 6.67 \times 10^7 \text{ s}^{-1}$. It also shows the masses, of which the cyclotron motion collapses. After the largest collapsing mass, $m = qBT/2\pi$, the curve approaches to an asymptotic value. This approach occurs at much lower masses, if the pulse width can be kept short enough. A limit case of the impulse excitation is that both the risetime of the pulse and the pulse width are very short. The equation for the final radius of gyration becomes $r = 2qUT/mLw$. By replacing w with qB/m and $2U/L$ with E , one obtains

$$r_{final} = ET/B.$$

Fig. 3

Fig. 2

Fig. 3 shows ion trajectories during impulse excitation at $T = 650 \text{ ns}$. The ion's center of gyration appears to be shifted to the negative y -direction, while it is excited by impulse. The constant term $-2qU/mLw$ in the equation of the velocity v_y^{off} helps understanding the shift of the center of gyration into the negative y -direction. For the time period T , this translation can be calculated as $y_T = -2qUT/mLw$. For ions with high m/z ratios, that is, with low cyclotron frequencies, the final radius of gyration can be approximated as $r_{final} = 2qUT/mLw$, which is the same value as the displacement of the center of gyration.

Trajectory calculations show, that all ions are accelerated to the same orbit, if the risetime of the impulse is very short and its duration less than the period of the ion's revolution in the cyclotron orbit. One of the limitations of impulse excitation is that double resonance ejections and sweep-out experiments, which are very useful in studying ion/molecule reactions, cannot be done, because it lacks the necessary selectivity. Yet, these selective resonance experiments can still be done in conventional manner, while impulse excitation is used for detection of ions. Experiments done with impulse excitation have shown, that it gives much more stable peak heights and does not require much "tuning" to obtain good quality transients.

INCORPORATION OF AVERAGED ION-ION INTERACTION INTO A MODEL FOR PEAK SHAPES IN FTMS

D. L. Rempel and M. L. Gross
Midwest Center for Mass Spectrometry ,

Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

Successful accurate exact mass measurement in Fourier transform mass spectrometry (FTMS) derives from a complete understanding of the ion resonant frequency's dependence on mass. The lack of total success in mass measurement through the use of the current mass calibration law¹ is apparently due to slight inaccuracies in the frequency-mass relationship upon which the current calibration law is based. These inaccuracies manifest themselves as ion number dependent mass measurement errors that change with excitation parameters, e^- beam parameters, and trap electric field shape.²

Computational models that give peak shape as a function of postulated conditions in the ion trap are useful in gaining insight into the mechanisms that affect an ion's apparent resonant frequency. This is because a distribution of ions of the same mass-to-charge ratio contribute a distribution of frequencies to a complex peak shape in actual practice. Such a model was used to explain the experimental observation of split peaks for a cubic trap and how compensating the cubic trap electric field removes this effect.³ This model has been revised to include the averaged interactions of ions.

Model assumptions include:

- No collisions during excitation and detection periods. The finite observation time, however, is included in the computation of the peak shape.
- Ions with the same z-mode amplitude are excited to the same cyclotron radius. The z-mode amplitude remains unchanged by the excitation.
- Each ion moves harmonically over a cylinder coaxial to the z axis with incommensurate frequencies (magnetron radius = 0.0).
- The z component of the forces between the ions is zero.
- Ions of the same species with the same cyclotron radius do not interact radially.
- The force between two ions with different cyclotron radii can be replaced with the force obtained by distributing the charge of one ion over its cylinder of motion so that the charge in an area of the cylinder is proportional to the time spent there.

A .0254 m, 304 SS cubic trap was used at $V_T = 1.0$ V. The magnetic induction was 1.2 Tesla. The experimental peak shapes were measured from the molecular ion of benzene, which was introduced at 5×10^{-8} Torr. Ionizing electron energy was 11.5 eV. The electron current was 160 nA and the beam time was varied from 15 ms to 1 s to change the ion number. An RF burst waveform with amplitude of .345 V_{b-p} and time of 700 μ s was applied to the molecular ion of benzene. The excitation was delayed 100 ms after the ionization to allow the ion cloud to approximate a thermal state.

Results obtained from the revised computational model show qualitative, experimentally observed features that have been attributed to ion-ion interaction. These features include-

- The elimination of peak splitting as the ion number is increased: compare, in Fig. 1, the peaks for 10000 and 140000 ions.
- The optimization and subsequent degradation of resolution as the ion number is increased. For the calculated peaks, the maximum amplitude on the graph is given per 1000 ions. For the measured peaks, the relative amplitude reads 1.0, 3.5, 4.96. Note that the experimental peak continues to increase in contrast to the calculation.
- The exaggeration of the high mass peak skirt for high ion number. Note that the degradation of the high mass skirt occurs more quickly for the calculated peak.

In addition, the calculation shows a shift in the ion population fraction that contributes to the main portion of the peak.

A MODEL FOR THE REDUCTION OF MASS MEASUREMENT ERRORS DUE TO ION-ION INTERACTION IN FTMS

S. S. Yang, D. L. Rempel and M. L. Gross

Midwest Center for Mass Spectrometry,
Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

The current calibration law created by Ledford et al. (1) which produces ~ppm level mass measurement errors for low ion number shows systematic error with increasing ion number. Experimental evidence suggests that relative ion abundance should be incorporated into the calibration procedure (2). By using the theory of Jeffries, Barlow and Dunn (JBD) (3), corrections for the current calibration law have been derived from the assumption of a relationship between relative ion number and peak intensity with a calibration constant K.

Experiment parameters were: .0254 m of 304 SS compensated cubic trap -- V_T (inner segment) = 1.007 V, V_R (outer segment) = 1.705 V; magnetic field = 1.2 T; beam current = 100 nA; beam voltage -- 70 eV on acetophenone for mass calibrations, 12.5 eV on benzene and ethylbenzene for frequency shift experiments; rf burst -- amplitude = .345 V_{b-p} , excitation time = 700 us.

It is postulated that $G_{\rho i}$ (as in ref. 3) satisfies the propositions: G_{ρ} is proportional to N (beam time X beam current X pressure) and relative ratio of G_{ρ} = relative ratio of A (peak intensity). Hence, $G_{\rho i} = A_i N K$.

From JBD theory, the first order frequency perturbation by space charge is $\partial \omega_i / \partial G_{\rho i} = -q / B \epsilon_0$, if $i \neq j$; or $\alpha (-q / B \epsilon_0)$, if $i = j$. Experiment result from Fig. 1 shows that α is about 0.83 instead of 0.0 (by ref. 4).

Inputting the masses and frequencies of two calibrant ions to calibration equation: $m = a / w + b / w^2$ (1) would solve a and b. Then the calibrated mass of test ion is obtained by the equation with test ion frequency. Relative error (ξ) = $(M_{\text{calib.}} - M_{\text{ext.}}) / M_{\text{ext.}}$.

The slope (as in table I) of the curve (ξ vs. N) (as Fig. 2) can be shown as: $d\xi / dN = (\partial \xi / \partial \omega)(\partial \omega / \partial G_{\rho})(dG_{\rho} / dN)$. Since $dG_{\rho} / dN = AK$, calibration constant K is:

$$K = \frac{\left(\frac{d\xi}{dN}\right) m_{\text{ext.}} \omega_T^3 (\omega_1 - \omega_2)^2}{f(m_1, m_2, m_{\text{ext.}}, \omega_1, \omega_2, \omega_T, A_1, A_2, A_T) \left(-\frac{q}{B \epsilon_0}\right)}$$

Here, subscripts 1,2 and T are represented for calibrant ion 1, 2 and test ion, respectively. Also, f which replaces a complicated expression from derivation is a function of masses, frequencies and peak intensities of the two calibrant ions and the test ion.

Once K is obtained, G_{ρ} is determined, frequency shift from space charge could be calculated. And, frequencies unperturbed by space charge would be obtained. Then space-charge-unperturbed calibrated mass is obtained by recalibration with these frequencies. In table II, the overall average value of K for the four sets is $0.911 \times 10^{17} \pm 0.189 \times 10^{17}$ (20.7 percent). With the result of K varying by 15 to 25 percent, it is expected that a factor of 4 to 6 reduction in ion-ion-interaction-caused errors could be obtained.

Elimination of z-Ejection in FT/ICR by rf Electric Field Shimming

Mingda Wang and Alan G. Marshall

Department of Chemistry (and Department of Biochemistry)
The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

In FT/ICR mass spectrometry, coherent ion cyclotron orbital motion is produced by resonant rf excitation. However, because the excitation electrodes are of finite dimensions, the desired transverse (to the applied magnetic field) rf field is accompanied by an rf field along the z- (magnetic field) direction, resulting in mass-dependent z-ejection and mass-dependent relative FT/ICR peak relative magnitudes. Addition of several "guard wires" of voltage-divided rf amplitude¹⁻³ allows the rf electric field to be "shimmed" to near-perfect uniformity (right).

Here we present two types of rf-shimmed ion traps. In the first type (Fig. 1, right), "guard wires" are placed only in front of the trapping electrodes. In the second type (Fig. 1, left), "guard wire rings" are placed inside the detector and trapping electrodes. For either arrangement, SIMION simulations were used to adjust the rf voltages applied (by voltage division) to the guard wires or rings so as to produce optimally uniform rf field within the trap. The virtual elimination of z-excitation is confirmed by the plots of magnitude-mode relative peak height vs. ICR orbital radius in Figure 2. Because the guard wires (or rings) tend to shield the ions from the trapping electrode potential, the shift in ICR frequency with trapping voltage is also reduced (Figure 3), but not as well as with a screened trap.⁴ In side-by-side tests of conventional and rf-shimmed traps mounted colinearly along the z-axis, the ICR signal strength was reduced to ~87% and ~25% by the addition of guard wires or guard rings, respectively. The authors thank Dr. Russell for sharing his unpublished results. This work was supported by NSF (CHE-8721498) and The Ohio State University.

**A "Screened" Electrostatic Ion Trap for Enhanced Mass Resolution,
Mass Accuracy, Reproducibility, MS/MS, and Upper Mass Limit in
Fourier Transform Ion Cyclotron Resonance Mass Spectrometry**

Mingda Wang and Alan G. Marshall*

Department of Chemistry and Department of Biochemistry,
The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

Until now, it was thought that the optimal static electromagnetic ion trap for Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometry should be designed to produce a *quadrupolar* electrical potential, for which the ion cyclotron frequency is independent of the ion's pre-excitation location within the trap. However, a quadrupolar potential results in a transverse (to the magnetic field) electric field which increases linearly with distance from the center of the trap. That radially linear electric field shifts the observed ICR frequency, increases the ICR orbital radius, and ultimately limits the highest mass-to-charge ratio ion which can be contained within the trap.

In this abstract, we present a new static electromagnetic ion "trap" in which screens which are grounded (or set to a specified voltage) placed just inside the usual "trapping" plates produce an electric potential which is *near-zero* almost everywhere within the trap.¹ The static electric field within the trap is reduced by more than an order of magnitude, as shown by the SIMION isopotential contours of Figure 2.

For experimental comparisons, we constructed a two-section trap (Figure 1) consisting of screened and unscreened (but otherwise identical) orthorhombic traps mounted colinearly end-to-end along the magnetic field axis.

Figure 1. Dual Screened and Unscreened Ion Traps

For the screened orthorhombic (2.5" x 2" x 2") trap, the experimental ICR frequency shift due to trapping voltage is reduced by a factor of ~60 compared to an unscreened conventional orthorhombic (2.5" x 2" x 2") ion trap (see Figure 3). The ICR signal induced on the detector electrodes of a screened trap is reduced to about 72% of that for the same-size unscreened trap. (Those measurements represent an average of the results obtained with the two traps placed either as shown in Figure 1 or interchanged left-to-right, to make sure that the effect was not due simply to the location of a given trap in the magnet.) As will be documented elsewhere,¹ the new screened trap offers higher mass resolution (and accuracy) and reproducibility during *detection* (due to more uniform electric field); higher mass resolution during *excitation* (since ICR frequency no longer varies significantly with ICR orbital radius) for improved MS/MS; and potentially much higher upper mass limit (since the radial electric field has been eliminated) than prior electromagnetic ion traps.

We acknowledge P. B. Grosshans for independent development of a similar idea. This work was supported by the National Science Foundation (CHE-8721498) and The Ohio State University.

Solution of the Equations of Ion Motion During the Ion Cyclotron Resonance Excitation Event

Peter B. Grosshans and Alan G. Marshall

Department of Chemistry (and Department of Biochemistry),
The Ohio State University, 120 West 18th Avenue, Columbus, Ohio 43210

In the past, the rate at which an ion's radius increases during the excitation event has been calculated as if the excitation plates were infinite in extent; this approximation overestimates the power input to the ion's motion owing to the presence of the detection and trapping plates. Here we have solved Laplace's Equation for the electrostatic (in the low frequency limit) potential exactly during the excitation event and expanded this solution in a Taylor series about the center of the ion trap. From this approximate potential, the equations of motion are then solved exactly with quite general initial conditions. The expression for the rate at which the cyclotron radius increases is of the same form as in the earlier model (the infinite plate model) with the exception of a correction factor. We conclude that the earlier model overstates the rate at which an ion's radius increases by 39% for a cubic ion trap.

We assume that the time-dependent potential field, $V(x,y,z,t)$, propagates instantaneously throughout the cell—a very accurate approximation for non-relativistic ion velocities. Let the magnetic field, $\mathbf{B}$, define the z -axis and let the trap have a square cross-section transverse to this axis; with electrodes at $x = \pm a/2$, $y = \pm a/2$, and $z = \pm L/2$; we then solve Laplace's Equation for $V(x,y,z,t)$:

$$\nabla^2 V(x,y,z,t) = 0 \quad \text{where} \quad \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \quad (1)$$

with the boundary conditions:

$$V(\pm \frac{a}{2}, y, z, t) = 0 \quad V(x, \pm \frac{a}{2}, z, t) = \pm \frac{V_{pp}}{2} \sin \omega_+ t \quad V(x, y, \pm \frac{L}{2}, t) = V_t$$

We have chosen the plates at $y = \pm a/2$ to be the excitation plates and we employ a single frequency excitation waveform at the modified cyclotron frequency, ω_+ , with peak-to-peak voltage, V_{pp} . Because ∇^2 is a linear operator, any linear combination of solutions to Eq. 1 is also a solution. Therefore, we can break this problem into two much simpler problems as summarized by the following equations:

$$V(x, y, z, t) = V_1(x, y, z) + V_2(x, y, z, t)$$

$$\nabla^2 V_1 = 0 \quad V_1(\pm \frac{a}{2}, y, z) = V_1(x, \pm \frac{a}{2}, z) = 0 \quad V_1(x, y, \pm \frac{L}{2}) = V_t \quad (2)$$

$$\nabla^2 V_2 = 0 \quad V_2(\pm \frac{a}{2}, y, z, t) = V_2(x, y, \pm \frac{L}{2}, t) = 0 \quad V_2(x, \pm \frac{a}{2}, z, t) = \pm \frac{V_{pp}}{2} \sin \omega_+ t$$

The solutions are:

$$V_1 = \frac{16V_t}{\pi^2} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n} \cos\left[\frac{(2m+1)\pi x}{a}\right] \cos\left[\frac{(2n+1)\pi y}{a}\right] \cosh\left[\frac{\kappa_{mn}\pi z}{a}\right]}{(2m+1)(2n+1) \cosh\left[\frac{\kappa_{mn}\pi L}{2a}\right]}$$

$$V_2 = \frac{8V_{pp} \sin \omega_+ t}{\pi^2} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n} \cos\left[\frac{(2m+1)\pi x}{a}\right] \cos\left[\frac{(2n+1)\pi z}{L}\right] \sinh\left[\frac{\kappa_{mn}\pi y}{a}\right]}{(2m+1)(2n+1) \sinh\left[\frac{\kappa_{mn}\pi}{2}\right]} \quad (3)$$

where $k_{mn} \equiv \sqrt{(2m+1)^2 + (2n+1)^2}$ and $\kappa_{mn} \equiv \sqrt{(2m+1)^2 + \frac{a^2}{L^2} (2n+1)^2}$

$V(x,y,z,t)$, from Equations 2 and 3, may be expanded about the center of the trap by use of the three variable Taylor series; neglecting terms of order 3 and higher, we have:

$$V(x,y,z,t) \approx V_1 \left[\gamma - \frac{\alpha}{2a^2} (x^2 + y^2 - 2zz^2) \right] + \frac{\beta V_{pp} \sin \omega_+ t}{a} y \quad (4)$$

$$\text{where } \alpha \equiv 16 \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n} (2m+1)}{(2n+1) \cosh \left[\frac{k_{mn} \pi L}{2a} \right]} \quad \beta \equiv \frac{8}{\pi} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n} \kappa_{mn}}{(2m+1)(2n+1) \sinh \left[\frac{\kappa_{mn} \pi}{2} \right]}$$

$$\text{and } \gamma \equiv \frac{16}{\pi^2} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{(-1)^{m+n}}{(2m+1)(2n+1) \cosh \left[\frac{k_{mn} \pi L}{2a} \right]}$$

These series for α , β , and γ converge rapidly; their functional dependence on the aspect ratio, L/a , of the trap is plotted in the figure below. The electric field, $\mathbf{E}$, is derived from this approximate potential and is then substituted into the Lorentz Force Equation

$$\mathbf{F} = m\mathbf{a} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \quad (5)$$

The differential equations of motion may then be solved by the Laplace Transform Method; we find that the cyclotron radius, ρ_c , increases at a rate given by:

$$\frac{\partial \rho_c}{\partial t} \approx \beta \frac{V_{pp}}{aB} \quad \text{whereas the infinite electrode approximation has} \quad \frac{\partial \rho_c}{\partial t} \approx \frac{V_{pp}}{aB} \quad (7)$$

The factor β is the only difference. It has a maximum value of 0.835 and a minimum value of 0; for a cubic trap, this factor is 0.72. Thus, the older formula overestimates the rate of radius increase by at least 20%, and by 39% for a cubic trap.

A New Method for Calculating the Signal Induced on ICR Detector Plates

Peter B. Grosshans, Alan G. Marshall, and Patrick Shields

Departments of Chemistry (and Biochemistry, and Physics),
The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

An analytic solution for the signal induced in on the detection plates of an FT/ICR cell can be derived for both rectangular and cylindrical geometries from basic electrostatics. With the assumption that the motion of the ions is non-relativistic, the potential within the cell is given by¹:

$$\Phi(\mathbf{r}) = \int_{V_c} \frac{\rho_f(\mathbf{r}') G(\mathbf{r}, \mathbf{r}')}{4\pi\epsilon_0} d\mathbf{r}' + \int_{S_c} \frac{d\mathbf{a}'}{4\pi} \left[G(\mathbf{r}, \mathbf{r}') \frac{\partial \Phi(\mathbf{r}')}{\partial n'} - \Phi(\mathbf{r}') \frac{\partial G(\mathbf{r}, \mathbf{r}')}{\partial n'} \right] \quad (1)$$

where V_c is the volume of the cell, S_c is the surface defined by the inner faces of the electrodes, ρ_f is the ionic charge density, ϵ_0 is the permittivity of free space, n' is the outward normal coordinate at the cell boundary, and the primed coordinates are integration variables. If we further assume that the potential on the plates is known (Dirichlet boundary conditions), then the Green function, $G(\mathbf{r}, \mathbf{r}')$, appropriate for the rectangular cell with plates at $x = 0, a$; $y = 0, b$; and $z = 0, c$; is given by:

$$G(\mathbf{r}, \mathbf{r}') = \frac{32}{\pi abc} \sum_{l,m,n=1}^{\infty} \frac{\sin\left(\frac{l\pi x}{a}\right) \sin\left(\frac{l\pi x'}{a}\right) \sin\left(\frac{m\pi y}{b}\right) \sin\left(\frac{m\pi y'}{b}\right) \sin\left(\frac{n\pi z}{c}\right) \sin\left(\frac{n\pi z'}{c}\right)}{\left(\frac{l}{a}\right)^2 + \left(\frac{m}{b}\right)^2 + \left(\frac{n}{c}\right)^2} \quad (2)$$

For the cylindrical cell the Green function is given by:

$$G(\mathbf{r}, \mathbf{r}') = \frac{8}{a^2 L} \sum_{m=0}^{\infty} \sum_{l,n=1}^{\infty} \frac{\epsilon_m \cos[m(\phi - \phi')] J_m\left(\frac{x_{ml}\rho}{a}\right) J_m\left(\frac{x_{ml}\rho'}{a}\right) \sin\left(\frac{n\pi z}{L}\right) \sin\left(\frac{n\pi z'}{L}\right)}{J_{m+1}^2(x_{ml}) \left[\left(\frac{x_{ml}}{a}\right)^2 + \left(\frac{n\pi}{L}\right)^2 \right]} \quad (3)$$

$\epsilon_m \equiv \begin{cases} 1 & \text{for } m=0 \\ 2 & \text{for } m \neq 0 \end{cases}$ and x_{ml} is the l^{th} zero of J_m , the Bessel function of order m .

One is usually interested in the differential charge induced between opposed detection plates by an ion of charge q and position, $\mathbf{r}_1$. For each detection plate one computes the induced surface charge density, σ , from

$$\sigma(\mathbf{r}, \mathbf{r}_1) = \epsilon_0 \frac{\partial \Phi(\mathbf{r}, \mathbf{r}_1)}{\partial n} = -\epsilon_0 E_n(\mathbf{r}, \mathbf{r}_1) \quad (4)$$

This charge density is then integrated over the surface of each detection plate to yield the total induced charge. The difference in induced charge between these plates is the required differential charge, ΔQ_1 . If the detection plates are those located at $y = 0$ and b , the result for the rectangular cell is:

$$\Delta Q_1(\mathbf{r}_1) = \frac{128q}{\pi^3 b^2} \sum_{l,m,n=1}^{\infty} \frac{m \sin\left[\frac{(2l-1)\pi x_1}{a}\right] \sin\left[\frac{2m\pi y_1}{b}\right] \sin\left[\frac{(2n-1)\pi z_1}{c}\right]}{(2l-1)(2n-1) \left[\left(\frac{(2l-1)}{a}\right)^2 + \left(\frac{2m}{b}\right)^2 + \left(\frac{(2n-1)}{c}\right)^2 \right]} \quad (5)$$

Similarly, for a cylindrical cell with trapping plates at $z = 0$ and L and radius, a , and with the ring electrode segmented into four equal quadrants:

$$\Delta Q(r_l) = \frac{-16q}{a^2 \pi^2} \sum_{l,m,n=1}^{\infty} \frac{\{(-1)^m \cos(m'\phi_l) - \sin(m'\phi_l)\} x_{m',l} J_{m'}\left(\frac{x_{m',l} \rho_l}{a}\right) \sin\left[\frac{(2n-1)\pi z_l}{L}\right]}{m'(2n-1)J_{m'+1}(x_{m',l}) \left[\left(\frac{x_{m',l}}{a}\right)^2 + \left(\frac{(2n-1)\pi}{L}\right)^2\right]} \quad (6)$$

where $m' \equiv 2m+1$. For N ions, the net differential charge induced is simply the linear superposition of the individual induced charges. Assuming that the detection circuit is essentially capacitive in the frequency range of interest with equivalent capacitance C_{eq} , the induced voltage, $V(t)$, between the detection plates is simply the differential charge divided by C_{eq} . Comisarow³ has derived an expression for the charge induced on one of the detection plates as a function of ion position; he finds

$$\Delta Q(r_l) = \frac{qy_l}{b} \quad (7)$$

where y_l is the y -coordinate of the ion's position and b is the spacing between the detection plates as above. Upon comparing Equation (7) to Equation (5), we see that Comisarow's approximation oversimplifies the problem. Indeed, when this result is put into the form of Equation (7), it is easy to see that it is equivalent to the infinite electrode approximation. Finally, we note that for an ion moving in a circular orbit of angular frequency, ω , and radius, r , from the z -axis, both Equations (5) and (6) can be put into the following form:

$$\Delta Q(t) = q \sum_{j=1}^{\infty} A_j \cos[(2j-1)\omega t + \phi_j] \quad (8)$$

Thus, the appearance of signals at odd harmonics of the fundamental frequency is predicted in a natural way by our theory (see figure below). This work was supported by the National Science Foundation (CHE-8721498) and The Ohio State University.

Precision in Determination of Relative Ion Abundances from FT/ICR Mass Spectra: Absorption Peak Area is Superior to Peak Height or Complex Area

Zhenmin Liang and Alan G. Marshall

Departments of Chemistry and Biochemistry
The Ohio State University, 120 West 18th Avenue, Columbus, Ohio 43210

In FT/ICR mass spectra, phase-corrected absorption-mode peak area is a direct measure of the number of detected ions of that ICR frequency, provided that the time-domain signal acquisition period, $T \gg \tau$, where τ is the time-domain damping constant. In this abstract, we discuss four methods for estimation of absorption-mode peak area: (a) direct integration or peak-fitting to the (phase-corrected) absorption-mode spectrum; (b) sum of the areas of the real and imaginary components of the complex FFT spectrum ("complex area");¹ (c) absorption-mode peak area obtained as a parameter from non-linear least-squares fit to the magnitude-mode spectrum; and (d) absorption-mode peak area obtained as a parameter from non-linear least-squares fit to the (phase-corrected) absorption-mode spectrum. We find that method (c) is best.

Precision as a function of signal-to-noise ratio and number of data points

It has previously been shown that the precision, $P(a)$, of spectral parameter, a (a = peak height, peak width, or peak center frequency), determined by non-linear least-squares fit to a single frequency-domain spectrum, is given by:^{2,3}

$$P(a) = c(a) \text{ SNR} \sqrt{K} \quad (1)$$

in which SNR is frequency-domain spectral peak height-to-noise ratio, K is the number of data points per (full) line width at half-maximum peak height, and $c(a)$ is a line shape-dependent constant.

Frequency-domain spectral precision

In Figures 1-2, we show that Eq. 1 can be extended to the determination of absorption-mode peak area, for various area-measuring means. When phase correction is difficult (as in FT/ICR), magnitude-mode peak height or even magnitude-mode peak area (mathematically non-integrable for Lorentzian peak shape) are often used in place of absorption-mode peak area.

We have discovered that absorption-mode peak area can be recovered from magnitude-mode as well as from (phase-corrected) absorption-mode spectra by least-squares fit. Interestingly (see Figures 1,2), higher precision is obtained by determination of absorption-mode peak area from non-linear least-squares fit to the magnitude-mode FT spectrum than by similar direct fits to the absorption-mode (or complex) FT spectrum.

Time-domain precision

Frequency-domain absorption-mode peak area is a measure of time-domain signal initial magnitude (which in turn is directly related to the number of detected ions in an FT/ICR experiment. Eq. 1 may be extended to the determination of time-domain signal initial magnitude, in which SNR and K are replaced by time-domain signal-to-noise ratio, snr , and number of data points, k , per time-domain damping period, τ .

Relation between time- and frequency-domain precision: effect of zero-filling

From computer-simulated data, we find that the precision of spectral parameters determined by least squares fit to a noisy single-frequency *time-domain* signal is higher than that determined by least squares fit to the corresponding *frequency domain* spectrum. One time-domain zero-fill before FFT increases the precision of the frequency domain fit to the same level as that from the time-domain data. Further zero-fills do *not* improve frequency-domain precision.

Experimental tests of theory

Figures 3 and 4 offer experimental FT/ICR mass spectral examples of the computer-simulated results shown in Figures 1 and 2. Figure 3 also includes precision based on magnitude-mode peak height (obtained from least-squares fit to magnitude-mode spectrum). Clearly, the theoretical predictions tend to overestimate the precision realized experimentally. The results nevertheless qualitatively support our theoretical predictions and show that absorption peak area (computed from best-fit to a magnitude-mode spectrum) offers the most precise measure of relative ion abundances from unphased FT/ICR mass spectra. EFFECT OF SAMPLING RATE ON FT/ICR MASS SPECTRA: IS OVERSAMPLING OVERRATED?

George M. Alber and Alan G. Marshall

Departments of Chemistry and Biochemistry, The Ohio State University
120 West 18th Avenue, Columbus, Ohio 43210

In Fourier transform spectrometry, an analog time-domain signal is sampled at equally spaced intervals and subjected to a discrete Fourier transform to yield a discrete frequency-domain spectrum. The Nyquist theorem requires that the time-domain signal be sampled at least twice per cycle of the highest frequency in the spectral bandwidth. It is well known that *under-sampling* (i.e., sampling at less than the Nyquist frequency) results in "foldover" ("aliasing") of signals whose frequencies exceed the Nyquist limit. Undersampling can in fact be used to advantage for simultaneous detection of ions of widely separated m/z values at ultrahigh resolution, by use of multiple foldover (1). However, *over-sampling* (i.e., sampling faster than twice the spectral bandwidth) has received much less attention. In this work, we discuss the effects and advantages of oversampling for FT/ICR mass spectra (2).

First, it is important to understand that the sampling process itself produces time-domain amplitude errors which appear as frequency-domain "quantization noise", as shown in Figure 1. An analog-to-digital converter (ADC) must assign each analog time-domain value to one of a finite number of (discrete) amplitude values. Thus, the ADC effectively "rounds off" the true analog signal to the nearest available discrete ADC

amplitude. The differences (errors) between discrete and analog values define a time-domain error ("quantization noise") signal.

Figure 2 (top) shows the frequency-domain spectrum produced by discrete FT of a Nyquist-sampled *noiseless* analog signal. The vertical scale has been expanded to show the quantization noise. Quantization noise may be reduced in two ways. First, one can (say) double the number of bits per ADC word, so that the average time-domain amplitude sampling error from the same analog time-domain signal is reduced, and the corresponding frequency-domain spectral signal-to-noise ratio increases by a factor of about $\sqrt{2}$ (see Figure 2, bottom left). Alternatively, one can *oversample* the time-domain signal by (say) a factor of two. Although the average time-domain amplitude sampling error for each time-domain data point is the same as before, the time-domain signal is sampled twice as often, so that the frequency-domain spectral bandwidth after FT is doubled. In effect, the quantization noise is "spread out" over twice the frequency range, and its rms magnitude in the original bandwidth of interest is reduced by a factor of about $\sqrt{2}$ (Figure 2, bottom right).

In practice, the *absolute* quantization error magnitude generated is very small. (≤ 1 part in $\sim 8,000$ for a 12-bit ADC). However, a practical advantage of oversampling is that the analog low-pass filter bandwidth can be made larger than the desired spectral bandwidth (since oversampling eliminates foldover from signals above the desired bandwidth), thereby reducing amplitude and phase distortion in the spectral bandwidth of interest.

ISOTOPE-RATIO MEASUREMENTS BY FT/ICR: ESTIMATING INITIAL
AMPLITUDES AND DAMPING CONSTANTS FROM SEGMENTED TIME SERIES

Dale W. Mitchell and Stephen E. DeLong

Department of Geological Sciences
State University of New York at Albany
Albany, NY 12222

Isotope geochemists routinely correct for instrumental fractionation effects in thermal ionization mass spectrometry and SIMS by a simple mass-dependent model. For Kr isotopes, for example, the model would predict that an isotope-ratio plot such as Fig. 1 should be linear according to:

$$\frac{(^{82}\text{Kr}/^{84}\text{Kr})_m - (^{82}\text{Kr}/^{84}\text{Kr})_t}{(^{82}\text{Kr}/^{84}\text{Kr})_m - (^{82}\text{Kr}/^{84}\text{Kr})_t} = \frac{(^{82}\text{Kr}/^{82}\text{Kr})_t}{82 - 84}$$

where the subscripts m and t refer to measured and true (or corrected) ratios, respectively, and the second term on the right is the ratio of the mass differences. For atmospheric Kr, $(^{82}\text{Kr}/^{82}\text{Kr})_t \approx 1$, so that an array of fractionated measurements should be linear with slope 1/2 and pass through the point $[(^{82}\text{Kr}/^{84}\text{Kr})_t, (^{82}\text{Kr}/^{84}\text{Kr})_t]$.

The FTMS data in Fig. 1 were collected at two different pressures by successively increasing the duration of the electron beam (BEM), so that the arrow marks an increasing number of ions. Obviously at low ion number the isotope ratios fall at or near the true values and move away with increasing BEM, with behavior becoming non-linear at the higher pressure presumably due to space-charge effects. The slope of the linear portions of these plots is ~1, however, rather than 1/2 as predicted for mass fractionation. We have observed similar behavior for laser desorption/ionization of solids, e.g., Ti metal, in which the isotope fractionation pattern linearly favors the most abundant mass. This suggests a damping mechanism in which the dominant isotopes survive longest in the transient and are thus favored in peak amplitudes. Empirically, this fractionation approximately follows $[I_1/I_2]_m = [I_1/I_2]_t * [I_2/I_2]_m$, where I_2 is the concentration of the most abundant isotope.

We can estimate for each mass the decay constants and amplitudes (at end of excitation) by segmentation of the signal. By dividing the original transient into shorter time series as a function of the time of the first data point of each segment, T_i , a plot of the log of the FT magnitude peak height, $\ln[M]$, vs. T_i is linear assuming that the transient is an exponentially decaying sinusoid. It can then be shown that

$$\ln[M] = -DT_1 + \ln\left\{ (A/2) \int_0^T g(t) \exp(-Dt) dt \right\}, \quad (1)$$

where M, A, D, τ , and $g(t)$ are the FT magnitude peak height, amplitude (at $T_i = 0$), decay constant, segment length, and apodization function, respectively.

We have applied this segmenting procedure to Kr in a set of experiments where BEM was varied from 2.5 ms to 25.0 ms in increments of 2.5 ms at a background pressures of 3.3×10^{-7} T with trapping voltage of 9.0 V. Other experimental parameters include: number of data points=32K, number of sweeps=1000, beam voltage=-50 V, beam current=1 A, sweep rate=3.2 KHz,

excitation voltage=75 V_{pp} (full bandwidth), bandwidth= 2.667 MHz. The transient was divided into 20 overlapping segments each 8K data points long and separated by 1000 points. Each segment was apodized by the Blackman-Harris 3-term window before transformation. Plots of ln[M] vs. T_i were fitted to a straight line whose slopes and intercepts were used with eq. (1) to find D and A for each isotope. Figure 2 shows the results of the extrapolation procedure for the same Kr isotope ratios displayed in Figure 1 and demonstrates that the observed fractionation is dominated by abundance-dependent differences in decay constants.

Figure 1. Kr isotope ratios measured on FTMS-2000 at two nominal pressures and trapping voltage = 7.5V. No segmentation of transients.

Figure 2. Comparison of Kr isotope ratios for full transients (unsegmented) vs. same ten experiments segmented and extrapolated to end of excite period. Trapping voltage = 9.0 V. Note scale expansion compared to Figure 1.

ICR EXPERIMENTS ON SHORT-LIVED ISOTOPES AND CLUSTERS: NEW THEORETICAL AND EXPERIMENTAL RESULTS

Mass spectrometers based on ICR techniques have been set up at CERN/Geneva and at the University of Mainz. The experiments have different aims, and therefore different methods are used for ion creation, excitation, and for the detection of the cyclotron resonances. In the following these techniques are described and the advantages and disadvantages are discussed.

After development at Mainz, an ICR apparatus has been set up at CERN/Geneva in order to perform high-resolution precise mass measurements of short-lived isotopes. These isotopes are produced by bombarding suitable targets with 600 MeV protons from a synchro cyclotron. They are available to the ICR device as a continuous beam of 60-keV ions to the ICR device delivered by the on-line isotope separator ISOLDE. The ions are stopped on a foil, surface-ionized and trapped in a first Penning trap (located in an electromagnet). Subsequently they are transferred[1] to a precision trap inside a superconducting magnet, where the mass measurement takes place. This is done by a narrow-band radio frequency (RF) field exciting the cyclotron motion of the stored ions. In resonance the ions absorb energy from the RF field. Afterwards the ions are kicked out of the trap and drift to a channel plate detector. In the inhomogeneous magnetic field the energy of the cyclotron motion is transformed into axial kinetic energy which shows up as a decrease of the time of flight (TOF) to the ion detector[2]. A resonance curve is obtained scanning the RF and measuring the TOF for each frequency point. So far a resolution of more than 2,000,000 has been achieved for mass 133. In a first application to short-lived isotopes evidence has been obtained for a first mass spectrometrical discrimination of two isomers in the same nucleus, namely in the case of ¹²²Cs[3].

It should be emphasized that the resonance observed is not at the reduced cyclotron frequency ν_+ but at an interharmonic of ν_+ and the magnetron frequency ν_- . Both frequencies add up for a perfect Penning trap to $\nu_+ + \nu_- = \nu_c$, where $\nu_c = (eB)/(2\pi M)$ is the cyclotron frequency of an ion of mass M and charge e in a homogeneous magnetic field B in the absence of any trapping potential. Extensive numerical calculations as well as analytical investigations show that a resonance ($\nu_{RF} = \nu_c$) can best be observed by catching the ions with a large magnetron but small cyclotron radius and by using a azimuthal quadrupole electric field for driving the RF transitions. The calculations are confirmed by experiments with a four-segment ring electrode[4]. The amplitude of this resonance is comparable to that of the reduced cyclotron frequency ν_+ using a dipole excitation via a ring split into two halves. The quadrupole excitation with

$\nu_+ + \nu_-$ makes the ions alternate between the cyclotron and the magnetron motion. The beating frequency between these motions depends on the amplitude of the driving RF field. Using these technique a new cooling scheme for ions stored in a Penning trap has been developed[4].

The apparatus at Mainz will be used for laser spectroscopy of cluster ions[5]. Here the trap is not just filled with one ion species as in the Geneva experiment. It is used for the preparation of the ion ensemble of interest, for storage while the interaction with the laser takes place and for the analysis of the products. While the resonance detection technique by TOF, applied at Geneva, is very sensitive (one ion per measurement cycle is enough to perform the experiments) it is also time consuming and becomes cumbersome, if different ion species of an unknown ion cloud have to be identified. In this case FT-ICR is the method of choice. For test experiments an apparatus using a Penning trap inside an electromagnet has been set up at Mainz. The conventional FT-ICR detection scheme has been tested and new detection schemes have been developed. For example by exciting the ions via one end cap and using the other as a pick-up electrode it is possible to directly detect the trapping frequencies of the ion ensembles [6]. The frequencies of these resonances do not involve the magnetic field like the cyclotron frequency does. Therefore it seems feasible to extend these experiments to RF traps.

It has also been shown that resonances at combinations of the reduced cyclotron frequency and the magnetron frequency, namely $\nu_+ + \nu_-$ and $\nu_+ - \nu_-$ can be observed directly without the resonance at ν_+ , which is the most strongest in conventional FT-ICR. This is done by adding the signals of two opposite ring segments instead of subtracting them [7].

With the help of these experiences a new Penning trap has been constructed for a superconducting magnet at Mainz. The new trap has a twelve-electrode configuration, eight of which form the ring electrode. With this scheme different types of excitation and detection can be performed. From the observation of the resonances at interharmonics of ν_+ and ν_- by use of two opposite electrodes it can easily be shown that a quadrupole detection arrangement should show only the resonance at $\nu_+ + \nu_-$ while the one at $\nu_+ - \nu_-$ must vanish. This has been confirmed experimentally[4]. The new detection scheme can be used in narrow-band excitation as well as in the broad-band mode. The experiments have been performed with ions produced by electron impact ionization of the rest gas in the trap as well as with carbon cluster ions produced by laser evaporation of a target placed at one of the endcaps. The experimental investigations will be continued using externally created cluster ions.

IN-SITU PYROLYSIS AND THERMAL DESORPTION IN AN
ION TRAP MASS SPECTROMETER

Steve Young and M. J. Coggiola
SRI International, Menlo Park, CA 94025

Normally, the Finnigan ITD is designed to accept only gas phase samples introduced through the GC transfer line. While a number of inlet variations have been reported, including some that allow solid sample analysis, they all generate a gas phase sample external to the ion trap. In the present experiment, a small loop of 0.005" diameter Chromel wire was located within one of the 0.045" diameter ion exit holes provided on the detector end cap. Electrical connection was made by a spring contact to a BNC feedthru that was added to the standard vacuum manifold. A tantalum shield was placed over the wire loop on the detector side to prevent photons emitted by the hot filament from reaching the multiplier directly. Solid samples were loaded onto the wire loop, either directly or dissolved in a suitable solvent. The trap assembly was then loaded into the vacuum manifold and pumped down.

Thermal desorption/pyrolysis mass spectra were then obtained by acquiring data in the usual manner while slowly ramping the current passing through the wire loop. Despite the use of the photon shield, heating currents were limited to the point where significant optical emission saturated the detector. Within the accessible temperature range (estimated to be up to 500 deg C), a number of solids including sucrose, 1,3-dimethylthymine, and cellulose fibers gave strong desorption and/or pyrolysis spectra.

In order to allow for a shorter cycling time for inorganic compounds, and to reduce the background interferences from a hot filament near the multiplier, an external vaporization chamber was built of 2-3/4" conflat parts. It was connected to the trap inlet via 3-1/2" of 1/4" o.d. stainless steel tubing. Since the conductance of this tube is 0.12 l/s and the exit conductance of the trap is 2 l/s, the trap operated at 6 mTorr with the vaporization chamber at 100 mTorr and a 1 ml/min flow rate of carrier gas. The heater filament in the vaporization chamber was 5/8" long, and either .030" x .001" rhenium or .100" x .0005" tungsten. Samples placed on the heater were ramped from room temperature to 1500+ deg C in about 6 minutes.

Samples such as cadmium and zinc evaporate over a narrow temperature range, giving fairly sharp "peaks" in the total ion chromatogram. Measured isotopic ratios agree well with standard values, as shown in Figure 1 for cadmium. As₂O₃ gave, at first, mixed oxides, then as the temperature increased, arsenic clusters appeared, as shown in Figure 2. Results using other compounds are listed in Table 1.

When the carrier gas used to entrain the evaporated materials was switched from helium to hydrogen, thermal desorption of As₂O₃ produced oxides, clusters, and hydrides of arsenic (see Table 1). The former appeared at lower temperatures than the latter. Zinc hydride was also observed during the thermal desorption of ZnCl₂ using hydrogen as a carrier gas.

This technique should prove useful for the analysis of heavy metals and inorganic compounds using the ITD.

Figure 1. Upper panel (left) shows the total ion chromatogram for the thermal desorption of cadmium. The lower panel shows the mass spectrum obtained by subtracting the average of scans 105 to 113 from the average of scans 119 to 123. Also shown is a table of measured isotope ratios.

Figure 2. The upper panel (below) shows a mass spectrum of the initial materials desorbed when As_2O_3 is evaporated from a hot rhenium filament. The lower panel is the spectrum taken later in the heating cycle, corresponding to higher temperatures.

Department of Electrical and Computer Engineering, Madison, WI 53706.

Recently, several techniques have been proposed and tested for the injection of ions into the trapped-ion cell of the Fourier transform mass spectrometer (FTMS). The objective of the external source/FTMS is to produce ions from any of a variety of ion sources, and in particular "messy" ion sources such as FAB, API, and ion sprays, which are external to the FTMS magnetic field. The externally-produced ions are injected in the trapped-ion cell of the FTMS for mass analysis. Such "messy" ion sources are incompatible with the low-pressure optimum operation of FTMS.

This paper investigates the properties of the RF-only quadrupole as an ion injection device for an external source/FTMS. Several RF-quadrupole/magnetic field configurations were studied by computer simulations. The models were based on the equations of motion of ions moving through an ideal quadrupole field with an externally-imposed magnetic fringe field. Some of the computer simulation results were tested by experiments on a quadrupole/FTMS system.

Several ensembles of ions were investigated in the simulations. Ions originated from a point ion source just in front of the quadrupole field. The ions were launched with initial energies of 1.0, 2.5, 5.0, or 10.0 eV. The ions were injected into the first quadrant of the RF-only quadrupole field at 15 locations as shown below. One quadrupole ion guide that was studied was 1.1-m long with 6.4-mm diameter rods and an RF frequency 870 kHz. Two RF voltages were used (500 V and 2000 V), which correspond to a low mass cutoff of m/z 460 and m/z 1860. Ions were injected into 3 T and 7 T magnetic fields with fringe fields that very closely approximated those measured. The trapped-ion cell dimensions were 2.5 cm x 2.5 cm x 7.6 cm. The front trap plate was held at 0 V until an ion entered the trap and passed the center, at which time the front trap plate voltage was raised to the same voltage as the back trap plate (3 V). Several different m/z ions were investigated including m/z 1000, 2000, 3000, 4000, and 5000.

In the simulations, an ion can be transmitted, trapped, or lost. A transmitted ion is one whose trajectory is stable through the quadrupole field; i.e., $(x^2 + y^2)^{1/2} < r_0$, where r_0 is the inscribed radius of the quadrupole structure. A trapped ion is one that is transmitted through the quadrupole field, enters the trapped ion cell, and is electrostatically reflected to the center of the cell from the back trap plate. The efficiency is defined as the percent of ions trapped relative to the number of ions that were injected.

Ions are lost by a) unstable trajectories in the quadrupoles; b) reflection because of the magnetic forces (magnetic mirror effect); and c) penetration of the back (transparent) trap plate due to high ion kinetic energy.

One important finding of these simulations is that some of the apparently desirable characteristics of the RF-only quadrupole ion guide are lost in the presence of a fringing magnetic field -- the magnetic mirror. For example, while the overall transmission through the quadrupole field appears to be mass independent, it appears to be less at higher RF-voltages (higher mass cut off). Also, the magnetic mirror affects the transmission efficiency more with low magnetic fields than with high magnetic fields. Higher RF-voltages appear to lead to an increased radial distribution about the z-axis (centerline) of the trapped-ion cell. Such an increase in the spatial distribution of injected ions will limit the coherent excitation of ions. Also, the ion injection/trapping efficiency increases with more intense magnetic fields. This is because the force exerted on the ions by the magnetic field is much stronger than the forces exerted by the quadrupole field. The strong magnetic fields tend to keep the ions bunched about the centerline. These findings are difficult to test experimentally, because at low RF voltage, the FTMS performance may be affected by the injection of large numbers of unwanted low-mass background ions that can lead to collisions and space-charge that affect the resolving power.

Those ions injected with high axial energies, for example, those at $0.4f_0$ and $0.8f_0$ are transmitted with low efficiency or not at all, and lower axial energies lead to higher efficiencies (40-50%). In practice, the ion source is tuned to minimize the angular distribution of the exiting ions. The simulations showed that ions with higher translational energies were trapped more efficiently than ions with lower translational energies. This result was confirmed by experiments with ions formed by particle-induced emission from solids and liquids.

In summary, the ion transmission properties of an RF-only quadrupole are different when it is operated in a spatially-varying magnetic field. Ion trapping is more efficient with higher magnetic fields. The higher the RF-voltage (higher low-mass cutoff), the lower the overall efficiency of injection and optimal ion trapping. A threshold ion energy is required for ions to penetrate the magnetic mirror. Further simulations and experimental studies should provide information on optimal operation of the RF-only quadrupole for ion injection into the FTMS.

**EXTERNAL ION SOURCES ON ION CYCLOTRON RESONANCE (ICR) MASS
SPECTROMETERS: ION-OPTICAL CONSIDERATIONS.**

INTRODUCTION

An ion moving with a velocity v perpendicular to the direction of a magnetic field B experiences a force F given by:

$$F = qvB$$

This force tends to move the ion in a circular orbit perpendicular to the direction of the magnetic field. The radius of the orbit and frequency of rotation are proportional to the mass-to-charge ratio of the ion. The radius of the orbit is given by:

$$r = \frac{mv}{qB}$$

The frequency of rotation is given by:

$$f = \frac{1}{2\pi} \left(\frac{Bq}{m} \right)$$

Trajectories of ions through an electrostatic lens in a magnetic field will be different for ions of different mass-to-charge ratios due to the magnetic component.

EXPERIMENTAL

A field desorption experiment has been performed inside the magnetic field of a Bruker Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. The arrangement consisted simply of a counter-electrode and focus electrode mounted on the front of the ICR trapping cell. The trapping plate voltage was not pulsed in these experiments.

RESULTS

The compound used in the experiments was polypropylene glycol (av. mol. wt. 1000). This compound was chosen because it tends to produce strong ion currents over a broad range of masses under field desorption conditions [1]. The appearance of the polymer envelope in any mass spectrum provides an indication of the extent of any mass discrimination.

It proved very difficult in these experiments to trap ions in the cell. The three inter-dependent variables which had to be tuned were: the potential on the emitter, the emitter heating current and the potential on the focus electrode. The counter-electrode was floated at -6kV in these experiments. One particular set of conditions was found, however, under which ions were trapped in the cell. The conditions were: an emitter potential of +25V, an emitter heating current of 15mA and a focus voltage of -215. An emitter heating current of 15mA is quite high in comparison to heating currents normally used in field desorption of this compound [2]. The spectrum obtained using a short acquisition time (0.001s) is shown in Figure 1. The resolution in the spectrum is obviously very poor. It does, however, suggest extreme mass discrimination.

CALCULATED RESULTS AND DISCUSSION

Trajectories through the system were calculated for ions originating from the emitter at initial angles of 1, 2 and 3 degrees to the axis of the system in the central horizontal plane. The magnetic field strength was 4.7 tesla. Trajectories for an ion of mass-to-charge ratio of 1000 are shown in Figure 2. The emitter potential referred to in the calculations is the potential at which the ions are formed. In practice the actual voltage applied to the emitter will be greater than this by an amount equal to the voltage drop across the sample layer in the intense electric field. The trajectories have been terminated when the ions were just beginning to make their way back out of the cell (i.e. the component of velocity in the x direction became zero). Table 1 shows the results of calculations as distances (in millimeters), beyond the back face of the trapping plate, to which ions have penetrated the cell. The extent of penetration into the cell will determine how many ions are in the cell at a particular time and how long ions remain in the cell. If the ions are not excited by an RF pulse, they will remain inside the cell for only a short period of time. Under conditions where an ion of m/z 1000 penetrates to the centre of the cell the time spent inside the cell is of the order of 10^{-8} seconds. On application of the RF ions will absorb energy in the "plane of spiral", increasing the radius of the spiral. An increase in the orbital radius moves the ions out to regions of much lower electric field strength, thereby trapping the ions for a longer period of time. Negative values in Table 1 indicate distances

In front of the trapping plate i.e. these ions did not enter the cell at all. The internal length of the ICR cell is 60 mm. Values of 60 mm in Table 1 indicate, therefore, that the ion has hit the rear trapping plate. The extent to which an ion will penetrate the cell will depend upon the ions kinetic energy in the x direction (direction of cell axis). If the ion has significant angular velocity in the "plane of spiral", a lower proportion of the kinetic energy will be in the x direction, and the ion will tend not to penetrate far into the cell. This may be particularly critical under conditions of very low electric field penetration into the cell, as was the case in these experiments. Larger angles of divergence off the emitter will have greater spiralling induced by the magnetic field. For a given energy, low mass ions will tend to have a greater proportion of energy in the "plane of spiral", and are therefore discriminated against.

On studying Table 1 it would seem that masses and initial angles of divergence of ions ultimately trapped in the ICR cell will be sensitive to the actual potential at the sample/vacuum interface at the emitter. For example, consider that this potential is between +1 and +2 volts. Ions of mass around 1000 and initial divergence angle around 2 degrees will tend to be trapped. Ions of low mass will not penetrate very far, if at all, into the cell. Ions of mass around 1000 with very low initial divergence angles will tend to strike the rear trapping plate, whilst those with angles closer to 3 degrees will not penetrate the cell sufficiently. The differences in penetration distance may be sufficient to cause only a relatively small mass range to be trapped.

CONCLUSION

Mass discrimination (particularly if a broad mass range is required) is a very important consideration when designing electrostatic lenses for use in conjunction with external ion sources on ICR mass spectrometers. Under conditions of very low electric field penetration into the trapping cell and/or divergent ion beams, such as in the field desorption experiments conducted, the mass discrimination can be quite extreme. than mass 1000 under the same

A SIMPLE DIFFERENTIALLY PUMPED
EXTERNAL SECONDARY ION SOURCE FOR FTMS

CARL F. IJAMES AND CHARLES L. WILKINS,
UNIVERSITY OF CALIFORNIA, RIVERSIDE, CA 92521

FTMS OFFERS MANY ADVANTAGES AS A MASS ANALYZER FOR HIGH MASS IONS DUE TO ITS EXTREMELY HIGH MASS RESOLUTION, THE ABILITY TO ACCURATELY MEASURE MASSES WITH ERRORS LESS THAN 5 PPM WITHOUT CALIBRANT PRESENT, AND GOOD SENSITIVITY. HOWEVER, TO REALIZE THESE ADVANTAGES REQUIRES OPERATION AT PRESSURES BELOW 10^{-8} TORR. THIS HAS MADE THE COUPLING OF FTMS WITH LIQUID-SIMS PROBLEMATIC SINCE COMMON MATRICES HAVE VAPOR PRESSURES OF 10^{-7} TO 10^{-6} TORR. ONE SOLUTION HAS BEEN TO GENERATE SECONDARY IONS OUTSIDE THE MAGNET, IN AN EXTERNAL, DIFFERENTIALLY PUMPED SOURCE (FOR EXAMPLE THE QUADRUPOLE-FTMS OF MCIVER). WHILE CERTAINLY SUCCESSFUL, THESE HAVE NECESSITATED CONSTRUCTION OF AN EXPENSIVE INSTRUMENT DEDICATED TO THIS PURPOSE.

AN ALTERNATIVE APPROACH IS TO UTILIZE THE EXISTING DIFFERENTIAL PUMPING CAPABILITIES OF THE COMMERCIALY AVAILABLE NICOLET FTMS-2000. TO AVOID ALIGNMENT AND HIGH-VOLTAGE DIFFICULTIES THE CESIUM ION GUN IS MOUNTED TRANSVERSE TO THE MAGNETIC FIELD, WITH THE SAMPLE LOCATED OVER THE PUMP THROAT. THIS ARRANGEMENT DOES NOT INTERFERE WITH ANY OF THE OTHER EXPERIMENTS POSSIBLE ON THE INSTRUMENT (SEE FIGURE 1). THIS PRODUCES THE SECONDARY IONS ABOUT 38 CM FROM THE SOURCE TRAP PLATE, AT A MAGNETIC FIELD STRENGTH OF 0.165 TESLA, COMPARED TO 3 TESLA AT THE CELL. THE IONS ARE REPELLED BY A BIAS PLACED ON THE PROBE AND MOVE TOWARDS THE CELL WHERE THEY ARE TRAPPED BY GATING THE SOURCE TRAP PLATE TO GROUND WHILE THE ION GUN IS PULSED ON. A PULSE OF 5 MS IS LONG ENOUGH TO ESTABLISH A UNIFORM ION POPULATION FREE OF MASS DISCRIMINATION EFFECTS. BY ALSO GROUNDING THE CONDUCTANCE LIMIT THE IONS MAY BE TRANSFERRED TO THE ANALYZER CELL FOR ANALYSIS AT LOWER PRESSURE.

FIGURE 2 SHOWS A SPECTRUM OF CESIUM IODIDE CLUSTERS RECORDED IN THE SOURCE CELL. AN ION WITH m/z 8187, CORRESPONDING TO THE $Cs(CsI)_3^{+}$ CLUSTER, IS CLEARLY VISIBLE. GLYCEROL AS A MATRIX YIELDS SOURCE AND ANALYZER PRESSURES OF 4×10^{-6} AND 2×10^{-8} TORR, RESPECTIVELY. MAGIC BULLET, DITHIOHREITOL/DITHIOERYTHRITOL, YIELDS PRESSURES OF 6×10^{-7} AND 8×10^{-9} TORR, RESPECTIVELY. SPECTRA OF HISTIDINE WERE RECORDED FROM EACH MATRIX AT SIMILAR SENSITIVITY. FIGURE 3 SHOWS THE SPECTRUM WITH MAGIC BULLET AS A MATRIX, AND CONTAINS ABUNDANT $[M+H]^{+}$ IONS, WITH m/z 156. EXTRAPOLATION OF THE MEASURED SIGNAL TO NOISE DOWN TO 2:1 PREDICTS A DETECTION LIMIT UNDER THESE CONDITIONS OF TENS OF NANOMILES. THE TOTAL IONIZATION TIME TO RECORD THIS SPECTRUM WAS ONLY 50 MS. THE INSET SHOWS THE MOLECULAR ION RECORDED AT A RESOLUTION OF 160,000 FWHH, DEMONSTRATING THE RESOLUTION CAPABILITIES OF FTMS WHEN OPERATED AT SUITABLE PRESSURES.

NEGATIVE IONIZATION IN QUADRUPOLE ION TRAP MASS SPECTROMETRY: EFFECTS OF APPLIED VOLTAGES:

D.W. Berberich*, R.A. Yost, University of Florida, Gainesville, FL, 32611.

* Present Address - Finnigan MAT, San Jose, CA, 94536.

Successful implementation of negative ion mass spectrometry in the quadrupole ion trap mass spectrometer (QITMS) depends upon the use of various electrical fields to control the mass range of ions that have stable trajectories, as well as the kinetic energy of these ions. The electric fields may be examined by viewing the Mathieu stability envelopes for ion motion in a quadrupole ion trap (Figure 1). A detailed discussion of the Mathieu equations may be found elsewhere (1). One may consider the Mathieu parameter ' a_z ' (y-axis) as the DC voltage (U) applied to the ion trap ring electrode, divided by the m/z (m) of a given ion, multiplied by some constant (C). Similarly, the Mathieu parameter ' q_z ' (x-axis) can be considered simply as the RF voltage (V) applied to the ion trap ring electrode, divided by the m/z of a given ion, multiplied by some constant (K). Using this simplification, it becomes evident that for a given DC potential, each m/z has a unique value of ' a_z ' assigned to it. Similarly, for a given RF potential, each m/z has a unique value of ' q_z ' assigned to it.

In the RF-only mode of operation (no DC voltage), the ion trap is operated along the ' a_z ' = 0 line (point A), which allows for the storage of positive and negative ions. Since positive ions are formed more readily than negative ions (100- to 1000-fold excess), negative ion signals are quenched by positive-negative ion recombination. In order to overcome this challenge, it is necessary to examine alternative operation modes. Application of a DC voltage (negative) to the ring electrode allows operation of the ion trap at points B and C. At point B, a narrow mass range of positive ions and a wide mass range of negative ions have stable trajectories in the ion trap, while at point C, only negative ions are stored in the ion trap. Operation of the ion trap at point ($a_z > 0.15$) prevents positive-negative ion recombination and allows for observation of negative ions.

The experiments were performed with a Finnigan MAT Ion Trap Mass Spectrometer (ITMS™) equipped with mass-selective storage and a variable dynode power supply. The following operating conditions were found to be optimum: reactant gas pressures between 2 and 4×10^{-5} torr; ionization times between 40 and 100 ms; negative chemical ionization reaction times between 20 and 300 ms; multiplier setting between 400 to 500 mV greater than 10^5 gain; and the DC voltage was on during isolation of negative ions in the ion trap.

The reactant ions from water and carbon tetrachloride (produced by dissociative electron capture) and sulfur hexafluoride (produced by electron capture) were isolated with a negative DC voltage pulse applied to the ring electrode. Undesired reactant ions were ejected with a supplemental RF voltage applied across the end cap electrodes. The isolation of OH^- ion from water is shown in Figure 2. The Cl^- and SF_6^- ions did not produce negative sample ions with the compounds examined, while the OH^- ion reacted by proton abstraction with most of the compounds examined. The OH^- NCI mass spectra of nearly all of the compounds examined are characterized by an $[\text{M-H}]^-$ ion and little or no fragmentation (Figure 3).

The most important parameter for successful negative ion formation and storage in the ion trap is the applied DC voltage. This voltage must be selected such that all positive ions are ejected from the ion trap (i.e., an ' a_z ' parameter greater than 0.15). Dissociative electron capture occurs in the ion trap for a variety of reactant gases, including ammonia, water, carbon tetrachloride, and ammonia; while electron capture occurs only for compounds with extremely high electron affinities (e.g., SF_6). The OH^- NCI mass spectra of most compounds produced a mass spectrum characterized by an abundant $[\text{M-H}]^-$ ion and little or no fragmentation. This information could be particularly useful for determining molecular weights of unknown compounds.

CALIBRATION AND ACCURATE MASS MEASUREMENT WITH GC-FTMS
USING AN EXTERNAL ION SOURCE

P. Grossmann, H.P. Kellerhals
Spectrospin AG, Industriest. 26, 8117 Fällanden, Switzerland

Introduction

The combination of Gas Chromatography with Mass Spectrometry (GCMS) is one of the powerful methods for organic quantitative analysis. In the last few years, the combination of GC with Fourier Transform Mass Spectrometry was several times described and shown to be very successful for obtaining high resolution GC-FTMS spectra. High resolution mass spectra are an important basis for elemental composition determinations. But the determining factor in elemental composition assignments is not the high resolution but the mass accuracy, which can be obtained. Controlling the experimental parameters and calibration procedures are therefore the important factors to get accurate masses.

In this work we describe some critical parameters which influence the mass accuracy in high resolution GC-FTMS. Propositions for attaining the best mass accuracy will be drawn from the experimental data.

Experimental

A GC for capillary gas chromatography with on-column injector (HP-5790A from Hewlett Packard) was coupled to the external differentially pumped ion source of a FTMS equipped with a 4.7 Tesla superconducting magnet (CMS 47 X from Spectrospin). The GC-FTMS interface consisted of a deactivated fused silica capillary, heated to about 200 °C and inserted directly into the outlet of the GC column (25m x 0.35 mm i.d., HP-1). Helium was used as a carrier gas. The pressure in the ion source was about 4×10^{-9} mbar. Perfluorotributylamin was used as a calibration gas.

Results

In a first attempt, the mass accuracies were measured without ejecting all the ions outside the interesting high resolution mass window out of the ICR-cell (prior to the exitation pulse). This procedure showed the following results:

- Calibrating the FTMS at different GC-elution temperatures has no effect on the mass accuracy.
- The resolutions (of the mass spectra) are dependent on peak intensities: The more intense the peak, the higher the resolution.
- Measuring the accurate masses at different times during sample elution shows that the mass varies systematically with peak intensity.

The results, obtained by measuring the accurate masses with ejection of all ions out of the ICR cell (except the one which is measured are summarized in table I.

Table I

Mass Accuracy Measurements in GC-FTMS Mode with Ion Ejection

Compound	Measurend Formula	Ion Nom.Mass	Mass Accuracy
Decane (Fragment)	C ₅ H ₁₁	71	- 0.44 ppm
Decane (M) ⁺	C ₁₀ H ₂₂	142	- 2.63 ppm
2,6-Dimethyl phenol	C ₈ H ₁₀ O ₁	122	- 0.98 ppm
2,6 Dimethyl aniline	C ₈ H ₁₁ N ₁	121	- 0.62 ppm
Tridecane	C ₁₃ H ₂₈	184	- 3.52 ppm

Conclusion

The presented results indicate that highly accurate and reliable mass measurements are possible with the GC-FTMS combination, if one pays attention to the following precautions:

- The carrier gas must flow into the ion source during the calibration procedure.
- Working without ion ejection of all ions outside the interesting mass window results in short cycle times and high peak intensities. But the measured masses are dependent on the peak intensities. Mass accuracy is therefore only medium.
- Working with ion ejection needs longer cycle times but highly accurate mass measurements can be done.

RESONANT MULTIPHOTON IONIZATION ON A FOURIER TRANSFORM MASS
SPECTROMETER WITH EXTERNAL ION SOURCE

M. Loepfe, P. Grossmann, M. Allemann, H.P. Kellerhals
Spectrospin AG, Industriest. 26, 8117 Fällanden, Switzerland

Introduction

In the past several years, lasers have been used in mass spectrometry mainly in two ways:

Laser desorption (LD) and Multiphoton Ionization (MUPI). LD involves the interaction of a laser beam with the sample substrate in the solid phase. Ions are therefore generated by direct interaction of the laser beam with the solid sample on the target. The multiphoton technique involves the interaction of laser photons with individual molecules, atoms or ions in the gas phase (solid samples have therefore first to be desorbed by an additional laser). The technique includes MUPI of both types, the resonance enhanced (REMPI) and non-resonance enhanced variety, the resonance ionization mass spectrometry (RIMS).

It has recently been demonstrated that REMPI exhibits very attractive features: Soft ionization for polar and/or thermally labile compounds, tuneable fragmentation controlled by the laser power and selective ionization of one species in a mixture by appropriate selection of the laser wavelength.

In this work we present the combination of REMPI with Fourier Transform Mass Spectrometry (FTMS). The experimental setup is described and measurements are presented to evaluate the performances.

Experimental

The FTMS used for this work is a Spectrospin CMS 47 X with external, differentially pumped ion source, equipped with a 4.7 Tesla superconducting magnet.

Liquid samples were introduced through the gas inlet, solid samples with the DIP or deposited on the target for LASER-desorption. Solid samples were evaporated by heating (DIP) or by laser evaporation, using a Nd-YAG laser. (wavelength 1064 nm, pulse length about 6 - 9 nsec, pulse energy was varied between 100 and 150 mJ). Ionization of the desorbed neutrals by the REMPI technique was done with a frequency doubled Eximer pumped dye laser: Eximer laser from Lambda Physik, type LPX 110 (308nm, 150 mJ). Dye-laser from Lambda Physik, type FL 3001, frequency doubled (245 - 275 nm, used laser energy about 0.04 mJ).

Results

The instrumental setup was first tested by measuring benzene. Scanning the wavelength and measuring the molecular ion and its $^{13}\text{C}_1$ isotope (m/z 78 and 79) showed that the two peaks were separated. In the broad band mode, the 70 eV EI-FTMS spectrum exhibits the well known fragmentation whereas in the REMPI spectrum only the molecular ion and no fragmentation was observed. The molecular ion could be measured with a resolution FWHH of $1'300'000$.

Coronene was introduced with the DIP and evaporated by heating or on the laser probe tip and desorbed with an additional Nd-YAG laser. Both REMPI broad band FTMS spectra showed only the molecular ion (m/z 300) and no fragmentation. By using the desorption laser (at 1064nm) and the ionization laser at 252.5 nm, the molecular ion was measured with a resolution (FWHH) of 160'000.

The REMPI FTMS spectrum of the dye Rhodamine B exhibits the quasi molecular ion ($M - Cl$)⁺ and the sodium and potassium attached ion ($M-HCl + Na$ and $M - HCl + K$). But compared to the normal LASER-desorption spectrum, less fragmentation and no signals from the target material are observed. Desorbing the Rhodamine B with a Nd-YAG laser (1064 nm, low laser energy) and ionizing the desorbed neutrals with 245 nm, one could attain a resolution (FWHH) of 115'000 of the m/z 443 ($M - Cl$)⁺ ion (see Figure).

Conclusion

The presented results demonstrate that the attractive features of REMPI (very soft and selective ionization with the possibility of tuning the fragmentation) can be combined with the salient features of FTMS: The capability for high resolution is fully preserved. Together with the inherent mass accuracy of FTMS, molecular weight determinations and elemental composition assignments of molecular ions and fragments are very much simplified.

USE OF HIGH VOLTAGE PULSES TO STUDY LASER DESORBED IONS IN A DUAL CELL FT/ICR

J.P.Honovich and S.P.Markey, National Institute of Mental Health, Bethesda, MD 20892

In the dual cell ions produced by electron impact are transferred by temporarily grounding the conductance limit plate which separates the two cells. However in laser desorption experiments, ion transfer is often observed even when the full trapping voltages are maintained on all plates. Since ions that are "unintentionally" transferred in this way are quite often structurally important organic ions, we have decided to make a time resolved study of this process by applying short high voltage pulses to components of the icr cell. Pure metal samples were used because they yielded more reproducible spectra and exhibited this same ion transfer phenomenon.

The top portion of Scheme 1 shows the relevant features of a Nicolet FTMS-2000 dual cell for laser desorption. The pure metal sheets (Mo, Ti or Nb) were cleaned with methanol and placed ~3mm from the source cell and irradiated by a focused ir pulsed laser (Tachisto model 215G, ~10.6 μm). The laser was fired repetitively at the same spot until the signal was reproducible (within ~20%). Ions enter the source cell through a 4mm hole in the trap plate, transit a 4.7625 cm source cell and enter the analyzer cell through a 2 mm hole in the conductance limit. Ions are then detected following a 1 sec trapping period. The high voltage pulses (up to -340V, rise time ~.5 μs) were generated by a homebuilt TTL/MOSFET circuit. The high voltage pulse is either applied as a negative pulse floating on the trapping voltage or as a positive voltage up to the trapping voltage from a -340 V (Scheme 1).

Initially, a high voltage pulse was applied to the probe tip to establish a true "time zero" of the experiment relative to the laser trigger pulse. Figure 1 shows the complementary behavior of the negative quench and the positive "window" pulse. It is noted that the effect of the pulse is delayed ~6 μs relative to the laser trigger from the computer, and that since the pulses are only ~1.5 μs wide, ions are produced and/or escape from the probe tip in a relatively short time window.

A negative quench pulse was applied to the analyzer trapping plate to investigate the time of ion arrival into the analyzer cell. Figure 2 shows that a 1.5 μs pulse has a dramatic effect ~9 μs after the laser trigger but diminishes after ~30 μs . Figure 3 shows an experiment with a 10 μs pulse conducted over a longer time period. After the initial sharp effect seen in Figure 2, there is gradual and increasing ability of the pulse to quench ions in the analyzer cell beginning at 200-300 μs .

Figure 1 can be interpreted as demonstrating a ~6 μs delay between the computer trigger and the laser discharge. The laser manufacturer acknowledges possible firing delays in the μs range. Figure 2 then implies that ions have transited from the probe tip to analyzer cell in ~3 μs , which requires that the Mo (92 daltons) ion energy be ~100 eV. It is difficult to justify the production and subsequent trapping of such energetic ions in the 2V trapping well. It is also difficult to reconcile the absence of a quenching effect in the 30 to 200 μs range.

The simplest explanation for these results is that ions which are observed to be unintentionally transferred are the result of creating a dense plasma by the laser ionization process. In the probe tip region, the ions are uninfluenced by the applied voltages for several microseconds. Likewise in the analyzer cell, initially a large number of ions are trapped and not influenced by the applied voltages for several hundred microseconds, perhaps until a number are lost or diffuse in the cell. This would be consistent with the observation that unintentional transfer usually occurs at higher laser powers. Since the geometry of the icr cell is rather open with large entry holes, the electric fields which move ions are probably relatively small even with the above applied voltages. This suggests a more careful design of the icr cell should be done to produce stronger electric fields near the probe tip to draw ions into the cell.

We would like to thank Dr. Peter Todd of Oak Ridge National Laboratory for the design and construction of the high voltage pulse circuitry and the National Research Council Fellowship Program for support of JPH.

SCHEME 1 10 US PULSE (-300V) ON ANALYSER TRAP

LASER DESORPTION WITHIN THE ION TRAP CAVITY: OPTIMIZATION AND APPLICATION

D.N. Heller, R.J. Cotter and O.M. Uy
The Johns Hopkins University, Baltimore, MD 21205

In previous work we demonstrated that a solids probe can be brought directly into the cavity of a Finnigan Ion Trap Detector (ITD) (1). A schematic diagram of this arrangement is shown in Figure 1. A non-conducting probe tip passes through a hole bored radially in the ring electrode. The probe tip sits flush with the inner wall of the ring electrode, where a CO_2 laser pulse is focussed onto it by a ZnSe lens.

This instrument was used to demonstrate the capabilities of laser desorption (LD) on the ITD. LD ions could be formed, trapped and analyzed within the ITD cavity. The ITD tuning remained the same as it was before the modifications were done, as long as the probe tip was in place. Pseudomolecular ions and fragmentation typical of CO_2 laser desorption were observed (Figure 2).

Lower mass ions did not need helium buffer gas to be trapped. For example, cluster ions K_2Cl_2^+ could be stored for 20 ms without helium, and resolution was found to increase over this long storage period. On the other hand helium was necessary to detect higher mass ions, as is the case with other ITD configurations. When using helium it was necessary to use short storage periods, 100 μs or less, because molecular ion intensity decreased over longer storage time.

The LD/ITD produced a sufficient number of ions to exceed the space charge limit, resulting in loss of resolution and mass assignment accuracy. This was controlled by minimizing the laser spot size and then adjusting the helium pressure for each sample. Unit resolution could then be obtained, with helium pressure typically 1×10^{-3} torr or higher.

Peak height was studied as a function of exclusion limit, which is the m/z value below which all ions have unstable orbits and are not trapped. In laser desorption MK^+ peak heights of sucrose and sucrose monocaprates were found to decrease dramatically as exclusion limit was raised above 40. This suggests that K^+ ions are stored before combining with desorbed neutrals, and that MK^+ complexes do not come off the probe already formed.

Because the electron filament assembly was left intact, laser-desorbed neutrals could be ionized by electron impact. This technique yields additional fragmentation due to the higher energy imparted to the molecule. Chemical ionization also took place when the LD/ITD was operated with the filament on, evidenced by appearance of MH^+ .

This work is part of our ongoing development of methods to rapidly identify marker lipids from bacteria. Molecular ions of the pigment serratamolide were observed when a lipid extract from the bacterium *Serratia marcescens* was placed on the probe. The LD/ITD was also used to produce molecular and fragment ions from lyso- (lacking one fatty acid) phosphatidylcholine, -phosphatidylethanolamine and -phosphatidylglycerol.

The three-dimensional quadrupole ion trap has recently become practical for mass spectrometry following the development of the mass selective instability mode of operation. Several features of ion trap make it attractive for combination with laser desorption: the "pulsed" nature of operation, the ability to do multiple stages of mass spectrometry, and the lack of pressure problems associated with the desorption. This paper describes the technique and results for laser desorption mass spectrometry (LDMS) experiments in the quadrupole ion trap.

The experiments were performed with the Finnigan MAT Ion Trap Mass Spectrometer (ITMSTM). The standard electrode structure was modified by drilling two 3.18 mm holes through the ring electrode, 180 degrees apart. These holes were aligned in the vacuum system such that a sample probe could be introduced into one them via the solids probe inlet. The laser beam impinged on the sample probe through an optical port and the other hole in the ring electrode. The sample was introduced on a probe constructed from a 1.25 cm diameter stainless steel rod fitted with a removable MacorTM tip. A Chromatix 1000 Nd:YAG laser was used; the 1064 nm wavelength output with a typical energy per pulse of 1.5 mJ was employed for all experiments.

The experimental scan functions were developed and data acquired using standard Finnigan software (ITMS Rev. B). A typical scan function for an LDMS experiment is shown in Figure 1. A variable delay trigger pulse from the ion trap control electronics, set via software, was amplified and used to trigger the laser. The duration of this delay was varied, depending on the length of the total scan function, to adjust the repetition rate of the laser output to about 10 Hz.

A typical ITMS laser desorption mass spectrum for trimethylphenylammonium chloride is shown in Figure 2. The intact cation is observed at m/z 136 with fragments at m/z 120 and 121. No higher mass cluster ions were observed for this compound, nor have they been seen for other compounds which have been examined. The ion trap has been demonstrated to be a very efficient instrument for performing MS/MS experiments in combination with conventional EI and CI ionization methods. This function is obtained by adding an appropriate amplitude dc voltage to the ring electrode, for parent ion isolation, followed by a "tickle voltage" to the end cap electrodes at the secular frequency of the parent ion. This technique is also possible for laser desorption ionization. The MS/MS spectrum in Figure 3 was obtained by mass selecting the laser desorbed, intact cation of trimethylphenylammonium chloride as the parent ion (m/z 136), then turning on the tickle voltage to kinetically excite the parent ion for CID.

Experiments were performed to determine the effect of ion trap operating parameters for rf trapping level (low-mass cutoff) and bath gas pressure during laser desorption. A plot of the low-mass cutoff versus ion intensity is shown in Figure 4; the trapping efficiency for laser-desorbed ions rises rapidly from the onset at an rf level corresponding to about 11 daltons, then quickly begins to level off prior to an rf level corresponding to about 20 daltons.

Research sponsored by the U. S. Department of Energy, Office of Basic Energy Sciences, under Contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc.

The ion trap is typically operated with a He bath gas pressure of about one millitorr. The results of experiments to investigate the effect of bath gas pressure on laser desorption mass spectra in the ion trap are shown in Figure 5. The decrease in signal from run to run is due to consumption of sample during the course of the experiment. This data suggests that the bath gas pressure is important to the trapping efficiency in LDMS; without damping collisions to trap the desorbed ions in the potential well they would continue through the trap and be lost.

AMMONIUM HYDROXIDE CHEMICAL IONIZATION MASS SPECTROMETRY

Robert B. Cody
Nicolet Analytical Instruments
6416 Schroeder Rd., Madison, Wisconsin 53711

Proton-transfer reactions are well-known in low-pressure chemical ionization mass spectrometry (LPCIMS) with ammonia reagent gas [1-3]. We have found that bimolecular ammonium attachment reactions can also occur for polar analytes [4]. Here we report a method for avoiding undesirable reactions [5] between ammonia and analyte ions. We also show that ammonium hydroxide is a convenient and inexpensive substitute for anhydrous ammonia as a reagent for LPCIMS.

Reactions can occur between ammonia and the ionized analyte [4,5] in ammonia chemical ionization. These reactions can cause a loss of sensitivity. A loss of selectivity can also occur because different reagent ions such as $[\text{NH}_3]^+$ and $[\text{NH}_4]^+$ may react with the analyte by different mechanisms. These problems can be eliminated by using a Fourier transform mass spectrometer with a dual trapped-ion cell to isolate the reagent ion from the reagent gas and from other reactive species. A schematic diagram of this experiment (which may be referred to as "isolated reagent ion chemical ionization") is shown in Figure 1. The reagent gas is introduced into one of the trapped ion cells (Cell 1) and the analyte is introduced into the other trapped-ion cell (Cell 2). Electron ionization produces ions from both the reagent gas and the analyte. The analyte ions are removed ("quenched") from Cell 2 while the ions in Cell 1 (primarily $[\text{NH}_3]^+$) react to produce $[\text{NH}_4]^+$. The $[\text{NH}_4]^+$ is then transferred to Cell 2 by grounding the common electrode (the "conductance limit") between the two cells. Ionization of the analyte occurs in Cell 2 by proton transfer from the transferred $[\text{NH}_4]^+$ or by ammonium attachment. Because the analyte is separated from the reagent gas, no undesirable reactions can occur between ammonia and the ionized analyte.

If ammonium hydroxide is used as the reagent gas, several reactive species such as $[\text{H}_2\text{O}]^+$, $[\text{H}_3\text{O}]^+$, $[\text{NH}_3]^+$, and $[\text{NH}_4]^+$ are present at short reaction times (a few ms). At longer reaction times (> 100 ms), the dominant reactive species is $[\text{NH}_4]^+$. Under typical LPCIMS conditions, ammonium hydroxide produces mass spectra that are virtually identical to those obtained with anhydrous ammonia.

Mass spectra obtained with "isolated reagent ion chemical ionization" can show striking differences from the chemical ionization mass spectra obtained with a single trapped-ion cell. This is illustrated in Figure 2 for ammonium hydroxide LPCIMS of phenetole. When the chemical ionization is carried out in a single trapped-ion cell (Figure 2a), the major analyte species is M^+ (m/z 122), formed by charge exchange from $[\text{NH}_3]^+$. If a dual trapped-ion cell are used ("isolated reagent ion chemical ionization", Figure 2b), the major analyte species are $[\text{M}+\text{H}]^+$ (m/z 123) and $[\text{M}+\text{NH}_4]^+$ (m/z 140), formed by reactions of $[\text{NH}_4]^+$.

ION TRAP TANDEM MASS SPECTROMETRY (MS/MS) FOR THE DETERMINATION OF EICOSANOIDS

John R. Simms and Robert J. Strife
The Procter and Gamble Company
Miami Valley Laboratories
P.O. Box 398707
Cincinnati, OH 45239-8707

Introduction -- Some arachidonic acid metabolites, generally called eicosanoids, have been implicated to play a role in the inflammatory response. New drug candidates for the anti-inflammatory category often exhibit inhibition of the cyclo-oxygenase (COX) and lipoxygenase (LOX) enzymes that are involved in the production of the mediators. Simple and sensitive assays are desirable for eicosanoids to evaluate COX/LOX inhibition. Validation of radioimmuno-assay data remains important.

Our original GC/MS/MS work was sensitivity limited by the low CAD efficiency of the sector B-E instrument (1). The role triple stage quadrupoles will play is still uncertain, particularly in regard to CAD efficiencies obtained for eicosanoids. The ion trap mass spectrometer (ITMS) gives 60-75% CAD efficiency consistently for these compounds. The ITMS has been demonstrated to obtain GC/MS data on 10-50 pg of various analytes. The objective of this work is to utilize the high CAD efficiency of the ITMS and the advantage of RF/DC parent ion isolation for the determination of eicosanoids, particularly, the inflammation mediators PGE₂ and LTB₄.

ITMS Modifications -- To ensure efficient transfer of these higher boiling eicosanoid derivatives we: a) installed a thermally-stable electron multiplier for operation of the ITMS at elevated temperatures (180°C) and b) improved the GC/ITMS interface, based on use of a short TSQ-70 transfer line. While the TSQ-70 transfer line is much more convenient to work with, the elevated temperature capability is the most critical factor for the transfer of these higher boiling derivatives.

Determination of PGE₂ -- Based on other work from our laboratory (2), the structurally simplest derivative and a chemical internal standard (CIS) are used in this study. The full scan mass spectrum of PGE₂ MeMOXTMS₂ derivative is shown in Figure 1. The mass spectrum of the CIS (16,16 dimethyl PGE₂) is dominated by m/z 295 (same ionic structure as the m/z 295 in the PGE₂ derivative spectrum), probably due to the formation of the more stable neutral fragment, a tertiary radical.

RF/DC isolation for MS/MS is employed as described in our previous work (3). This type of scan is crucial for the analysis of target compounds in complex matrices (4). It allows storage of one m/z value and ejects ions of both lower and higher masses out of the trap. In this case the parent ions isolated for MS/MS are m/z 225 and m/z 295 for PGE₂ and 16,16 dimethyl PGE₂ derivative, respectively.

Daughter ion spectra are obtainable on 100 pg. Figure 2 shows the spectrum from the GC/MS/MS analysis of the PGE₂ derivative (parent ion m/z 225). The major daughter ion is m/z 155 (-C₅H₁₀). This is a backbone specific fragmentation predicted to be highly selective for the analyte. One of the advantages of the ITMS is that all daughter ions are collected and therefore selectivity of the different types of transitions can be ascertained in a single run. The daughter ion spectra of the chemical internal standard (parent ion m/z 295) is shown in Figure 3. The major daughter ion is m/z 205 (-TMSOH), a derivative specific fragmentation. This transition is predicted to be less selective than the backbone specific fragmentation. The second largest daughter ion m/z 173 (-TMSOH, -CH₂OH) is a doubly derivative specific fragmentation and is predicted to be more selective than m/z 295⁺→205⁺.

Initial LTB₄ work -- The full scan mass spectrum of LTB₄ MeTMS₂ is similar to that obtained on other types of mass spectrometers. The most intense ion above m/z 200 is m/z 293. Qualitatively this seemed to be the best choice for the parent ion in the MS/MS experiment.

The daughter ion spectra of m/z 293 is shown in figure 4. The most intense daughter ion is m/z 203 (-TMSOH), a derivative specific fragmentation. The next most intense daughter ion is m/z 189, a rearrangement ion from loss of TMS-O-CH₃. This transition may be more selective than the loss of TMSOH due to unusual rearrangement involved to produce the specific loss of 104 u.

We are currently evaluating spiked urine and cell culture media using the above described GC/MS/MS techniques. We hope to determine the most selective detection scheme for both LTB₄ and PGE₂ in biological samples with minimal sample preparation.

Cincinnati, OH 45239-8707

INTRODUCTION -- The Ion Trap Mass Spectrometer is known for its ability to analyze very small quantities of material. For instance, it is well documented that full-scan GC/MS experiments can be performed at the 10-50 pg level for a number of analytes. Our work has been aimed at exploiting the capabilities of the ion trap using combined RF/DC voltage scan functions¹.

Our principle areas of interest are: 1) high sensitivity tandem mass spectrometry (MS/MS) assays of crude biological extracts²; the trap consistently gives 60-100% observed CAD efficiencies and RF/DC is necessary to eliminate matrix ions efficiently; 2) reactive collisions of CI reagent ions stored mass-selectively by using RF/DC³.

In this paper we report on quantitation of a drug [I] with a chemical or [¹³C],[¹⁸O] stable-isotope internal standard (CIS and SIS, [II] and [III], respectively). The structures are shown in Figure 1. This particular assay is run routinely on a triple-sector-quadrupole instrument⁴.

Mass Spectrometry -- The EI mass spectrum of [I] is uncomplicated (Figure 2). McLafferty cleavage produces the odd-electron enol ion (m/z 248). Alpha cleavage of the ketone could produce the even-electron ion at m/z 233. The ion at m/z 248 was subject to RF/DC isolation and MS/MS¹. It was dissociated with 100% efficiency to only m/z 233. Loss of the methyl radical had two sources -- the t-butyl group or the methyl-phenone form of the McLafferty product (supporting isotope data not shown). This reveals other paths to m/z 233 in the EI mass spectrum. A similar spectrum is obtained for [II] and in [III] the ions are shifted by 3 u. The SIS contained less than .1% of [I].

Quantitation -- Two calibration lines were established, one using the CIS and the other using the SIS. Sample introduction was by capillary GC (Figure 3) using a high split ratio (100:1). The calibration ran from 100 pg to 10 ng (7 points) of analyte, [I], with 5 ng internal standard going to the ion trap, in both cases. Linearity over the range and the relative standard deviation (RSD) at the 100 pg level of [I] were examined (Table 1).

The calibration solutions were first examined using a typical quadrupole mass spectrometer in the selected-ion-monitoring (SIM) mode (Table 1, A,B). The regression lines were then examined in three modes on the ITMS: 1) RF-only, full scan, with automatic gain control (AGC), 2) RF/DC mass-selective storage followed by detection (analogous to SIM) and finally 3) the RF/DC isolation followed by MS/MS and detection of daughter ions.

ITMS Results -- Regression lines obtained with the co-eluting SIS gave unacceptable results while the chemical internal standard worked well in all modes tested. (Table 1, C-G). Co-elution of the internal standard is undesirable in the present configuration of the ITMS.

AGC-RF only -- Because of the relatively high concentration of the co-eluting SIS, low ionization times are selected by AGC. Therefore, for several points the number of analyte ions created is small, causing poor ion statistics and scatter in the data (Table 1, C). On the other hand, the CIS [II] is separated from the analyte on the column and AGC imparts a favorable dynamic range (Table 1, D). Long ionization times are selected for small amounts of analyte. We are examining more narrowly bracketed applications of the SIS.

RF/DC -- In this case, to avoid the problem cited in AGC control, m/z 248 and m/z 251 must be created, isolated, and analyzed in an alternate fashion, using separate RF/DC scan functions. For instance, in the case of 100 pg of analyte (m/z 248), a 10 ms ionization pulse will produce far too many ions from the 5 ng of SIS (m/z 251). However, the RF/DC sequence will reject those ions before m/z 248 is analyzed, correcting any space charge condition.

The data scatter (Table 1, E) is computer hardware related. The scan functions are continuously accessed from the hard disk of the PC and this is a slow process. Only two scans per second are acquired resulting in poor definition of the capillary peak and poor averaging of the data. The CIS works well (Table 1, F). It uses the same scan function as the analyte (m/z 248). No alternating is required. Typically, four scans are averaged every 250 ms.

RF/DC MS/MS -- The result was a linear calibration line using the CIS. The RSD was less than 4% (Table 1, G). These compounds represent a most favorable case -- only one daughter ion is formed and with 100% efficiency. We are now proceeding to examine these same calibration lines from spiked plasma samples with on-column injection of 1 μ l volumes of crude extracts.

We believe the problem with the stable-isotope internal standard will be overcome by small changes in computer hardware. RF/DC isolation will still be necessary to accommodate high dilution ratios. Finally, in drug development programs it is likely that related chemical internal standards are more readily available. The GC/MS/MS results presented here are encouraging.

PHASE-SYNCHRONIZATION OF THE ION ENSEMBLE THROUGH OFF-RESONANCE EXCITATION IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE

Curtiss D. Hanson, Mauro E. Castro, David H. Russell
Texas A&M University, Department of Chemistry
College Station, Texas 77843

The FT-ICR signal is produced by accelerating an ion population into a cyclotroding packet which induces an image current in the receive plates of the ICR cell. The performance characteristics associated with FT-ICR (e.g., sensitivity, mass resolution, mass range, and Fellgett advantage) arise from the ability to produce a spatially defined ion packet from an initially random ion ensemble. Spatial definition of the ion packet is defined by a combination of the radial distribution (distribution of kinetic energy in the X-Y plane) and the radial dispersion (angular distribution). In most FT-ICR experiments (performed with electron impact ionization) the radial distribution of the initially formed ions is small and the ions have near-thermal kinetic energies. Consequently, the radial distribution of the ions does not adversely affect ion detection. It is important to note that some ICR experiments (e.g., experiments utilizing methods which involve momentum transfer, such as SIMS, collisional ionization, or ion injection from an external source) are not adequately described by models based on electron impact ionization of a static gas.

The principle factor in the production of a coherent ion packet is the ability to drive an ensemble of ions having initially random velocity vectors (e.g., random phase angles) into coherent motion (i.e., having a narrow angular distribution). We recently demonstrated that the final radial distribution of a population of ions is dependent upon how quickly the random ensemble is "driven" into coherent motion (*1*); thus, ion detection by FT-ICR is a direct result of the phase angle synchronization of the initially random ion population. Phase synchronization of ions trapped in an FT-ICR cell occurs through interaction with an applied electric field. Because no mechanism exists for moving ions out-of-phase with respect to the electric field, phase synchronization is *directional*. For example, ions which have the same relative phase angle will experience identical force vectors at any time during the oscillation of the electric field. As long as the forces acting on two ions are the same, the trajectories of the ions will be the same. Thus, two ions driven into phase coherent motion by an applied electric field, will be influenced by identical forces following phase synchronization. Because the two ions have similar trajectories, they continue to move as a phase coherent packet. Therefore, once an initially random ensemble of ions driven into phase coherent motion, it will remain coherent (in the absence of collisions or inhomogeneous fields).

The mechanism for both ion excitation and phase advancement is the application of a resonant oscillating electric field. An ion moving in-phase with the applied rf is continuously accelerated (acceleration is caused by the synchronous alignment of the ion's motion with the force vectors produced by the rf field) whereas an ion moving out-of-phase ($\neq 0$) with the applied rf field experiences a synchronous *misalignment* of the velocity and electric field force vectors. The misalignment of an out-of-phase ion with the applied rf electric field creates a net force perpendicular to the ion motion ($F_{\perp} = qE_{\perp} = qE \sin \gamma$). The frequency shift required to move an out-of-phase ion into synchronous alignment with the applied electric field is achieved by effect of $F_{\perp}$ on the ions angular frequency. The perpendicular component of the applied electric field causes a shift in the angular frequency of the ion (i.e., $\omega_{rf} \neq \omega_{ion}$) allowing phase advancement and synchronization of the ion ensemble to occur.

In a cubic FT-ICR cell, a high mass ion cannot interact with a resonant oscillating electric field as long a low mass ion because of the discrete (energy) boundaries of the cell. The impact of phase synchronization and phase advancement therefore increases with increasing mass and energy. High mass ions injected into the ICR cell (from an external ion source or from a surface bombarded by an energetic particle) with significant translational energies yield a poorly defined ion packet following excitation. The combined effects of both increasing the deviation of the different radii and relative center shifts results in an inability to produce coherent ion motion for high mass ions having

Figure 1. The plot contained in Figure 1 illustrates the decrease in the degree of coherence (defined by $(r_{ave} - r_{dev})/r_{ave}$) which is obtained by resonant acceleration as a function of mass.

initially significant (ca. 3 eV) kinetic energies and random phases. The plot contained in Figure 1 illustrates the decrease in the degree of coherence (defined by $(r_{\text{ave}} - r_{\text{dev}})/r_{\text{ave}}$) which is obtained by resonant acceleration as a function of mass. In this relationship, r_{ave} is the average radius achieved by the ion ensemble following excitation and r_{dev} is average deviation of the different ions about that radius. Such a deviation is therefore a function of both the center shift and radial deviation

In a typical broadband FT-ICR experiment, ion excitation is achieved by sweeping an rf oscillator over a range of frequencies corresponding to the mass range of interest. Individual ions experience a net gain of translational energy as their respective frequencies come into resonance. Although ions only receive a net gain in kinetic energy during resonant excitation, ions experience the electric field force during the entire excitation period. Because phase synchronization is directional, ions are driven into coherence through interaction with the electric field prior to resonant acceleration. Ions which interact with an electric field prior to a resonant excitation are phase synchronized prior to a net gain of translational energy. Contained in Figure 2 is a plot of the effect of sweep duration on the relative dimensions of the ion ensemble. The degree of coherence achieved for four ions ($\gamma=0, 90, 180, 270$ and 3 eV of kinetic energy) of m/z 500 is determined for different interaction times prior to resonant excitation. From this relationship, it is clear that longer interaction times with the rf electric field prior to resonant excitation results in a better defined ion packet for detection by FT-ICR. In order to understand, the processes of phase angle synchronization of the ion ensemble, the effect of ion interaction with a non-resonant rf electric field must be examined.

The effect of frequency swept phase synchronization on ion detection has been observed experimentally. Early Cs⁺ desorption experiments showed a dramatic loss of signal when the translationally hot ions were detected in a high resolution narrow band mode compared to a broad band detection scheme. That is, in the narrowband mode (either direct or heterodyne) off-resonant excitation does not occur. Similar observations have been made for tandem quadrupole/FT-ICR experiments. Although detection of high mass ions is possible by broadband frequency sweep excitation (chirp), the signal is greatly attenuated in the narrowband mode (i.e., near resonant excitation with reduced interaction time with the electric field). Observations such as these are difficult to quantitate, but are consistent with the problems (which we attribute to phase synchronization) presently limiting the high mass analytical utility of FT-ICR.

The process of phase synchronization on the dimensions of the ion packet following excitation is difficult to evaluate in a simple cubic ICR cell. Ions which are produced as a result of electron impact have kinetic energies corresponding to that of the neutrals prior to ionization. Thus, ions are driven into phase coherence quickly and accelerated as a well defined ion packet, thus the impact of phase synchronization is negligible. On the other hand, ions which are formed with appreciable kinetic energies are introduced into the cell with undefined velocities and spatial locations. Direct measurements of the spatial dimensions of the ion packet in a simple cubic cell is difficult due to the lack of an unambiguous diagnostic procedure for probing the effect of phase advancement and ion excitation. By utilizing energy selective partitioning in a two-section cell it is possible to evaluate the effects of ion kinetic energy and phase synchronization on the dimensions of the ion ensemble following ion excitation. Such studies of the dynamics of ion detection are further illustrated by computer simulations of ion motion. The objective of this paper is to discuss the process of phase advancement and evaluate the effects of off-resonant acceleration prior to resonant excitation on the formation of a coherent ion packet for detection by FT-ICR.

THE EFFECT OF MAGNETIC INHOMOGENEITIES ON ION PARTITIONING IN A TWO-SECTION FT-ICR CELL

E. L. Kerley, C. D. Hanson, M. E. Castro, and D. H. Russell

To achieve maximum performance in Fourier transform ion cyclotron resonance (FT-ICR), ion detection must occur in the absence of ion-neutral collisions. Because the duration of observation of the time domain ICR signal directly determines sensitivity and resolution, ICR detection is most effective at pressures of 10^{-8} torr or less. The pressure limitations on FT-ICR detection can be circumvented by separating sample introduction and mass analysis. Separation of these steps can be achieved either temporally (e.g. by the use of pulsed valves^{1,2}) or spatially (e.g. by the use of external ion sources^{3,4,5,6} and the two-section cell⁷). In each of these approaches, the desired result is coupling of a high pressure (10^{-7} torr or greater) experimental step (e.g., ionization, ion-molecule reaction, or collision-induced dissociation) with ion detection at low pressure (10^{-8} torr). Remote source techniques require that ions move from the source into the detection region; however, movement of ions from one region to another requires that the ions be accelerated toward the detection cell. That is, ions which have relatively low translational energy along the axis between source and cell (Z-axis) are accelerated. Thus, the process of Z-axis excitation changes the conditions under which ion detection is performed.

Here, we describe the effects of axial magnetic inhomogeneities on ion partitioning and subsequent trapping of the ions in a two-section cell FT-ICR. Axial inhomogeneities arise because of the weakly ferromagnetic or strongly paramagnetic properties of the materials used for construction of ICR cells. The effects of axial inhomogeneities on the FT-ICR signal have been studied previously and were found to have little effect on resolution or signal broadening.⁸ Factors influencing ion partitioning in two-section cells have also been considered (e.g. pressure or ion mass) but without considering the effects of magnetic inhomogeneities.^{9,10,11} Axial magnetic inhomogeneities localized in the conductance limit aperture of a two-section cell constructed of high magnetic susceptibility material cause significant redirection and spatial distribution of low energy ions entering the ion cell. Therefore, a semi-quantitative description of trapped ion distributions due to low-energy injection through an axially inhomogeneous magnetic region is useful for considering the design requirements for external ion source FT-ICR instruments. For example, some type of ion guide (either rf only quadrupoles or electrostatic lens elements) is required for external ion source instruments. The effect of a given means of injection on ion detection must be considered. Ions which are injected into the ion cell must have relatively low Z-axis kinetic energies. Thus, at some point along the ion path (source to ion cell) low energy ions must pass through a potentially inhomogeneous magnetic field resulting in ill-defined ion trapping conditions and reduced instrument performance.

Magnetic field topologies for two two-section cell materials were calculated by using the Poisson/Superfish codes.¹² The Poisson representation of the magnetic field was solved numerically by implementing a nonuniform triangular mesh.¹³ Input for the program consists of defining the parent magnetic field strength (H), the geometry of the two-section cell, and the magnetic permeability ($1+\chi_m$) of the cell material. Magnetic susceptibilities (χ_m) were measured by the de Guoy method. Calculations were performed on a VAX 11/780 computer at TAMU. Ion trajectories were calculated and displayed using the trajectory calculation program SIMION (V4.0)¹⁴ on a math co-processor equipped PC/AT type IBM compatible computer. SIMION allows placement of electrodes in a user defined array as well as allowing magnetic fields to be defined along any axis within the array. Magnetic fields were vectorially added by coordinate as estimated from the Poisson plots. The Poisson plot for 304 SS used as cell material at TAMU ($\chi_m=0.16$) is diagrammed in Figure 1.

Using SIMION, ions were placed in a two-section FT-ICR cell such that their cyclotron orbit guiding centers coincided with the Z-axis. The ions had 0.01 eV of translational energy in the X-Y plane and various energies directed along the positive Z-axis. Figure 2 shows a trajectory plot of ten ions ranging from 0.19 to 3.48 eV of Z-axis energy as they are allowed to undergo partitioning through the axial inhomogeneity defined above. It is

Figure 1. Poisson plot of two-section cell constructed of paramagnetic 304 SS bathed in a 3 tesla magnetic field.

apparent that the conductance limit aperture inhomogeneity dramatically affects ion partitioning trajectories. It is noteworthy that no deflection of the ion paths is observed for the same calculations performed on an oxygen free hard copper cell (not shown). Three basic trajectories (or combinations of these) are observed for the stainless steel cell; (i) the ion partitions but gains energy in the X-Y plane usually followed by collision with the conductance limit, (ii) the ion collides with the conductance limit during the first pass, or (iii) the ion undergoes reflection and subsequent collision with the conductance limit. In the first case, ions can normally be trapped in the second cell region by proper timing of the conductance limit grounding pulse. Guiding center shifts occur for all ions upon entering the axial inhomogeneity within the aperture. Projection of the data in Figure 2 onto the X-Y plane shows that the axial inhomogeneity induces significant complexity on ion partitioning trajectories at low translational energy. In addition, one observes that ions formed with little spatial distribution and equal energy in the cyclotron orbit (X-Y plane energy) are distributed spatially and can gain significant energy in the X-Y plane upon partitioning through the axial inhomogeneity. The mechanism for cyclotron orbit energy gain is deflection into the X-Y plane due to the X-Y component of the magnetic field in the conductance limit aperture.

Figure 2. Y-Z plane projection of the trajectories of ten m/z 100 ions with E_z varying from 0.19 to 3.48 eV as they partition through an axial inhomogeneity.

The effect of ion mass on partitioning through an axial magnetic inhomogeneity was considered in a second study. Ions ranging from m/z 100 to 1000 were placed in the cell with 0.01 eV in the X-Y plane and 0.758 eV along the positive Z-axis. Similar results to the energy study were obtained.

Two conclusions emerge for the partitioning of ions in a two-section FT-ICR cell with an axial magnetic inhomogeneity in the region of the conductance limit aperture. First, ion deflection into the X-Y plane (measured as the X-Y plane projection of the ion's trajectory in the inhomogeneous region or the guiding center shift) decreases with increasing ion momentum. Second, the energy gain in the cyclotron coordinate during ion partitioning roughly increases with increasing momentum and is highly path sensitive. Whether energy is varied with a set m/z ratio or m/z was varied for a given injection energy, it is apparent that significant energy gain and ion deflection results for low-momentum ion injection through a magnetically inhomogeneous region. The resulting trapped ion packet has poor spatial and significant energetic distributions.

MEASUREMENTS OF KINETIC ENERGIES OF ION MOLECULE REACTION PRODUCT IONS
BY FOURIER TRANSFORM ION CYCLOTRON RESONANCE

M.E. Castro, E.L. Kerley, C.D. Hanson, D.H. Russell

Department of Chemistry, Texas A & M University, College Station, Texas 77843.

Fourier-transform ion cyclotron resonance (FT-ICR) is a versatile method for studying ion molecule reactions; however it is difficult to use FT-ICR to study dynamics of chemical reactions. For example, infrared chemiluminescence and laser induced fluorescence for determination of product ions internal energies would be extremely difficult by ICR. In addition, determination of product ion kinetic energies by ICR methods is also quite difficult. Such experiments have associated with them large errors due to undefined ion conditions (*i.e.*, ion translational energy and spatial location in the ICR cell). The inability to accurately measure either the reactant or product kinetic energies limits the utility of the instrument for chemical dynamics.

Recently, we have demonstrated that both ion location and translational energy can be mapped in a two section cell.¹ Because the radius of the cyclotron orbit depends on kinetic energy, partitioning can be used to measure radial kinetic energies. Furthermore, ion manipulation by a phase-specific excite-deexcite sequence results in defined ion location along the Z-axis.² By using the conductance limit to monitor both initial and final ion conditions, a two-section cell experiment can be designed to measure ion kinetic energies.

Kinetic energy release studies (KERD) require a uniform excitation field. The electric field lines produced in a cubic FT-ICR cell are perturbed by the detection plates which are held at a ground potential during excitation. Figure 1A contains a plot of the equipotential lines in a cell utilizing flat receive plates. It can be seen from the figure that the excitation field lines for a cubic cell contain significant radial inhomogeneities. The inhomogeneities result in electric field vectors which are not uniformly applied in the Y direction. Ions influenced by electric field vectors having components in the X direction have correspondingly different perpendicular components of the electric field during ion excitation. The difference in the angles of the applied electric field vectors produces ions having initially different spatial locations to acquire different translational energies following excitation. The resulting kinetic energy distribution limits the accuracy of detailed studies of the kinetic energies of reaction product ions. To address this issue, we have developed cell designs which significantly improve the excitation profiles such that uniform excitation can be accomplished. By replacing the detection plates with rods, the perturbations caused by the grounded detection plates are reduced resulting in an improved excitation field in the X-Y plane. Shown in Figure 1B is a plot of the equipotential lines in a cell utilizing rod receivers. The perturbations arising from the interaction of the detection plates are removed resulting in an electric field that is uniformly applied in the Y direction. The improved field lines result in a smaller kinetic energy distribution of the ion ensemble.

Although the use of receive rods improves the excitation in the X-Y plane, the interaction of the trapping field along the Z-axis causes axial inhomogeneities in the Z-direction. The resulting Z-axis excitation results in

Figure 1. (A) Excitation field contours for the cubic ion cell with flat receive electrodes; (B) contours as in (A) for rod receive electrodes

non uniform excitation along that axis. To address this issue, two different cell designs have been evaluated. Shown in Figure 2 is the excitation field lines generated in a FT-ICR cell having hemispherical trap plates. It can be seen from the plot that the excitation is homogeneous throughout 80% of the cell dimensions. The ions existing at the extremes of the cell receive *no excitation* and therefore do not interact with the performed studies. The homogeneity of the excitation field can be further enhanced by incorporating electric field shimming rings. Shimming the rf excitation field was first demonstrated by Hipple and coworkers (*Phys. Rev.* 1951, 82, 697) with the introduction of the omegatron cell. The uniform excitation is achieved by linearly decreasing the magnitude of the voltages applied to the rings. This is accomplished by a voltage divider comprised of inductance-free resistors. Use of inductance-free resistors insures that there is no variation in the amplitude throughout the frequency range as well as eliminating any propagation delay across the voltage divider. By regulating the voltages applied to the rings, the field lines are redirected to produce a field which is homogeneous throughout ca. 95% of the dimensions of the ion cell. The increased homogeneity (X-Y plane) of the rf electric field enhances the uniform acceleration of the sample ions. Therefore, this type of cell design increases the ability to produce and maintain the coherent ion packet. Contained in Figure 3 is a comparison of the excitation profiles for a shimmed field corrected cell *vis-a-vis* a cubic FT-ICR cell. The excitation applied in the Y direction is dependent upon the X-Z position of the ion in the cubic trap. The amount of translational energy that an ion acquires in during a specific excitation period (dE/dT) is therefore inhomogeneous and results in a kinetic energy distribution. The excitation profile in a shimmed cell results in a small energy distribution and is therefore useful for the measurement of kinetic energies of reaction product ions.

A FIELD CORRECTED ION CELL FOR INCREASED PERFORMANCE IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE

Curtiss D. Hanson, Eric L. Kerley, Mauro E. Castro, and David H. Russell
Department of Chemistry, Texas A & M University
College Station, Texas 77843

The basis for mass analysis by FT-ICR is the motion of ions in a homogeneous magnetic field. Electric fields are required to modify ion motion (i.e., trapping and excitation fields). Application of inhomogeneous electric fields complicates the ion motion and leads to both loss of resolution and sensitivity. The signal is produced by observing the cyclotroding motion of a *coherent* ensemble of ions (i.e., an ion population which is both temporally and spatially coherent). Therefore, the performance characteristics associated with FT-ICR (e.g., sensitivity, mass resolution, mass range, and Fellgett advantage) arise from the ability to produce and maintain a coherent ion packet. An ion population having initially random velocities and phase angles must be driven into phase synchronous motion prior to detection.

Phase synchronization and production of the coherent ion packet requires a uniform excitation field. The electric field lines produced in a cubic FT-ICR cell are perturbed by the detection plates which are held at a ground potential during excitation. The inhomogeneities result in electric field vectors which are not uniformly applied in the Y direction. Ions influenced by electric field vectors having components in the X direction have correspondingly different perpendicular components of the electric field during ion excitation. The difference in the angles of the applied electric field vectors produces ions having initially different spatial locations and phase angles to be aligned with different temporal vectors following excitation. Such differences in the alignments of the ions following excitation corresponds to a inability to phase synchronize the ion population. The cubic ICR cell exhibits radially inhomogeneous fields which complicates both ion trapping and ion detection. Furthermore, radially inhomogeneous excitation field have been shown to cause acceleration of the ions in the Z-direction. Such coupling of the axial and radial motions of the ion population results in loss of signal and the inability to maintain a constant ion density.

We recently introduced a novel cell design which replaces the detection plates of a cubic ICR cell with rods. Utilization of receive rods significantly reduces the radial inhomogeneities in the X-Y plane created by the interaction of the rf electric field with large receive plates. Use of receive rods *vis-a-vis* receive plates results in no loss of signal sensitivity because the same number of field lines terminate on the rods as do on plate receive surfaces. The improvement of the excitation field coupled with a reduction of the capacitance of the receive surface results in an improved ability to detect ions at small radii.

Although the excitation field lines are significantly improved in the X-Y plane, interaction from the trapping plates perturbs the excitation field lines along the Z-axis. The homogeneity of the excitation field can be further enhanced by incorporating electric field shimming rings (see Figure 1). Shimming the rf excitation field was first demonstrated by Hipple and coworkers (*Phys. Rev.* 1951, 82, 697) with the introduction of the omegatron cell. The uniform excitation is achieved by linearly decreasing the magnitude of the voltages applied to the rings. This is accomplished by a voltage divider comprised of inductance-free resistors. Use of inductance-free resistors insures that there is no roll-off of the amplitude throughout the frequency range as well as eliminating any propagation delay across the voltage divider. By regulating the voltages applied to the rings, the field lines are redirected to produce a field which is homogeneous throughout ca. 95% of the dimensions of the ion cell. The increased homogeneity (X-Y plane) of the rf electric field enhances the uniform acceleration of the sample ions. Therefore, this type of cell design increases the ability to produce and maintain the coherent ion packet.

The fundamental principle of FT-ICR is the relationship between the cyclotron frequency and m/z ratio for a given ion population. It has been shown that the motion of ions in the crossed electric and magnetic

Figure 1. An FT-ICR cell is field corrected by shimming the applied electric fields. Shimming is accomplished by using a series of voltage divided rings.

Figure 2. A plot of frequency shifts observed in a cubic, elongated and shimmed cell.

field lines arising from the trapping field cause coupling of the electric and magnetic fields (creating both ω_e and ω_d). The complicated ion motion arising from the ExB field results in loss of signal sensitivity and frequency shifts in the observe orbital frequency. The addition of the shimming rings to the ICR cell also reshapes the trapping field such that ion detection occurs in a field free region. Elimination of the ExB field effects removes the effects of ω_e and ω_d and therefore the observed frequency is equal to the ions natural cyclotron frequency. Shown in Figure 2 is the effect of the electrostatic trapping field on the observed frequency of bromobenzene (m/z 156). Frequency measurements were acquired in a two section cell comprised of an elongated FT-ICR cell ($5 \times 5 \times 7$ cm) mounted colinearly with a cubic shimmed cell ($5 \times 5 \times 5$ cm). Using combination FT allowed direct comparison of the cells under the same conditions (e.g., sample pressure, ion density, trapping voltage, etc.). It can be seen from the plot that although the elongated cell induces a smaller frequency shift than predicted for a cubic FT-ICR cell (as predicted by McIver), frequency measurements are significantly improved in a shimmed cell. Furthermore, both detected signal and peak shape are significantly enhanced in the field-corrected cell. At high trapping voltages loss of signal definition and the coherent motion of ions leads to a decrease in the signal-to-noise ratio. The degradation of peak shapes as a function of the applied electrostatic field was first proposed by Gross and co-workers. Shown in Figure 4 A&B are the narrowband mass spectra of bromobenzene achieved at a trapping voltage of 10v. Distortions of the peak shapes were not observed in the field-corrected ICR cell.

By shimming the electric fields it is possible to make frequency measurements *solely* in the presence of the magnetic field. This process eliminates both the effect of inhomogeneous excitation fields and ExB trapping effects. The result of this instrumental modification of the FT-ICR cell results in significant improvements in both ion detection and frequency measurements.

Figure 3. A comparison of narrowband spectra of bromobenzene illustrates the difference in peak shapes and signal sensitivity obtained at high trap voltages for A) a field corrected cell and B) a cubic cell.

PULSED ION INJECTION WITH AN EXTERNAL SOURCE TIME-OF-FLIGHT FTMS

S.C. Beu, D. A. Laude, Jr., J. D. Hogan

Department of Chemistry, University of Texas, Austin Texas 78712

A tandem time-of-flight Fourier transform mass spectrometer (TOF/FTMS) has been constructed as a robust and versatile tandem mass spectrometer with unique capabilities for both fundamental studies of ion motion in the external source FTMS and for improved chemical analysis in realistic sampling environments. Initial experiments with the TOF-FTMS focused on development of high injection efficiency ion optics, TOF detection through the magnet, investigation of ion trapping methodologies, and procedures for front end mass selection. A diagram of the external source TOF/FTMS in its present configuration is shown in Figure 1. The system includes a 2T, 8 inch bore superconducting magnet, ultrahigh vacuum analyzer chamber, trapped ion cell and support assembly, differentially pumped pulsed electron ionization source with associated ion focusing lenses, and microchannel plate detector for TOF analysis. The field provided by this magnet is homogeneous to within two hundred parts per million over a three inch wide cubic region at the center of the magnet bore. The analyzer vacuum chamber has a total length of 1.5 meters to allow the source chamber to be mounted outside the fringing fields of the magnet. This ensures that the source electron beam is not adversely affected by the magnetic field. A conductance limit separates the ion source from the analyzer chamber and provides a pressure differential in excess of 10^3 . Electrostatic injection of ions from source to analyzer presently employs three appropriately spaced unipotential lenses to achieve near-unit injection efficiency. The first unipotential lens focuses ions out of the source and through a conductance limit aperture into the analyzer vacuum chamber. A second lens located adjacent to the analyzer side of the conductance limit focuses the ions down the length of the analyzer chamber and into a third lens located near the strong fringing field of the magnet. This third lens provides the critical focusing required to minimize ion interactions with the strong radial component of the fringing field and insure efficient injection of ions into the magnet. This series of electrostatic lenses focuses 80 to 90% of a 5uA ion beam out of the source so that it impinges on the rear trap plate of the trapped ion cell. Plots of kinetic energy distribution at the source and trap in Figure 2 are nearly identical, with the 10% reduction in longitudinal kinetic energy likely imparted to radial motion which is insufficient to reflect ions.

A fundamental requirement of the TOF/FTMS instrument as we have configured it is that acceptable TOF spectra be generated for an ion bundle which passes through the fringing field into the magnet, traverses the trapped ion cell with grounded trap plates, and then exits the magnetic field to strike a channeltron or microchannel plate detector situated outside the field. Potential disadvantages are that the ion beam will not make it through the magnet to the detector, or will generate mass spectra which are perturbed during flight by the magnetic field or electrostatic focusing. As Figure 3 demonstrates however, TOF spectra are obtained which exhibit no mass intensity discrimination and are within 5% of expected flight times based on simple TOF calculations. An additional advantage of this design is that the TOF spectrum provides an immediate indication of longitudinal kinetic energy loss or translation to radial energy. A current TOF mass resolution of about 20 will be improved in the new source operated at higher acceleration potentials.

Several ion trapping procedures have been examined in preliminary experiments including the continuous creation and injection of ions which enter the cell with trap plates grounded and are trapped when trap plate potentials above the kinetic energy of ions in the cell are established, and the pulsed introduction of ions from the source with subsequent mass selection and gated trapping. When used in conjunction with a decelerator tube positioned in front of the cell, ions injected with high efficiency at high velocities can be

trapped with small trapping voltages after deceleration. In our case, pulsed deceleration was found to easily increase sensitivity by a factor of 10 or more. A third trapping mechanism we have observed with the TOF-FTMS instrument is referred to as accumulated trapping. Even if the trap plate potentials are maintained so that a potential well exists continuously during the injection of ions with kinetic energy higher than the trapping voltages, ions are accumulated. This effect is unexpected because ions of kinetic energy greater than the trap potentials should not be retained in the cell. Because trapping potentials are maintained throughout the beam event, some longitudinal energy loss mechanism must decrease ion velocity in the well during the several microsecond flight time across the well. Possible mechanisms for this loss are: 1) ion-neutral or ion-ion collisions, 2) ion-surface collisions, and 3) translation of $V_{||}$ to $V_{\perp}$ due to electric or magnetic fields inhomogeneities in the cell. Estimates of collision rate discount ion-neutral and ion-ion interactions at the pressures and ion densities for these experiments, and our focus instead is on the latter mechanisms. Figure 4 contrasts accumulated trapping spectra of naphthalene at 8 and 18 eV accelerating potentials and suggests the possibility of a surface collision effect with increased fragmentation associated with increased internal energy deposition.

The ability to select ions in the first mass analyzer for subsequent dissociation or manipulation is essential in any tandem mass spectrometer. Hence considerable effort was devoted to developing precisely timed control of electrode potentials in the TOF tube. Although present time-of-flight mass resolution on our instrument is limited by current source design, the timing sequences are in place. This is demonstrated in Figure 3b as m/z 219 of PFTBA is selectively trapped in the cell while other ions traverse the cell and strike the TOF detector. A time-of-flight source with appropriate geometry and optics for improved mass resolution out of the source is currently being constructed.

ANALYTICAL APPLICATIONS OF LASER DESORPTION AND PHOTODISSOCIATION FOURIER TRANSFORM MASS SPECTROMETRY

Lydia M. Nuwaysir and Charles L. Wilkins
University of California, Riverside
Riverside, CA 92521-0403

Collaborative research efforts have led to the FTMS analysis of various samples synthesized in other laboratories. Frequently, laser desorption FTMS was able to provide analytical information where other methods had failed. For some samples FTMS provided additional data, previously unavailable, or results superior to other analytical methods.

LD/FTMS spectra of a series of methylmethacrylate/butylacrylate (MMA/BA) copolymers of different composition ratios display higher molecular weight distributions than those obtained by GPC using narrow molecular weight polystyrene standards as calibrants. As expected, as MMA to BA ratio decreases (from MMA/BA 90:10 to 70:30), the relative abundances of different composition oligomer ions shift to reflect the change in sample mix ratio.

The LD/FTMS spectrum of Zr-Pt complex was obtained to resolve whether or not the complex exists as the monomer, dimer, or a higher oligomer. The low volatility and solubility of the complex precluded characterization by thermal desorption and FAB. Abundant ions were observed which supported the proposed monomer empirical formula. Although no dimer or oligomer ions were observed, ions present at masses significantly greater than monomer ions provided evidence for the existence of some type of dimer structure or impurity. The high resolution spectrum of the monomer region is shown in Figure 1.

Figure 1: High Resolution LD/FTMS spectrum of $([\mu(\eta^5\text{-C}_5\text{H}_4)\text{P}(\text{C}_6\text{H}_5)_2]_2\text{ZrCl}(\text{CH}_3))\text{-Pt}(\text{CH}_3)_2$

The electrode bound polymer film formed by the reductive polymerization of an iron complex containing 4-methyl-4'-vinyl-2,2'-bipyridine (vbpy) was analyzed by LD/FTMS. Due to the steric bulk of the complex, many believed that only end-to-end dimerization of the vinyl groups could occur. Previous mass spectral analysis by thermal desorption showed the presence of monomeric vbpy and the two and three unit vbpy oligomers. In comparison the LD/FTMS spectrum clearly displays evidence for the formation of normal "polyvinyl-type" chain oligomers up to 14 vbpy units, with the most abundant oligomer in the envelope containing 7 vbpy units (Figure 2).

Figure 2: LD/FTMS spectrum of Poly-Methylvinylbipyridine.

LD/FTMS confirmed the synthesis of a bromine substituted tetraphenyl porphyrin iron chloride sample. The spectrum contained molecular ions and fragment ions resulting from loss of Cl and sequential loss of Br and HBr from the porphyrin. UV photodissociation of isolated $[M-Cl]^+$ ions resulted in the production of fragment ions, similar to those produced by laser desorption however the higher energetics of the photodissociation process led to an increase in the abundance of lower mass fragment ions relative to higher mass fragment ions.

CONFIRMATION OF NEWLY IDENTIFIED AMPICILLIN METABOLITES

SOMCHAI SUWANRUMPHA AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, HOUSTON, TEXAS 77024

Ampicillin, D(-)-(α)-aminobenzylpenicillin, is a β -lactam antibiotic. Penicilloic acid and piperazine-2,5-dione have been reported as ampicillin metabolites in human urine samples. The structures of ampicillin and its known metabolites are shown in Fig. 1. The ion chromatogram was obtained from a urine sample after orally administering 500 mG of ampicillin using thermospray LC/MS. Selected ion chromatograms of this urine sample show 5 separated chromatographic peaks for ions that are characteristic of ampicillin and its known metabolites (Fig. 2). The components under chromatographic peaks 1, 2, and 5 are identified as penicilloic acid, ampicillin, and piperazine-2,5-dione by comparing the retention times and mass spectra of pure compounds. The mass spectra of chromatographic peaks 3 and 4 display ions that are characteristic of the fragment ions of ampicillin and its known metabolites. However, the identities of these compounds can not be determined from these mass spectra.

Fig. 1: Structures of ampicillin and its known metabolites

Fig. 2: The mass chromatograms of the urine sample after orally administering 500 mG of ampicillin.

The urine sample was collected as the solvent eluted from the analytical column corresponding to cut that contained peaks 3 and 4. The samples were evaporated to dryness under vacuum at room temperature. The FAB mass spectrum of this urine extract displays many ions that represent the unknown compounds and other unknown endogenous components in the urine. Several fragment ion spectra were obtained for the selected ion to determine the molecular ion of the unknown ampicillin metabolites. Only the ions at m/z 324 and m/z 350 exhibited fragment ion characteristic of a β -lactam ring (the thiazolidine ring at m/z 160). The FAB MS/MS spectrum of the ion at m/z 350 shows fragment ions corresponding to a combination of ampicillin and ampicillin piperazine-2,5-dione.

The FAB MS/MS spectrum of ion at m/z 324 shows fragment ions of the thiazolidine ring and the benzylamine group at m/z 160 and m/z 106, respectively (Fig. 3). Scheme 1 shows the structure of the ion at m/z 324 as penicilloic acid. The structure was deduced using the assumption that these unknown metabolites should have a similar structure as ampicillin and must fragment to give rise to a thiazolidine ring and a benzylamine group.

Ampicillin penicilloic acid was synthesized and the product contains two major components which have the same retention time as components 3 and 4 using LC/MS under the same conditions. These two compounds were separated using a semi-preparative column. The FAB mass spectra of penicilloic acid 3 and penicilloic acid 4 show the protonated molecule at m/z 324 and proton bound dimer at m/z 647. The ion at m/z 336 was not observed when *m*-nitrobenzyl alcohol was used as a matrix. The FAB MS/MS spectra of ion at m/z 324 from penicilloic acid 3 and penicilloic acid 4 are similar to each other and also comparable to the FAB MS/MS spectrum in Fig. 3. The FAB mass spectrum of penicilloic acid 3 and FAB MS/MS spectrum of protonated penicilloic acid 3 (at m/z 324) are shown in Figures 4 and 5. Components 3 and 4 in urine samples were identified as stereoisomers of penicilloic acid. The structure of these two compounds are (3S,5R) penicilloic acid and its epimer, (3S,5S) penicilloic acid.

The epimerization of penicilloic acids are demonstrated by incubation of an aqueous solution containing penicilloic acid 3. An increase in the amount of penicilloic acid 4 and a decrease in the amount of penicilloic acid 3 was observed using HPLC with UV detection. The conversion of penicilloic acid 3 to penicilloic acid 4 was observed by incubation of an aqueous solution of penicilloic acid 4.

Fig. 3: FAB MS/MS spectrum of ion at m/z 324 from urine extract containing peaks 3 and 4.

Scheme 1: Postulated structure of fragment ions in Fig. 3.

Fig. 4: FAB mass spectrum of penilloic acid 3.

Fig. 5: FAB MS/MS spectrum of protonated penilloic acid 3.

Penilloic acid can arise from the decarboxylation of penicilloic acid. It is known to be a degradation product of penicillins. Experiments were performed to determine whether the penilloic acid in urine sample is a metabolite of ampicillin or a degradation product of ampicillin and its known metabolites. A urine sample was collected from a human subject 2 hours after orally administering ampicillin. The urine sample was immediately frozen at -78°C and analyzed the same day using LC/MS. The selected ion chromatograms of this urine sample display chromatographic peaks 1, 2, and 3 which are identified as penicilloic acid, ampicillin, and penilloic acid, respectively. The blank urine sample spiked with ampicillin was incubated at 37°C for 2 hours. Then, the urine sample was treated and analyzed using the same procedure as previously described. No detectable amount of penicilloic acid was observed. The similar results were observed in a blank urine sample spiked with penicilloic acid or piperazine-2,5-dione. However, penilloic acid 3 was detected in a urine sample that was spiked with ampicillin and was kept at -5°C for 72 hours.

CONCLUSION: Mass spectrometry was used in the structural elucidation and identification of ampicillin and two known metabolites, ampicillin penicilloic acid and ampicillin piperazine-2,5-dione. Two additional unreported ampicillin metabolites were detected in urine samples using thermospray LC/MS. These ampicillin metabolites were identified as (3S,5R) penilloic acid and its epimer, (3S,5S) penilloic acid using MS/MS. The identifications were based on the fact that metabolites products usually contain a substructure of the parent drug.

ACKNOWLEDGEMENTS: We thank Dr. Marvin L. Vestal and Dr. Donald A. Flory for their valuable assistance and the Texas Advanced Research Program for partial support of this work.

NOVEL PATHWAYS FOR THE OXIDATIVE DEGRADATION OF ALIPHATIC CHAINS IN CANNABINOID METABOLISM.

D.J. Harvey,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.

Introduction

Many cannabinoids, such as delta-9-tetrahydrocannabinol (THC, I), the active constituent of marihuana, are metabolized by beta-oxidation of the pentyl chain to acids with C₃ and C₁ chains (Scheme 1). However, metabolites also occur with C₄ and C₂ chains; these are formed by undescribed mechanisms which appear not to involve intermediates that are common to the pathways leading to beta-oxidation. The mechanisms leading to formation of these metabolites are investigated in this paper.

Scheme 1. Metabolism of delta-9-THC by two stages of beta-oxidation.

Methods

Mice (Charles River, CD-1, male) were treated (IP) with one of the primary THC metabolites: 2'-, 3'-, 4'- or 5'-hydroxy-delta-9-THC, killed after 1 hr, and the hepatic metabolites were extracted. After concentration by chromatography on Sephadex LH-20, they were converted into TMS, Me/TMS and [²H₉]TMS derivatives and examined by GC/MS using a VG 70/70F mass spectrometer (70 eV) interfaced to a Varian 2440 gas chromatograph containing a 25 m x 0.2 mm OV-1 fused-silica capillary column.

Results

Metabolites were identified by mass spectral comparison with published data. 5'-Hydroxy-delta-9-THC, as reported previously (1), gave hydroxylated derivatives of the beta-oxidation product, 4',5'-bis,nor-delta-9-THC-3'-oic acid as the major metabolites (Scheme 2); no metabolites containing C₄ or C₂ side-chains were formed. 4'- (Fig. 1) and 3'-hydroxy-delta-9-THC (Fig. 2), unexpectedly, also gave these products by undescribed biochemical pathways. 4'-Hydroxy-delta-9-THC additionally gave the acids containing four carbon atoms in the side-chain (Scheme 2), thus identifying their source. 3'-Hydroxy-delta-9-THC gave metabolites with a hydroxy-ethyl side-chain (two carbon chain, Scheme 2), again by an undescribed mechanism; compounds of this type are known to be major metabolites of cannabidiol in humans but their mechanism of formation has not been determined. 2'-Hydroxy-delta-9-THC was not metabolized by oxidative mechanisms.

These results show that the 3'-oic acids are not only products of classical beta-oxidation, but can be formed by other mechanisms. These may, however involve a common delta-3' intermediate by elimination of water from either 3'- or 4'-hydroxy-5'-oic acid. The mechanism involving loss of three carbon atoms from 3'-hydroxy-delta-9-THC, on the other hand, is not related as the product is an alcohol rather than an acid.

Fig. 1. Limited ion chromatogram (m/z 300-700) of metabolites of 4'-OH-delta-9-THC. Major metabolites: peak 4, 6-OH,3'-oic acid; 5, 7-OH-3'-oic acid; 7, 6-OH,4'-oic acid; 14, 4'-OH,11-oic acid.

Fig. 2. Limited ion chromatogram (m/z 300-700) of metabolites of 3'-OH-delta-9-THC. Major metabolites: peak 8, 2',7-di-OH-3',4',5'-tris,nor-THC; 16, 3',6-di-OH-THC; 17, 11-OH-THC,3'-oic acid; 19, 3',7-di-OH-THC.

A METHOD FOR THE IDENTIFICATION OF TETRAHYDROCANNABINOL METABOLITES BY GC/MS
USING CATALYTIC HYDROGENATION.

D.J. Harvey and N.K. Brown,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.

Introduction

Tetrahydrocannabinols (THC), of which the delta-9-isomer (I) is the major psychoactive constituent of marihuana, are extensively metabolized by hydroxylation. The TMS derivatives of these compounds frequently give similar and undiagnostic mass spectra and the quantities produced in the usually complex mixtures are frequently too low to permit isolation. This paper describes a method to facilitate identification by converting the metabolites into hydroxy-hexahydrocannabinols (hydroxy-HHCs) by catalytic hydrogenation. Most of the reference compounds for these products can readily be synthesised from available isomeric hydroxy-THCs.

I, delta-9-THC

Methods

Reference samples of the following compounds were available: 1'-, 2'-, 3'-, 4'-, 5'-, 8-alpha-, 8-beta- and 11-hydroxy-delta-9-THC, and 7-alpha-, 7-beta-, 10-alpha-, 10-beta- and 11-hydroxy-delta-8-THC. 12-Hydroxy-delta-9-THC was synthesized. These compounds were hydrogenated for 5 min. over a rhodium/alumina catalyst to the 9-(R)- and 9-(S)- isomers of the appropriately hydroxylated HHC. 6a-, 9-alpha- and 9-beta-hydroxy-HHC were synthesized from THC epoxides by reduction with LiAlH_4 . GC/MS data of the TMS derivatives of these compounds were recorded with a VG 70/70F mass spectrometer (70 eV) interfaced to a Varian 2440 gas chromatograph containing a 25 m x 0.2 mm OV-1 fused-silica capillary column. Metabolism of delta-11-THC was performed with mouse liver microsomes, metabolites were hydrogenated as above except that the reaction was allowed to proceed overnight.

Results

Scheme 1 shows the structures of the available hydroxy-THCs and hydroxy-HHCs and their conversion by catalytic hydrogenation to hydroxy-HHCs. All reactions proceeded quantitatively and the TMS derivatives of the hydroxy-HHCs gave informative spectra with, in most cases, a very abundant and unique diagnostic ion. These are listed in Table 1. Two compounds, isomeric about C-9 were produced, but, except for the compounds hydroxylated at C-9 or C-11, the spectra of these isomers were almost identical. All compounds except the TMS derivatives of 10-alpha- and 10-beta-hydroxy-HHC gave unique spectra. In many cases they also gave unique base peaks, but for those compounds that did not, eg, 8-beta- and 9-beta-hydroxy-HHC, other major peaks in the spectrum were diagnostic as listed in Table 1. In general, HHCs containing an equatorial hydroxy group in the terpene ring, eg, 8-beta- and 9-beta-hydroxy-HHC, gave abundant molecular ions, whereas those compounds with an axial hydroxy-group tended to show a more favourable loss of TMSOH . HHCs hydroxylated at the 7- and 10-positions usually gave spectra with ions (eg m/z 143, 157) initiated by alpha-cleavage at the adjacent tertiary carbon atom. Diagnostic ions in the spectra of the side-chain hydroxylated HHCs were the same as those reported earlier for other cannabinoids (1).

This method for structural determination of hydroxy-THCs was evaluated for metabolites of delta-11-THC from rat liver microsomes where the same metabolites were found as reported earlier (2) with the major metabolite being 6-beta-hydroxy-delta-11-THC.

CANNABICHROMENE METABOLISM IN THE RABBIT: A NEW METHOD FOR METABOLITE IDENTIFICATION AND THE CHARACTERIZATION OF EIGHT NEW DIHYDROXY METABOLITES.

D.J. Harvey and N.K. Brown,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.

Introduction

Cannabichromene (CBC, I), although a relatively minor cannabinoid from *Cannabis sativa* L., the source of the drug marihuana, can be the second most abundant cannabinoid in certain strains of the plant grown in the USA. A major problem encountered in the identification of its metabolites by mass spectrometry is the dominance of the chromenyl ion (a,b, Scheme 1); this suppresses, often to zero, the abundance of structurally informative fragment ions. This problem has now been overcome by catalytic hydrogenation of the cyclic double-bond (concomitantly with the acyclic double-bond) to redirect the fragmentation to the site of metabolic attack.

Scheme 1. Formation of the chromenyl ion from CBC metabolites

Methods

CBC metabolites were extracted from rabbit hepatic microsomal preparations, concentrated by chromatography on Sephadex LH-20 and converted into TMS and [$^2\text{H}_9$]TMS derivatives both before and after hydrogenation over a rhodium/alumina catalyst. Metabolites were examined by GC/MS using a VG 70/70F mass spectrometer (70 eV) interfaced to a Varian 2440 gas chromatograph containing a 25 m x 0.2 mm OV-1 fused-silica capillary column.

Results

Fig. 1 shows a limited ion (m/z 300-700) profile of the metabolites of CBC from the rabbit. The mass spectrum of the TMS derivative of a representative metabolite, 3"-hydroxy-CBC, is shown in Fig. 2. The abundant chromenyl ion at m/z 391 clearly indicates that the metabolite is hydroxylated in the pentyl chain, but the major ion diagnostic of the position of hydroxy substitution, m/z 330, is not significantly larger than the background ions. Spectra of other hydroxy metabolites were even less diagnostic. After catalytic hydrogenation, the formation of the chromenyl ion was considerably suppressed and fragmentation was initiated by charge localisation on the derivatized hydroxy function, giving the mass spectrum shown in Fig. 3. The ion diagnostic of the position of hydroxylation (m/z 334) is now the base peak. Other metabolites behaved similarly allowing the structural assignments shown in the legend to Fig. 1 to be made. 12 Monohydroxy and 8 new dihydroxy metabolites, an epoxide and its derived dihydrodiol were identified.

Fig. 1. CBC metabolites from the rabbit. Major peaks are: 7, 3"-OH; 8, 4"-OH; 9, 6'-OH; 11, 5'-OH; 13, 5"-OH; 18, 3",5'-di-OH; 19, 4",5'-di-OH.

METABOLISM OF CANNABIDIOL BY THE DOG: IDENTIFICATION OF GLUCOSE CONJUGATES
AS THE MAJOR URINARY METABOLITES AT EARLY TIMES AFTER DRUG ADMINISTRATION.

D.J. Harvey and E. Samara,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.
and Faculty of Medicine, The Hebrew University, Jerusalem, Israel.

Introduction

Cannabidiol (CBD, I) is a major non-psychoactive cannabinoid from *Cannabis sativa*; it has clinically useful anticonvulsant properties. Its urinary metabolites are being studied in man, dog and rat. This paper describes the identification, by GC/MS, of unconjugated metabolites of which 37 were found, and a series of glucose conjugates which were excreted as the major metabolites at early times after drug administration. This is only the second report of such *O*-glucosides as drug metabolites in mammals.

Methods

Three dogs were treated (IV) with CBD and urine samples were collected at intervals for 25 hours. Metabolites were hydrolysed (beta-glucuronidase, type VII), extracted with ethyl acetate, concentrated by Sephadex LH-20 column chromatography, and converted into TMS, [²H₉]TMS, Me/TMS and Me-Oxime/TMS derivatives for examination by EI GC/MS. The mass spectrometer was a VG 70/70F interfaced to a Varian 2440 gas chromatograph and the GLC column was a 25 m x 0.2 mm OV-1 fused-silica capillary terminating inside the ion source. Spectra were acquired with a VG 11-250 data system at 70 eV.

Results

Fig. 1 shows a limited ion chromatogram of the metabolites of CBD in a pooled sample of urine collected over 25 hours after drug administration. Unconjugated metabolites were identified from their EI spectra which contained diagnostic retro-Diels-Alder (a) and tropylium ions (b). The shifts in these ions, coupled with the appearance of abundant additional diagnostic ions were sufficient to enable most metabolites to be identified.

Metabolites were mainly products of beta-oxidation with additional hydroxylation at C-6 rather than at C-7 which is the major position hydroxylated by most other species. Major metabolites are identified in the Figure legend. At early times, glucose conjugates of 4'-, 5'-hydroxy- and 6-oxo-CBD were the major metabolites (Fig. 2). EI spectra of the TMS derivatives contained ions diagnostic of the sugar [e.g. m/z 450, 361 (base peak), 217, 147, 129, 103] and the aglycone. The latter ions were formed by

Fig. 1. Metabolites of CBD extracted from the 0-25 hour dog urine sample. Major metabolites are: peak 3, 6-hydroxy-2",3",4",5"-tetrakis,nor-CBD-1"-oic acid; peak 16, 6-hydroxy-4",5"-bis,nor-CBD-3"-oic acid; peak 18, 6-oxo-4",5"-bis,nor-CBD-3"-oic acid; peak 30, 4"-hydroxy-CBD-7-oic acid; peak 31, 4",6,7-trihydroxy-CBD, peak 32, 6-hydroxy-CBD-5"-oic acid; peak 42, CBD-5",7-dioic acid.

Fig. 2. Metabolites of CBD extracted from the 0-3 hour urine sample. The metabolites in scans 100-400 are the same as those shown in Fig. 1

TMS migration to the aglycone thus characterising the conjugates as phenol glucosides. Hydrolysis gave the free metabolites which were also identified by GC/MS.

TANDEM (MS/MS) MASS SPECTROMETRY UTILIZING ELECTRON IMPACT IONIZATION AND MULTIPLE REACTION MONITORING FOR THE RAPID, SENSITIVE, AND SPECIFIC IDENTIFICATION AND QUANTITATION OF MORPHINE IN WHOLE BLOOD WITH 5 METER CAPILLARY COLUMN CHROMATOGRAPHY. W.H. PHILLIPS, JR., N. Wade, K. Ota, R. Kitagawa, D. Warden, S. Zehnder, T. Appel, and G. Davis. California Department of Justice, Toxicology Unit, Sacramento, California 95820

ABSTRACT: The power of tandem (MS/MS) mass spectrometry virtually eliminates background interferences and increases sensitivity, thus allowing for a minimum of sample cleanup. A single step liquid-liquid extraction procedure with pentafluoropropionic anhydride derivatization of the resultant extract and 5 meter column chromatography provides a 3 minutes analysis of free morphine in blood samples. The specificity of the method is further enhanced by multiple reaction monitoring which is essentially selective ion recording of two quadrupoles. The first quadrupole is set to transmit only the molecular ion, 577, which then undergoes collision induced dissociation with argon. The last quadrupole is set to transmit only the daughter ion, 414. In the next scan, the ion, 414, is then analyzed for its daughter ion, 266. Deuterated morphine was included as an internal standard and analyzed similarly. Linear and reproducible calibration curves have been obtained for morphine at concentrations from 1.0 to 500 ng/ml achieving correlation coefficients of greater than 0.994. A signal to noise ratio of approximately 7:1 was observed for the 1.0 ng/ml samples.

INSTRUMENTS: A model TRIO-3 Triple Quadrupole Mass Spectrometer (VG MassLab) with a Model 5890A GC (Hewlett-Packard) controlled by a micro PDP 11/73 computer (Digital Equipment Corp.) was employed when operated in the electron impact (EI) mode. The ion source temperature was maintained at 200°C and electron energy of 70eV was routinely used. Sample automation was accomplished by a Model 7673A autosampler (Hewlett-Packard). The instrument's quadrupole sets (Q_1 and Q_3) were both calibrated prior to each use with perfluorotributylamine (FC-43). Argon was used as the collision gas.

A fused silica capillary column, DB-5 (J&W Scientific, Inc.) 30-M x 0.25MM i.d., was cut into six, 6 meter lengths. One five meter length was installed. The helium head pressure was maintained at less than 1.0 PSI with an apparent linear velocity of 68 cm/sec at a GC temperature of 300°C. A split ratio of 10:1 was employed. From an initial temperature of 100°C, the oven was programmed at 70°C/min to 300°C, and held for 2 minutes. The injector and transfer line were maintained at 250°C and 200°C, respectively.

EXTRACTIONS: Disposable syringized glass vials and teflon lined screw caps were used in all analyses. Blood obtained from a local blood bank and screened by radioimmunoassay for opiates and free morphine (Diagnostic Products Corp. Coat-A-Count), was determined to be negative for opiates. Morphine standards were prepared by spiking with appropriate volumes of 100 ng/ml stock morphine in methanol. For each set of unknowns, at least 3 blood standards of known concentration, one quality control specimen and one blank blood were analyzed. 100 μ l of 1.0 μ g/ml morphine-d₃ internal standard was added to each 2 ml aliquot of specimen. The pH of the specimen was adjusted to approximately 9.0 with 1 ml of carbonate/bicarbonate buffer. The mixture was extracted with 8 ml of ethyl acetate for 10 minutes on a rotator at 12 rpm. Extraction tubes were centrifuged at 3,000 rpm for 10 minutes and the organic layer transferred to clean disposable 15 ml centrifuge tubes and evaporated to dryness, using a vortex-evaporator heated to 70°C.

DERIVATIZATION: Pentafluoropropionic anhydride (PFP)(100 μ l) was added to the dry extract, which was then stoppered and heated for 15 minutes at 70°C in a heating block. The derivatized extracts were allowed to cool at room temperature for 5 minutes and again evaporated to dryness in a vortex-evaporator heated to 70°C and reconstituted with heptane (60 μ l). 1.0 μ l was injected into the GC MS/MS by autosampler.

RESULTS AND DISCUSSION: Figure 1 is the EI spectra of 3,6 di-PFP-morphine molecular weight 577, as seen at the intermediate detector (refer to ion optics diagram Fig. 11) prior to MS/MS analysis. The most abundant fragment occurs at 414 and corresponds to the loss of a pentafluoropropionate group from the morphine derivative. Figure 3 shows the daughter ion spectrum of the 577 molecular ion, which thus supports the hypothesis that the 414 is a daughter ion of 577. The reverse of a daughter ion scan is a parent ion scan and should and indeed does verify that 577 is the parent of 414 (fig 4). The neutral loss scan (fig 5) verifies the results of these experiments. This development was done utilizing the direct probe. As a further verification of the first parent to daughter transition, 577 to 414, of the 3,6 di-PFP-morphine, the parent ion 414 was transmitted with an expected loss of 163 from the 6 position corresponding to the remaining PFP group. What was observed was a loss of 148 and a corresponding daughter of 266 (fig 6). It is assumed that the oxygen of the 6 position remains, due to the aromatic charge distribution of the phenolic ring of the morphine, and some sort of a hydrogen rearrangement occurs. Without proper deuteration studies, exact details of this rearrangement are unknown. The daughter transition from 414 to 266 AMU is confirmed by its corresponding parent scan and is also verified by the neutral loss scan of 148.

The collision induced dissociation (CID) of a parent ion to its corresponding daughters has two components that are associated, the collision energy and collision gas pressure. Small changes in either, but particularly collision energy can have dramatic effects in parent to daughter production. Figure 7 depicts the ratio of the intensity of the M/Z 266 to 414 transition as the collision energy and collision gas pressure are varied. The best transmission of both 414 and 266, and 577 to 414 occurred with the collision energy set at 20 volts and argon collision gas pressure of 2.8 millitorr. This would likely vary from instrument to instrument.

To compare the selectivity of the MS/MS multiple reaction monitoring (MRM) to the GC/MS selective ion recording (SIR), drug free blood and a 1 ng/ml morphine blood standard were extracted, derivatized and analyzed by each technique. Ions monitored for SIR included M/Z 414, 417, 577, and 580. Ion transitions monitored for MRM included M/Z 414 to 266, 417 to 269, 577 to 414, and 580 to 417. A signal to noise ratio of approximately 7:1 was consistently observed for the 1 ng/ml (1 part-per-billion) whole blood samples analyzed by MS/MS MRM using a simple single step extraction and derivatization (fig 9,10). Using SIR, it was difficult to detect the internal standard which was spiked at 50 ng/ml, and no discernable peak was seen for the 1.0 ng/ml morphine.

As of this time, 14 consecutive standard curves ranging in concentration from 1 ng/ml to 500 ng/ml and with correlation coefficients of greater than 0.994 have been obtained. Figure (8) shows a representative calibration graph for morphine.

Tandem mass spectrometry (MS/MS) in combination with short capillary chromatography has been found to be a powerful tool in the analysis of a difficult compound. The results of the application demonstrate that GC/MS/MS for the analysis of morphine can be selective, and sensitivity is enhanced by way of the virtual elimination of background interference even with a minimum of sample cleanup. The use of a short, 5 meter capillary column to introduce the sample, enables rapid autosampler analysis. Approximately 60 samples can be extracted and analyzed in an 8 hour day. The gas chromatographic oven program used is not optimized for morphine analysis, but had been developed for general use in baseline separation of several drugs, including methamphetamine, meperidine, phenylephrine, codeine and diazepam. A high isothermal temperature could, in fact, shorten analysis time even further. A trade off in shorter column life maybe realized, but with 5.0 meters of column at risk, the savings in decreased analyst time and increased case throughput is well worth the cost.

AN IMPROVED METHOD FOR EXTRACTING OPIATES FROM URINE
SAMPLES PRIOR TO FULL SCAN GC/MS ANALYSIS

J. de Kanel and T. Hall
Toxicology Testing Service Inc., Miami, Florida

Drug testing to monitor employees is increasing dramatically. Most of these analyses are performed with the ultimate identification of the substance resting on mass spectrometry using selected ion monitoring (SIM) of as few as three ions. As has been pointed out by de Jong, et al. (1988) when recommending the use of MS/MS, this may not be sufficient. The argument that some other compound does not yield these same few ions, in the same relative ratios, may not be pertinent. In a urine or blood extract the GC does not resolve all compounds from each other. If a mixture of compounds co-chromatographs and yields the correct ion ratios within 20%, for the ions being monitored, an incorrect identification may occur.

With the implementation of Federal regulations requiring quantitation of drugs including codeine and morphine, a simple method which would produce clean extracts suitable for GC/MS is required. A method which produces full scan spectra and enables quantitation begins with hydrolysis. After hydrolysis at 15 psig of 2 mL of urine to which 600 ng of each deuterated analog and ethyl morphine have been added as internal standards the pH is adjusted to approximately 8.5 with KOH. Samples are then transferred to extraction tubes containing 0.26 grams of sodium sesquicarbonate, 1.5 grams sodium chloride and 1.5 mL solvent (100 mL 1,2 dichloroethane + 63 mL isopropanol + 100 mL dichloromethane + 140 mL iso-octane). The top organic layer is transferred to a 10 X 75 mm culture tube and evaporated to dryness at 90 degrees C in an aluminum dry block under a gentle stream of nitrogen. After drying the nitrogen flow is stopped and 100 uL of BSTFA is added to each tube and is allowed to reflux for 15 minutes. Evaporate off the BSTFA with nitrogen in about 20 seconds and immediately remove from the heat. Dissolve the residue in DMSO and extract with iso-octane by vortexing for 30 seconds. Transfer the top iso-octane layer to a new test tube and evaporate just to dryness. Cover tube and store under nitrogen until ready for GC/MS analysis. A J&W on-column injector and a 12 meter 0.32 mm DB-5 column with a 1 micron film thickness is used. The extract is reconstituted with iso-octane just prior to injection.

Analysis of control samples during a 6 month period for codeine and morphine at 50, 100, 300, 450, 600, 900 and 1000 ng/mL prepared in negative urine produced excellent results. A sample chromatogram for codeine and morphine at 300 ng/mL, the Federally mandated action level, is given in Figure 1. It shows well resolved peaks for trimethylsilyl (TMS) derivatives of codeine (406), ethyl morphine (423) and morphine (434). Mass spectra for TMS derivatives of codeine and morphine are shown in Figures 2 and 3. These spectra are obtained by subtraction of spectra due to their deuterated analogs. Derivatives of D-3 codeine and D-3 morphine chromatograph approximately 1 to 2 seconds earlier than their non-deuterated analogs. This permits subtraction of the internal standard if it is present at the same or less concentration than the non-deuterated analog. Automatic quantitation of codeine and morphine is accomplished by integration of the TMS derivatives' molecular ions at 371 and 429 respectively (Figure 4). Data for linear calibration curves from 50 to 900 ng/mL is displayed in Table 1.

TABLE 1

ION RATIO	INTERNAL STANDARD	EQUATION	CORRELATION COEFFICIENT
371/374	D-3 codeine	$C = 245x + 34$	0.996
371/385	ethyl morphine	$C = 261x + 24$	0.995
429/432	D-3 morphine	$C = 190x + 49$	0.997
429/385	ethyl morphine	$C = 940x + 76$	0.946

C = concentration

x = ion ratio

In conclusion, this method produces extracts which are clean enough for reconstructed ion chromatograms of urine extract analyses to show resolved peaks for codeine and morphine at the Federally mandated action level of 300 ng/mL. Full scan mass spectra can be obtained at this level by subtracting the spectrum due to the deuterated analog. Codeine may be quantitated using calibration curves obtained with both codeine D-3 and ethyl morphine as internal standards. Morphine is best quantitated using morphine D-3 as an internal standard. Ethyl morphine was successfully used for many analyses but it is apparently not a sufficiently good surrogate for morphine and any variation in experimental conditions greatly decreased precision in morphine quantitation. Quantitation within 10% of the level expected has been obtained for a control urine sample purchased from Hycor Biomedical, Inc. containing 400 ng/mL of both codeine and morphine as morphine glucuronide.

Triple Quadrupole and Quadrupole Ion Trap Tandem Mass Spectrometry (MS/MS) for the Determination of Morphine Alkaloids

Jodie V. Johnson and Richard A. Yost

Chemistry Department, University of Florida, Gainesville, FL 32611

Introduction. The task of determining morphine alkaloids in physiological fluids has been and continues to be a major analytical challenge due to the effective low dosage of the morphine alkaloids. Over the past decade, triple quadrupole (TQMS) tandem mass spectrometry (MS/MS) has been successfully used for the determination of a variety of trace analytes in complex matrices with little or no sample cleanup or separation. Recently, a quadrupole ion trap (ITMS) has been developed which has the capability of performing MS/MS. The objectives of this research were a) to characterize and optimize the MS and MS/MS behavior of the morphine alkaloids, b) to compare the MS and MS/MS capabilities of the TQMS and ITMS, and c) to evaluate TQMS and ITMS MS/MS for the determination of trace levels of morphine alkaloids.

Experimental. All data were acquired on Finnigan MAT TSQ70 and ITMS tandem mass spectrometers. The ITMS was operated in the RF-only mode for the results presented here. Samples were introduced into the TSQ70 via a short (2.5 m) capillary GC column for optimization studies and via solids probe (SP) for quantitation. With the ITMS, all samples were introduced via a solids probe. Electron energies of 70 and 100 eV were used for EI and PCI, respectively, on the TSQ70. The RF level of the ITMS was maintained at 10 amu during the ionization and CI reaction time periods. The TSQ70 ion source was maintained at 150°C while the ITMS was kept at 100°C. After optimization of their respective CAD parameters, the sensitivities of the two tandem mass spectrometers were compared for the SP/EI-CAD of the M^+ ion determination of morphine standards in methanol.

Characterization of Normal MS. The EI normal mass spectra on the TQMS and ITMS are characterized by relatively strong M^+ ions at m/z 285 (100 and 20 %RA on the TQMS and ITMS, respectively) and extensive fragmentation (Figure 1). The higher relative abundances of low m/z ions to high m/z ions in the ITMS spectrum is most likely due to poor trapping of the higher m/z ions at an ionization RF level of 10 amu. Due to the short ion residence times (μs) in the ion source, the TQMS required 1-2 torr of CH_4 to achieve PCI. In contrast, with the capability to trap ions and, thus, have long CI reaction times (ms), the ITMS required only 2×10^{-5} torr CH_4 . The PCI normal mass spectra on both instruments are characterized by a large $(M+H-H_2O)^+$ ion at m/z 268 (100 %RA) and the $(M+H)^+$ ion at m/z 286 (30-40 %RA). The TQMS and ITMS sensitivities for the $(M+H)^+$ ions were ca. 30 and 2 times, respectively, those for the M^+ ions. Thus, it was anticipated that PCI would be the preferred ionization technique.

Characterization of Daughter MS. The EI-CAD daughter spectra of the M^+ ions (m/z 285) are characterized by efficient fragmentation of the parent molecular ion to produce only a relatively few, characteristic daughter ions, with the m/z 162 daughter ion being the most abundant and characteristic of the morphines (Figure 2). The PCI-CAD daughter spectrum of the $(M+H)^+$ ion obtained on the TQMS is characterized by inefficient fragmentation to a large number of low intensity daughter ions. With the ITMS, it has not been possible to fragment the $(M+H)^+$ ion of morphine under several different sets of CAD conditions. Although on the TQMS PCI was 30 times more sensitive than EI, PCI-CAD was only 5 times more sensitive than EI-CAD due to the inefficient CAD of the $(M+H)^+$ ion. Due to the inability to fragment the $(M+H)^+$ efficiently on both instruments, the EI-CAD of the M^+ ion was only chosen for further study.

Optimization of EI-CAD Parameters. The CAD fragmentation of the M^+ ion on the TQMS is largely controlled by the ion's axial energy (collision energy) and collision gas pressure. The maximum yield of the m/z 162 was found to occur with a collision energy of approximately 20 eV and a collision gas pressure of approximately 3 mtorr nitrogen. With 2.0 mtorr nitrogen collision gas, a maximum overall CAD efficiency of 65% was obtained with 20 eV collision energy.

The CAD fragmentation of the M^+ ion on the ITMS is affected by the frequency, magnitude, and length of time for which the auxiliary AC voltage (tickle voltage) is applied. The maximum CAD is achieved at the secular frequency of the parent ion while the width of the effective tickle frequency band increases (decreases

the mass resolution of parent ion resonance) with increasing tickle voltage and tickle time. The resolution of parent ion resonance increases with an increase in the RF voltage applied during the CAD period. With judicious selection of conditions, it is possible to excite only the parent ion of interest. The extent of CAD increases with increasing tickle voltage and tickle time. With variation of the tickle voltage, a maximum overall CAD efficiency of 95% was obtained with 500 mV tickle voltage and 10 ms tickle time.

Quantitative Comparison of the TQMS and ITMS. With the optimized EI and CAD conditions, calibration curves were obtained for the SP/EI-CAD of the M^+ ion of morphine in methanol. With selected reaction monitoring (SRM) of $285^+ \rightarrow 162^+$, the TQMS had a limit of detection (LOD) of approximately 10 ng of morphine applied to the probe. With a wide mass range scanning (m/z 160 to 330, 0.3 s), identifiable daughter spectra could be obtained on the TQMS on 50 ng of morphine (Figure 3). In contrast, the ITMS required about 75 ng of morphine to obtain comparable spectra (Figure 4). This was attributed to the Rulon fitting on the ion trap which mates with the end of the solids probe. As this Rulon fitting was at 100 C and morphine was not vaporized until above a SP temperature of 250 C, considerable broadening and tailing of the morphine peak occurred.

Conclusions. Although PCI was a more sensitive than EI, the EI M^+ ion was more efficiently fragmented than the PCI ($M+H$) $^+$ ion. Thus, EI-CAD was the preferred method for the determination of morphine in these studies. Although the ITMS yields a higher overall CAD efficiency than the TQMS, the lack of a heated solids probe interface to the ion trap results in the ITMS having a higher LOD than the TQMS. Finally, LODs of 10 and 30 ng of morphine on the solids probe were obtained for EI-selected reaction monitoring and EI-CAD daughter scanning, respectively, with the TQMS.

IDENTIFICATION OF FOUR PREVIOUSLY UNREPORTED METABOLITES OF COCAINE
IN HUMAN URINE SPECIMENS

J.Y. Zhang and R.L. Foltz

Center for Human Toxicology, University of Utah, Salt Lake City, UT 84108

Cocaine remains one of the most widely abused illicit drugs in the United States. Although the major metabolites of cocaine have been extensively studied, some of the minor metabolites have not been previously reported. In order to further elucidate the metabolic pathways of cocaine in man, we undertook a search for additional cocaine metabolites in urine specimens previously found to contain high concentrations of benzoylecgonine.

Two ml of urine was hydrolyzed with 20,000 units of β -glucuronidase in 4 ml of sodium acetate buffer (pH=5) overnight at 37°C. After the incubation, the solution was adjusted to pH 8.5 with 1 N NH₄OH and extracted twice with 5 ml of chloroform:isopropanol (3:1). Then 5 ml of 0.1 N HCL was added and the solution was shaken for 15 min. The organic layer was discarded, the aqueous phase was adjusted to pH 8.5 and extracted twice with 5 ml of chloroform:isopropanol (3:1). The organic layer was evaporated to dryness and derivatized with 70 μ l of pentafluoropropionic anhydride (PFPA) and 30 μ l 1,1,1,3,3,3-hexafluoroisopropanol (HFIP) by heating at 70°C for 10 min. After the derivative was evaporated to dryness, 20 μ l of ethyl acetate was added, and a 1 μ l aliquot of the solution was injected into the GC-MS.

The GC/MS used was a Finnigan-MAT model 800 Ion Trap Detector (ITD) combined with a Hewlett-Packard 5890 gas chromatograph. The chromatographic column was a 20 m x 0.2 mm DB5 fused-silica capillary column (J&W Scientific, Rancho Cordova, CA). The GC oven was initially held at 100°C for 0.5 min, then temperature programmed at 15°C/min to a final temperature of 300°C.

The total ion current chromatogram of a derivatized urine extract is shown in Figure 1. Cocaine and 11 of its metabolites are detectable. Four previously unreported metabolites were identified: ecgonidine (1), methyl-norecgonidine (5), norecgonine methyl ester (6) and m-hydroxybenzoylecgonine (8). Their structures were confirmed by comparison of their mass spectra (Figures 2a-2d) and their retention times with those obtained for synthetic standards. Other cocaine metabolites identified in this urine specimen were benzoylecgonine (7), ecgonine methyl ester (4), ecgonine (2), methylecgonidine (3), norcocaine (11), m-hydroxycocaine (10) and p-hydroxycocaine (12). Also, cinnamoylcocaine (14), which is often present in coca leaves and in illicit preparations of cocaine, was detected in this urine specimen along with its metabolite, cinnamoylcocaine (13).

The known metabolites of cocaine are shown in Figure 3. The arrows indicate likely metabolic pathways. The main biotransformations include: deesterification, N-demethylation, and arylhydroxylation.

CHARACTERIZATION OF URINARY METABOLITES OF
NAPAMEZOLE HCL IN RATS, DOGS, MONKEYS AND HUMANS.

Judith A. Johnson, Nellie A. Seger, Robert F. Stack
and David P. Benziger
Department of Drug Metabolism and Pharmacokinetics
Sterling Research Group, Rensselaer, NY 12144.

Napamezole HCL is an orally active naphthalenyl imidazole anti-depressant agent. It is structurally novel in that it lacks the fused three-ring system of the tricyclic antidepressives and physiologically novel in that it has both alpha-2 adrenergic antagonist activity and serotonin selective uptake inhibitory activity.

Following oral administration, napamezole was well absorbed in all species and excreted primarily via the kidneys. Dogs and monkeys excreted 80% of the dose in urine in 72 hr while rats excreted slightly less (50-60%). Intact napamezole represented less than 2% of the dose in rat urine but accounted for approximately 16% and 11% of the dose in dog and monkey urine, respectively. In humans, there was an apparent dichotomy of subject populations based upon the extent of drug metabolism. Poor metabolizers excreted up to 80% of the dose into the urine as intact drug while extensive metabolizers had less than 20% intact drug excreted into the urine.

Twelve different metabolites plus the parent compound were isolated and characterized. Structural analysis by mass spectrometry revealed alterations of the aromatic and imidazole moieties of napamezole by oxidation, hydroxylation, cleavage and conjugation. A considerable interspecies divergency was observed. The biotransformation pattern was most complex in the rat (10 metabolites) compared to the dog (5 metabolites), monkey (2 metabolites) and human (2 metabolites).

The biotransformation of napamezole in rats, dogs, monkeys and humans may be summarized as follows. Hydroxylation and conjugation were the major routes of metabolism. Two different metabolites OH(A) and OH(B), each with an intact dihydroimidazole ring and hydroxylation on the aromatic ring, were isolated based on differences in retention time by HPLC. Free OH(A) was isolated in rat urine while free OH(B) was found in both rat and dog urine. Two different glucuronide conjugates of OH(A) were observed in rat, monkey and human urine while a sulfate conjugate of OH(A) was observed in dog, monkey and human urine. A glucuronide conjugate of OH(B) was isolated in rat urine. A "catechol" like compound, both free and conjugated, was identified in rat urine. Although the possibility exists that the O-methyl may be an artifact of purification, the dihydroxy configuration is of metabolic origin.

A metabolite hydroxylated in the alpha position on the dihydroimidazole ring was isolated in rat urine. The formation of carbinolamines from substituted amines has been proposed to take place during the intermediary oxidative metabolism of a number of drugs. In the biotransformation of napamezole, the existence of a carbinolamine intermediate represents a potential route for the conversion of the drug to the ring-opened carboxylic acid metabolite observed in dog urine. Oxidative ring opening is a significant metabolic route for several tertiary N-heterocycles.

Imidazole metabolites with hydroxyl substitutions on the aromatic ring were observed in both free and conjugated forms. One cannot determine unequivocally whether the imidazole moiety in these metabolites arose from alpha-C-hydroxylation and dehydration via the mechanism proposed for metabolite R7. However, since there was no mass spectral evidence to support an acyclic linear aldehyde intermediate with a hydroxyl substitution on the aromatic ring, it is probable that some other mechanism is involved.

SUMMARY OF METABOLITES OF NAPAMEZOLE

IDENTIFICATION OF PHASE II METABOLITES OF PSYCHOTROPIC
DRUGS USING HPLC COMBINED WITH FAB-MS

G. McKay, C.-J. Jackson, Y.-Z. Shu, J.W. Hubbard,
E.M. Hawes and K.K. Midha

College of Pharmacy, University of Saskatchewan,
Saskatoon, Saskatchewan, Canada, S7N 0W0

Psychotropic drugs like fluphenazine, doxepin and haloperidol have been shown to undergo a wide variety of metabolic transformations *in vivo*. When plasma samples obtained from patients and healthy volunteers given such medication are examined indirect evidence indicates that various phase II conjugated metabolites may be present. The indirect evidence has been obtained after enzymatic or non enzymatic hydrolysis followed by analysis for the parent drug or functionalized metabolite(s). When such experiments are performed there is an apparent and significant increase in the measured levels of parent drug or metabolite. The conclusion reached from such studies is that conjugated metabolites are present in significant concentrations. In order to obtain direct evidence for the identification of phase II metabolites of psychotropic drugs a series of preliminary experiments were designed using rats.

EXPERIMENTAL

Animal Studies:

The phase II metabolism of doxepin, fluphenazine and haloperidol was studied on separate occasions in female Lewis rats (220-350 g) which were anesthetized with aqueous urethane solution (2 ml, 66 mg/ml, i.p.). The common bile duct was cannulated with polyethylene tubing (PE-10, 1.0 mm O.D.) and blank bile was collected for the first hour. An aqueous solution of the drug in question (25 mg/kg) was injected into the peritoneal cavity, after which the incision was closed with surgery clips. Bile was collected over a period of 4-8 h.

Instrumentation:

1) HPLC Conditions - Two Waters M-45 solvent delivery pumps were used controlled by a Waters 720 gradient system controller. A Waters Model 441 ultraviolet detector (254 nm) and Rheodyne valve loop injector were employed. Data was recorded on a Hewlett Packard Model 3390A integrator. The column was packed in-house with Spherisorb nitrile (3 μ m, 0.46 x 15 cm) and operated at 50°C (Sys-Tec, CH 1445) under gradient conditions. During the entire period the flow rate was maintained at 1.5 ml/min.

2) Mass Spectrometry - Fast atom bombardment mass spectrometry was performed on the various HPLC eluted and collected peaks. Two instruments were employed - a VG 70SQ and VG 7070 HE. Both positive and negative ion spectra were recorded depending on the suspected identity of the peaks. In all cases the FAB gas was argon; gun emission 6KV and sample matrix glycerol and/or thioglycerol. Data was collected using a Dec II/250J data system, spectra were averaged and background subtracted to remove matrix ions.

Figure 1 - HPLC chromatograms of blank bile and bile obtained from the same rat previously administered fluphenazine (25 mg/kg, i.p.). Peaks A, B, C and D were collected and analyzed by FAB-MS.

RESULTS AND DISCUSSION

Administration of fluphenazine resulted in the production of at least four peaks (A, B, C and D, Figure 1) which when individually analyzed by FAB-MS were tentatively identified as 7-hydroxyfluphenazine plus sulfate, fluphenazine sulfate, 7-O-glucuronide fluphenazine and fluphenazine glucuronide respectively. The FAB-MS of all these metabolites yielded quasi-molecular ion information which was reinforced in some cases by the presence of natiurated adduct ions. In addition the aglycone or de-sulfated fragment ions could also be readily identified.

In the case of peak A, Figure 1, the resultant FAB-MS with a quasi-molecular ion at m/z 534 demonstrated a very low abundance of a fragment ion at m/z 518. This would tend to indicate the additional oxygen in this species is in the form of a hydroxyl group rather than a sulfoxide which readily lose 16 amu under FAB conditions. We can not say however whether the sulfation of this hydroxylated metabolite is on the phenol or alcohol hydroxyl moiety. In addition the assignment of the hydroxyl group to the 7-position of the phenothiazine ring is based on the previously reported location of hydroxylation during phase I metabolism. Peak B in this chromatogram appears to be a mixture of peaks A and C and a previously unreported poly oxygenated metabolite giving rise to m/z 646.

Haloperidol and doxepin phase II metabolites were more simple in that unambiguous assignments of haloperidol glucuronide and two isomeric glucuronides of hydroxylated doxepin could be made (data not shown). In the case of doxepin, sufficient quantities of these metabolites were collected to obtain NMR data in order to confidently assign the metabolites as (E)-3 and (E)-2-O-glucuronide doxepin respectively.

The comparison of the spectra obtained to authentic reference spectra in most cases facilitated the assignment of metabolite structures.

These results are for the most part the first direct evidence for the presence of these metabolites in rat bile. Their importance in the human disposition of these drugs still remains to be clarified.

UTILITY OF LC-MS AND TANDEM MS FOR THE ANALYSIS OF THE RAT URINARY
METABOLITES OF PYRILAMINE

W.A. Korfmacher, J.P. Freeman, J. Bloom, T.A. Getek and C.L. Holder
National Center for Toxicological Research, Jefferson, AR 72079

INTRODUCTION

Pyrilamine maleate is a member of a class of antihistamines that is used in cold and allergy formulations. At least one member of this class of antihistamines has been shown to be carcinogenic in laboratory animals (1). Therefore, there is a continued interest in the metabolic products of these compounds. Thermospray (TS) is a mass spectrometric (MS) ionization technique that is ideal for direct high performance liquid chromatography-mass spectrometric (HPLC-MS) analysis of samples (2,3). We have recently shown that TSMS is a useful technique for the analysis of several antihistamines and their metabolites (4-7). Recently, Lee and Yost (8) described the utility of tandem mass spectrometry for the identification of drug metabolites. In this study, we have used high performance liquid chromatography-thermospray mass spectrometry (HPLC-TSMS) combined with tandem mass spectrometry for the direct analysis of urinary extracts from rats which have been dosed with pyrilamine.

EXPERIMENTAL

A gradient HPLC system was connected to one inlet of a mixing T; the other inlet was connected to a syringe pump. The gradient HPLC was programmed from 100% 0.5 M ammonium acetate in water to 100% methanol over a 10 minute period at a constant flow rate of 1 ml/min through the HPLC column. The HPLC column was a 25 cm x 4.6 mm Supelco 5 μ m LC-18 column. The syringe pump was filled with a solution of 0.3 M ammonium acetate in water and was operated at a flow rate of 0.4 ml/min. The total effluent from the two pumps was mixed in the T and flowed into the mass spectrometer. The mass spectrometer (MS) was a Finnigan-MAT TSQ 70 triple quadrupole MS instrument equipped with a Finnigan-MAT thermospray probe and controller. When operated in the tandem MS mode, the collision gas was argon set to about 0.5 mtorr and collision energy of 25 EV. Both parent ion spectra and daughter ion spectra were obtained.

RESULTS AND DISCUSSION

Based on our previous studies of the TSMS/MS characteristics of pyrilamine and related metabolites, it was known that all of these compounds produced an m/z 121 ion in the daughter ion spectra produced from the collision-activated dissociation (CAD) of their $[MH]^+$ ions (4). In addition, it was observed that the m/z 107 ion in the daughter ion spectra of these metabolites was indicative of an O-dealkylated pyrilamine metabolite (4). Therefore, as shown in Figure 1, the rat urinary extract sample was analyzed via HPLC-TSMS/MS in the parent ion mode set to obtain parent ion spectra for the m/z 121 ion. In addition, a parent ion analysis for the m/z 107 ion was also performed. These parent ion analyses provided several new potential metabolites for further analysis. Daughter ion spectra for these potential metabolites were then obtained. For example, Fig. 2 shows the m/z 272 daughter ion analysis of the sample; m/z 272 corresponds to the $[MH]^+$ ion for O-dealkylated pyrilamine. By this method, several unexpected metabolites were detected and preliminary structures have been assigned to them. The success of this experiment was due to a combination of the separation of these metabolites in time via the gradient HPLC system and the ability to search for potential metabolites using the parent ion mode of the tandem MS system followed by the use of daughter ion spectra to give a preliminary identification of these metabolites.

Figure 1 Mass chromatograms for the m/z 121 parent ion analysis of the rat urine extract sample.

Figure 2 Mass chromatograms from the m/z 272 daughter ion analysis of the rat urine extract sample. Peak I is the O-dealkylated pyrilamine metabolite.

CONCLUSIONS

HPLC-TSMS and HPLC-TSMS/MS were successfully utilized for the direct analysis of a rat urinary extract which contained several metabolites of pyrilamine. By using the parent ion MS mode, potential pyrilamine metabolites were located in the sample. By successive use of the daughter ion MS mode, individual pyrilamine metabolites could then be characterized.

CHARACTERIZATION OF THE METABOLITES OF TIBENELAST FROM URINE IN MALE HUMANS USING LIQUID SECONDARY ION (LSIMS), DIRECT PROBE CHEMICAL IONIZATION (DCI) AND THERMOSPRAY (TSP) MASS SPECTROMETRY

Peyton, A.L., Ziege, E.A., Goodwin, R.M. and Breau, A.P.
Lilly Research Laboratories, Indianapolis, IN 46285

INTRODUCTION Tibenelast, (figure 1, I), has been identified as a potential antiasthma compound. After pharmacokinetic steady state was achieved with tibenelast, each volunteer received approximately 50 mg (100 μ Ci) of radiolabeled tibenelast. The major urinary metabolite was identified as the glucuronide conjugate of tibenelast by LSIMS (figure 1, IV). Minor metabolites of tibenelast, the conjugates of the O-desethylated metabolites, (figure 1, II+III) were identified by thermospray LC/MS.

METHODS AND PROCEDURES **Direct Chemical Ionization (DCI) Analyses** DCI analyses were performed on a Nermag R 30-10 triple stage. The samples, dissolved in methanol, were applied onto the direct probe filament tip that was initially at ground then increased to 600 mA at 30 mA/min. The ion source was maintained at 120 °C with an ammonia gas pressure of 7×10^{-5} torr. A mass range of 200-700 amu was scanned every 0.5 seconds.

Liquid Secondary Ion Mass Spectrometry (LSIMS) LSIMS analyses were performed on a Nermag R 10-10 single stage quadrupole mass spectrometer equipped with a cesium ion gun. The sample, dissolved in methanol, was applied to the probe tip that was coated with glycerol. The cesium gun operated at a heater current of 250-300 mA to produce a cesium ion beam of 0.8 mA. The mass range of 200-1200 amu was scanned every 10 seconds.

LC/MS All TSP spectra were obtained using a model TS101 Vestec TSP interface installed on a Finnigan 4500 MS/DS. The TSP source block temperature was 250 °C. TSP probe tip temperature was 230 °C. All analyses were performed in the discharge-on mode at a flow of 1 ml/min. Most acquisitions scanned across a 30-50 amu mass range in 2 seconds. Samples were introduced via manual injection using a 50 μ l fixed loop. The mobile phase with eluting peaks passed from the column to a U.V. detector set at 313 nm and then to the TSP probe.

RESULTS and DISCUSSION The DCI analysis of a standard of O-desethyl tibenelast (figure 1, II+III) produced a prominent pseudomolecular ion and an intense ammonium adduct ion. Treatment of the standard with ethereal diazomethane produced the methyl ester with the pseudomolecular ion shifted 14 mass units. DCI analysis of isolated O-desethyl tibenelast did not produce the prominent ions observed with the standards. Selected ion display of the pseudomolecular ion revealed a major peak at scan #21 indicating that a pure component at this mass was possibly in the sample (figure 2). Treatment of the component with diazomethane did not affect the major ions present.

The LSIMS spectrum of the putative glucuronide had significant ions (figure 3) that corresponded to the mono and di-natriated adducts of a postulated glucuronide (figure 1, IV). The assignment of these peaks as natriated adducts was supported by the intense natriation of the glycerol matrix ions. The ion at $m/z=556$ was the glycerol adduct of the mono-natriated glucuronide. LSIMS was not successful for the analysis of other putative glucuronides. These samples were successfully analyzed by Thermospray LC/MS.

The TSP spectrum of other isolated glucuronides produced prominent pseudomolecular ions at $m/z=239$ indicative of the aglycone of O-desethylated tibenelast glucuronide. Thermospray LC/MS did not yield molecular ion information of the intact glucuronides, only the aglycones.

The LSIMS experiments were limited by the presence of sodium in the matrix, a common problem in FAB and LSIMS mass spectrometry. The DCI analyses produced excellent results with standards but interferences dominated the sample spectra. Thermospray LC/MS was able to overcome the matrix problems associated with other techniques.

Research, Jefferson, AR 72079

INTRODUCTION

Thenyldiamine and tripeleennamine are ethylenediamine-type antihistamines. Antihistamines in this class have been used in various over-the-counter cold remedies. The determination of the metabolism and toxicity of these compounds is of interest because similar antihistaminic drugs have been found to be carcinogenic in laboratory animals (1). The use of microbial systems to model phase I mammalian drug metabolism has been reported (2,3). Research in our laboratories has also shown the applicability of microbial models to complement mammalian metabolism studies of various classes of antihistamines (4,5).

Thermospray (TS) is a recently developed mass spectrometric (MS) ionization technique that is ideal for direct high performance liquid chromatography-mass spectrometric (HPLC-MS) analysis of samples (6,7). In this report, we describe the direct HPLC-TSMS analysis of methylene chloride extracts containing microbial metabolites of these two antihistamines.

EXPERIMENTAL

Biotransformation Conditions. Typically, 5 mg of the antihistamine was dissolved in 0.5 ml sterile physiological saline and then incubated with cultures of the filamentous fungus Cunninghamella elegans ATCC 9245. Methylene chloride extracts of these fungal cultures were evaporated to a dry residue and then redissolved into 5 ml of the mobile phase prior to injection into the HPLC-TSMS system.

HPLC-TSMS System. An Isco (Lincoln, NE) model LC-5000 syringe pump was connected to a Rheodyne (Cotati, CA) 7125 injector that included a 20- μ l sample loop. The mobile phase was pumped through a 25 cm x 4.6 mm Altex (Berkeley, CA) Ultrasphere 5 μ m Cyano-phase HPLC column at a flow rate of 1.0 ml/min. The mobile phase consisted of 0.1 M ammonium acetate in water adjusted to pH 5 with acetic acid/acetonitrile (75/25, v/v). The HPLC eluant went directly into the TSMS interface. TSMS analysis was performed using a Delsi-Nermag (Houston, TX) R1010C quadrupole mass spectrometer equipped with a Delsi-Nermag TS source and a Vestec (Houston, TX) TS interface. The TS source was operated in the positive ion, "filament off", and "discharge off" mode. Typically, the TS source block was set to 160 °C, and the control temperature was set to 132 °C.

RESULTS AND DISCUSSION

The parent compounds and the N-demethylated metabolites provided [MH]⁺ ions as the base peak in their TS mass spectra. The N-oxide metabolites provided [MH]⁺ ions plus several fragment ions in their TS mass spectra. Figures 1 and 2 show the LC mass chromatograms for the thenyldiamine extract and the tripeleennamine extract, respectively.

CONCLUSIONS

By this method, TS mass spectra of the N-oxide and N-demethylated metabolites of these antihistamines were obtained directly from the on-line HPLC-TSMS analyses. These results demonstrate the utility of HPLC-TSMS for the direct analysis of thenyldiamine and tripeleennamine and their methylene chloride-extractable microbial metabolites.

Figure 1. LC mass chromatograms from the HPLC-TSMS analysis of an extract from the fungal metabolism of thenyldiamine, displaying (a) m/z 246, (b) m/z 262, (c) m/z 278, and (d) the RIC. Peak I is N-desmethylthenyldiamine; peak II is thenyldiamine; peak III is thenyldiamine N-oxide.

Figure 2. LC mass chromatograms from the HPLC-TSMS analysis of an extract from the fungal metabolism of tripeleonnamine, displaying (a) m/z 242, (b) m/z 256, (c) m/z 272, and (d) the RIC. Peak IV is N-desmethyltripeleonnamine; peak V is tripeleonnamine; peak VI is tripeleonnamine N-oxide.

THE DETERMINATION OF SERUM URIC ACID BY ISOTOPE DILUTION LC/MS AND LC/MS/MS

Michael J. Welch, Richard G. Christensen, and Polly Ellerbe
Center for Analytical Chemistry
National Institute of Standards and Technology
Gaithersburg, MD 20899

INTRODUCTION

Quantitation using LC/MS is often difficult to perform with satisfactory precision because of rapid fluctuations and drift in the signal. One approach to overcoming these problems is to use an isotope labeled internal standard, which coelutes with the analyte.

Provided the peak is sufficiently wide, enough alternating measurements of the intensities of the unlabeled and labeled ions can be made to average out the rapid fluctuations. Drift problems are partially overcome by using the coeluting internal standard. Even then, absolute ratios measured for a given sample can vary considerably with time. Performing measurements of standard mixtures (that are close in ratio to the samples) between measurements of samples can largely overcome this problem.

We chose to test how well quantitation could be performed using isotope dilution/LC/MS by measuring uric acid in SRM 909, Lyophilized Human Serum. The concentration of uric acid in this SRM was determined by an isotope dilution/GC/MS candidate definitive method. Results from this GC/MS method are very precise and are free of significant bias. The method is however, very time-consuming. The serum is spiked with a known amount of uric acid- $^{15}\text{N}_2$, the uric acid is isolated from most of the serum matrix with use of an anion exchange column, the sample is freeze-dried, the uric acid is converted to a tetra(t-butyl-dimethylsilyl) derivative, and the derivatized mixture is injected onto a nonpolar capillary column interfaced directly to a magnetic sector mass spectrometer extensively modified for high precision isotope dilution measurements.

An LC/MS method would require less sample preparation and no derivatization. If results proved satisfactory, LC/MS methods could be rapidly developed and instituted for determinations not requiring the precision and accuracy of a definitive method.

In contrast to the GC/MS method, the LC method we developed is very simple. After spiking the serum with a labeled internal standard, the serum is treated to precipitate protein. The supernatant is then ready, without further treatment, for injection onto the HPLC column.

Because LC does not have the resolving power of GC, separation from all interferences is less likely with LC. The addition of a collision induced dissociation (CID) step should add sufficient specificity for accurate measurements of analytes in complex matrices. We wanted to test whether this additional step was necessary and whether it would have adverse effects on the precision.

EXPERIMENTAL

Reconstituted serum (SRM 909) was spiked with a known amount of uric acid- $^{15}\text{N}_2$ and treated with trichloroacetic acid to precipitate protein. Fifty microliters of the supernatant was then injected directly onto a C-18 HPLC column which was interfaced to a triple quadrupole mass spectrometer via a thermospray device. Best results were obtained when the thermospray ion source was tuned for best signal stability, rather than for maximum sensitivity. For tuning we bypassed the HPLC column with a constant flow

of a solution of our eluting solvent containing uric acid at about the concentration of our samples. The eluting solvent was an aqueous solution of 0.075 M ammonium acetate and 0.003 M tetrabutylammonium hydroxide adjusted to pH 5.2. For the LC/MS measurements, (M-H)⁻ ions for the unlabeled and labeled forms of uric acid were measured and their ratio calculated. To determine the quantity of uric acid in the serum, such ratios were compared with ratios from uric acid standard solutions spiked with the same concentration of labeled uric acid as were the samples. Injections of samples and standards were alternated to provide frequent checks on the instrument stability.

For the LC/MS/MS measurements, we selected the (M-H)⁻ ions generated by thermospray, performed CID on them, and measured the intensity of specific fragment ions. The instrument was set in the neutral loss mode for monitoring loss of 43 from m/z 167 and loss of 44 from 169. This loss of 44 suggests that one of the labeled nitrogens is lost in the fragmentation.

RESULTS

The results for three samples of SRM 909 measured by LC/MS are shown in Table 1. The precision was very good for these three samples. However, our other experiences with quantitation by LC/MS suggest that cv's of 1 - 1.5 % are more typical. The results are slightly higher (3%) than the certified value, suggesting the possibility of a small interference in the measurements. Nevertheless, the ease of the method and the satisfactory results, in terms of both accuracy and precision, demonstrates that isotope dilution LC/MS can be a viable technique for quantitation.

The results from the LC/MS/MS measurements of these same samples are also shown in Table 1. They agreed better with the certified value than did the LC/MS results, suggesting that the MS/MS process may have eliminated the interference that affected the LC/MS results. Precision of the measurements was very good and again, somewhat better than we would expect for this type of measurement.

These evaluations demonstrate that the combination of isotope dilution with LC/MS can provide accurate and precise results. This technique should be very useful for determining analytes that are difficult to measure by GC/MS, provided an isotope labeled internal standard is available. The use of a CID step provides additional specificity, with little loss of precision and little increase in effort.

Table 1
URIC ACID IN SRM 909 USING LC/MS AND LC/MS/MS

QUANTITATIVE DETERMINATION OF LEUCINE TRANSAMINATION IN THE FETUS
FOLLOWING TRACER INFUSION OF ^{15}N - ^{13}C - LEUCINE

K. A. Brown, M. A. Evans, M. S. Schaefer, E. A. Liechty. Mass Spectrometry Research Laboratory, Dept. of Pharmacology and Toxicology and Dept. of Pediatrics, Indiana Univ. School of Medicine, Indianapolis, Indiana 46223.

The use of ^{15}N - ^{13}C -leucine as tracer combined with MS analysis provides a method by which the reversible transamination of leucine in the fetus can be dissected from irreversible degradative processes involving the carbon skeleton. Transamination of the stable isotope of leucine to the ketoacid produces a subsequent tracer enrichment of alpha-ketoisocaproic acid (KIC). Quantitative GC-MS-SIM allows for accurate and repeated assessment of the rates for both leucine transamination to KIC and irreversible degradation of the carbon skeleton to isovaleryl-CoA.

METHODS AND RESULTS

Whole blood and plasma amino acid concentrations are determined by standard ion exchange chromatography. Branched chain alpha keto acids are determined by a modification of the HPLC procedure described by Koike et.al. (1984). Alpha-ketoglutarate is used as the internal standard.

Isotopic enriched leucine is determined as the N-propyl, N-acetyl ester by the method of Matthews (1979). A Finnigan 4500 with a 15 meter, 0.25mm I.D., DB-17 Column with a flow rate of 1.5 ml/min of helium was used for the analysis. The oven temperature profile was 80° for 1 minute to 260° at 10°/min. Injector temperature was set at 250° and transfer line at 280°. Injections were made under splitless conditions. Chemical ionization was used and the molecular ions at m/e 216, 217 and 218 were monitored by selective ion monitoring to determine the isotopic ratio of the non-labelled (m/z 216) singly labelled (1- ^{13}C ; m/z 217) and doubly labelled (1- ^{13}C , ^{15}N ; m/z 218) species of leucine respectively (Fig. 1).

Isotopic enrichment of keto-isocaproate was determined by modifications of procedures described by Wolfe (1984). In brief, samples were deproteinized with 50% SSA, centrifuged at 10,000g, 0° C for 30 minutes, and transferred to reaction vessels. The samples were then derivatized with OPDA at 100° for 30 minutes. Following drying with anhydrous sodium sulfate, samples were extracted with methylene chloride and evaporated to dryness. BSTFA (50 ul) and pyridine (25 ul) were then added to the extraction vial, heated to 70° for 20 minutes, and sealed. A Hewlett Packard 5970 MSD outfitted with a 15 meter, 0.25mm I.D., DB-5 column with a flow rate of 0.85 ml/min of helium was used for analysis. The oven

temperature profile was 130° for 1 minute to 260° at 10°/min. Injector temperature was set at 250° while the transfer line was at 280°. A 10:1 split injection was used. Ionization was by electron impact and the ion ratio at 232/233 determined by SIM for non-labelled and singly labelled (1-¹³C) KIC was used to calculate ¹³C isotopic enrichment.

Combined with the quantitative HPLC analyses for leucine and KIC, these GC/MS procedures provided a sensitive and repeatable method for monitoring of leucine metabolism as a marker for protein synthesis and amino acid oxidation on a repeated basis in the intact fetus.

**ISOTOPE DILUTION METHOD FOR QUANTITATIVE GAS CHROMATOGRAPHY -
MASS SPECTROMETRY OF HYDROXY AND KETO ACIDS IN URINE.**

E. Y. Osei-Twum and O. A. Mamer, The Biomedical Mass Spectrometry
Unit, McGill University, Montreal, Quebec H3A 1A3.

Introduction.

The work described here involves primary hyperoxaluria which is a general term for two rare genetic disorders characterized biochemically by the continuous synthesis and excretion of excessive oxalic acid.

In type I (glycolic aciduria), the oxalic acid is excreted together with large quantities of glyoxylic and glycolic acids. Alpha-ketoglutarate:glyoxylate carbonylase activity has been implicated in this disorder¹.

In type II (glyceric aciduria), large amounts of glyceric acid, which is formed from the reduction of hydroxypyruvate, is excreted. The hydroxypyruvate is thought to accumulate because of reduced leukocyte D-glyceric dehydrogenase activity¹.

The existing methods for the analysis of these hydroxy and keto acids involve enzyme assay for each compound; in the case of hydroxypyruvate, one does not exist.

We are working on a method, part of which is described here, which will analyse for all five organic acids in a single GC-MS run.

Methods.

Synthesis of the Internal Standards. 2,2-²H₂-glycolic and 3,3-²H₂-glyceric acids were synthesized by diazotizing perdeuterated glycine and 3,3-dideuteroserine, respectively.

X = Y = D, Glycine

X = H, Y = CD₂OD,
Sérine

X = Y = D, Glycolic Acid

X = H, Y = CD₂OD,
Glyceric Acid

Extraction and Silylation of Organic Acids. Aqueous solution of, or urine containing the five hydroxy and keto acids was spiked with deuterated internal standards. The sample was then treated as shown in the opposite scheme. The TBDMS derivatives are then analysed by GC-MS.

Results and Discussion.

The sodium borodeuteride reduction afforded the monodeuterated glycolic and glyceric acids from glyoxylic and hydroxypyruvic acids, respectively. EI spectra

show intense $[M-t-Bu]^+$ ion for the TBDMS derivatives of all the hydroxy acids. The ammonia CI give very interesting results; glycolic acid shows the $[M+H]^+$ ion as the most abundant. On the other hand oxalic acid gives the $[M+NH_4]^+$ as the base peak. This indicates that oxalic acid-TBDMS is a poorer proton acceptor than ammonia. The mass spectrum below is that of glycolic acid consisting of $NaBD_4$ -reduced glyoxylic, glycolic- d_0 , and glycolic- d_2 .

Selected ion monitoring was performed on a urine extract of the hydroxy acids after silylation. The ions at m/z 305, 306, 307 for glycolic acid, 336 and 338 for oxalic acid (^{12}C and $^{13}C_2$), and 449 and 450 for glyceric acid were monitored. The SIM TIC below shows the three compound at 9.05 min. for glycolic acid, 9.60 min. for oxalic acid, and 15.2 min. for glyceric acid. The glyceric acid is known to extract poorly. The isotope dilution technique, however, corrects for this.

DETERMINATION OF ^{13}C -, ^{15}N -, AND ^2H -ENRICHMENT USING CAPILLARY GAS CHROMATOGRAPHY - REACTION INTERFACE / MASS SPECTROMETRY (GC-RIMS)

Donald H. Chace and Fred P. Abramson

The George Washington University Medical Center, Washington, D.C., 20037

We have expanded the ability of a capillary gas chromatographic-reaction interface mass spectrometer technique (GC-RIMS) from the selective detection¹ of ^{13}C , ^{15}N , and ^2H (D) to quantify their enrichments. The microwaved-powered reaction interface converts materials from their original forms into small molecules whose mass spectra serve to identify and quantify the nuclides which make up each analyte¹. The presence of carbon, nitrogen, and hydrogen is followed by monitoring the isotopic variants of CO_2 , NO , and H_2 . Chromatograms showing only enriched ^{13}C and ^{15}N are produced by subtracting the abundance of naturally occurring isotopes from the observed $M + 1$ signal. A selective chromatogram of HD is obtained by measuring HD at m/z 3,0219 with a resolution of 2000. Mole enrichment of ^{13}C or ^{15}N is quantified by measuring the ratio of enriched $^{13}\text{CO}_2$ to $^{12}\text{CO}_2$ or enriched ^{15}NO to ^{14}NO .

When isotope dilution studies are done in biological experiments, one usually has a fixed amount of an unlabeled, endogenous compound and a variable, small amount of its labeled analog. Phenytoin was the test molecule for these experiments because: isotope ratio measurements in RIMS do not depend on structure; phenytoin is commercially available in a variety of isotopic forms; and our familiarity with its chemical properties. Prior to an isotope dilution study, an analyst must decide how much labeled compound is to be administered so that it can be detected and quantified in the presence of its unlabeled analog. The quantity of label administered is determined in part by the method and its detection limits for enrichment. To reduce any alteration in pool sizes, the concentration of a labeled compound is kept low. Therefore, a method with the ability to detect low levels of enrichment is preferred. We have carried out a series of experiments to determine the characteristics of GC-RIMS in measuring ^{13}C - and ^{15}N - enrichment as well as the detection limits of deuterium.

In separate experiments, either [2- ^{13}C -, 1,3- $^{15}\text{N}_2$]- (99 atom %, Cambridge Isotopes), [2,4,5- $^{13}\text{C}_3$]-, (90 atom %, Cambridge Isotopes), or [ring-D- 10], (99 atom %, MSD Isotopes)- phenytoin was added to 0.5 μg , 5 μg , and 50 μg of phenytoin to produce mole ratios ranging from 0.00059 - 0.494. For deuterium experiments, 2.5 μg of [ethyl D₅]-primidone (98 atom %, KOR Isotopes) was also added to each sample as an internal standard. Samples were derivatized by extractive ethylation using tert-butylammonium hydroxide and ethyl iodide in methylene chloride. The derivatives were reconstituted in toluene to produce a final volume of 100 μL . One μL of this derivatized extract was analyzed by GC-RIMS thus yielding 5, 50, or 500 ng of unlabeled phenytoin on column.

A Varian Model 3300 gas chromatograph equipped with a Varian Model 1075 split/splitless injector was used with a 30 meter DB-5, 0.25 mm i.d., 0.25 μm film thickness, capillary column (J & W). Ultra pure carrier grade helium fitted with high purity stainless steel regulators was operated at 38 - 40 psi to produce a helium flow of 1 or 2 mL/min. The injector temperature was 265°C and the initial column temperature was 80°C. Following injection of a 1 μL sample, the chromatograph was programmed at multiple rates up to 250 °C. All experiments were carried out on a Dupont 21-492 mass spectrometer which was equipped with a Trek Model 667 power supply. This power supply was controlled by a Teknivent data acquisition interface, software, and an IBM XT Model 286 computer.

Selective detection of ^{13}C was achieved using SO_2 as the reactant gas and monitoring $^{12}\text{CO}_2$ at m/z 44 and $^{13}\text{CO}_2$ at m/z 45. The isotopic contribution of $^{13}\text{C}^{16}\text{O}_2$ and $^{12}\text{C}^{17}\text{O}^{16}\text{O}$ at m/z 45 from unenriched material was 1.19% which is equivalent to its natural abundance. A chromatogram showing only enriched ^{13}C can be generated using Equation 1.

$$\text{Eq.1} \quad \text{Enriched } m/z \text{ 45} = \text{Measured } m/z \text{ 45} - [0.0119 * \text{Measured } m/z \text{ 44}]$$

Selective detection of ^{15}N was achieved using SO_2 as the reactant gas and monitoring ^{14}NO at m/z 30 and ^{15}NO at m/z 31. The isotopic contribution of $^{15}\text{N}^{16}\text{O}$ and $^{14}\text{N}^{17}\text{O}$ at m/z 31 from unenriched material was determined experimentally to be 0.440%, slightly greater than the theoretical 0.403%. We used this factor and equation 2 to generate a RIMS capillary chromatogram showing only ^{15}N -enriched substances.

$$\text{Eq.2} \quad \text{Enriched } m/z \text{ 31} = \text{Measured } m/z \text{ 31} - [0.00440 * \text{Measured } m/z \text{ 30}]$$

Selective detection of deuterium was achieved using H_2 as the reactant gas and monitoring HD at m/z 3,0219 with a resolution of 2000. A D- enriched chromatogram could not be generated because H_2 , the reactant gas, was greatly off scale. However, the natural abundance of deuterium is low and this means a calculation similar to equations 1 and 2 is not needed.

For each sample derivatized and analyzed, the mole enrichment was obtained by calculating the ratio of moles of ^{13}C , ^{15}N , or D present in labeled diethylphenytoin in excess of natural abundance to moles of ^{12}C , ^{14}N , or H present in the mixture including both unlabeled and labeled diethylphenytoin.

Enrichment of ^{13}C - or ^{15}N - labeled phenytoin was determined using GC-RIMS by measuring the ratio of the area under the peak at the retention time (r.t.) of diethylphenytoin (14.6 min.) in the enriched isotope chromatogram (generated using equation 1 or 2) to the area under the same peak in $^{12}\text{CO}_2$ or ^{14}NO chromatogram (representing total $^{12}\text{CO}_2$ or ^{14}NO). The observed mole ratio of D-labeled phenytoin to D-labeled primidone was also calculated in a similar manner. These enrichment data can also be manipulated using conventional mathematical expressions such as the atom % excess (A.P.E.) and the $\delta/\text{‰}$ (delta per mil).

The enrichments found at 3 concentrations of phenytoin were plotted against the calculated enrichments for ^{15}N and ^{13}C . A regression analysis was performed using a weighting of $1/y^2$ on the data set for each isotope. The reproducibility of RIMS was determined by analyzing 6 replicates each of samples with calculated mole enrichments of 0.008, 0.00198, and 0.0095 for ^{13}C , ^{15}N , and D, respectively, in the presence of 500 ng of phenytoin on column.

The experimentally determined ^{13}C enrichment for 500, 50, and 5 ng of unlabeled phenytoin on column was linear with a correlation coefficient of the entire data set of 0.96. The slope of this regression was 1.29 indicating that the determined ^{13}C enrichment corresponds closely to the calculated enrichment. The coefficient of

variation for the analysis of a sample at a calculated mole enrichment of 0.008 was 3%. As little as 10, 3, and 2.5 ng of ^{13}C -labeled phenytoin were detected in the presence of 500, 50 and 5 ng of unlabeled phenytoin, respectively. The lowest detectable mole enrichment for ^{13}C labeled phenytoin was 0.0028. This is equivalent to a calculated atom % excess (A.P.E.) 0.28 or a δ ‰ of 234.

As with ^{13}C , the experimentally determined ^{15}N -enrichment for 500, 50, and 5 ng of unlabeled phenytoin was found to be linear with a correlation coefficient of the entire data set was 0.98. The slope of the regression was 0.95 indicating that the determined ^{15}N enrichment corresponds closely to the calculated enrichment. The coefficient of variation for a sample representing an calculated mole enrichment of 0.002 was 6%. As little as 0.3 ng of ^{15}N -labeled phenytoin was detected in the presence of 500, 50, or 5 ng of unlabeled phenytoin. The lowest mole enrichment detected was 0.00059 which is equivalent to a calculated A.P.E. of 0.059 or a δ ‰ of 148.

A segment of a RIMS chromatogram showing ^{14}NO at m/z 30 and ^{15}NO at m/z 31 for 0.3 ng of ^{15}N -labeled phenytoin in the presence of 50 ng of unlabeled phenytoin is shown in Figures 1a and 1b. An enriched ^{15}N chromatogram computed using equation 2 is shown in Figure 1c.

To evaluate the linearity of the deuterium analysis, the experimentally determined ratio of D-labeled phenytoin to D-labeled primidone was calculated and plotted against the calculated mole ratio. The correlation coefficient of the entire data set was 0.92 with a slope of the regression of 0.6. These results indicate that the quantity of ^2H -labeled phenytoin detected corresponds linearly with the quantity of D-labeled phenytoin added. Because the internal standard is not an isotopic variant of the analyte, the slope is not expected to be unity. The coefficient of variation of a sample representing a mole enrichment of 0.009 was 4%. The detection limits were 1 ng of D-labeled phenytoin in the presence of 500 ng of unlabeled phenytoin. The enrichment could not be experimentally determined although a theoretical mole enrichment of 0.00096 for this mixture was calculated. In practice, D-enrichment can be evaluated from the ratio of deuterium to carbon in each peak.

RIMS offers several advantages over conventional GC/MS methods in that it is a structure-independent technique for determining isotope ratios. Not only can RIMS quantify enrichment of a preselected set of compounds of interest but also any other compound present in a chromatogram which had become enriched through metabolism. This makes RIMS versatile. GC-RIMS also has the ability to quantify enrichment of more than one isotope simultaneously, e.g. ^{13}C , ^{15}N . Another characteristic of GC-RIMS is that the mass spectra enriched compounds can be obtained by turning off the reaction interface power, repeating the chromatographic analysis and analyzing the mass spectra at the retention time of the enriched compound found using RIMS. Multiple collector isotope ratio instruments lack this capability. Reproducibility is 3-6%. The limits of detection are 100 fold poorer than that available from on-line combustion GC-multiple collector isotope ratio mass spectrometers, however we show good quantitation for mole enrichments low enough to enable many biological experiments.

QUANTIFICATION OF THIODIGLYCOL IN URINE AFTER MUSTARD GAS EXPOSURE.
E.M. Jakubowski, C.L. Woodard, M.M. Mershon, T.W. Dolzine, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, Edgewood, MD. 21010-5425.

A new assay has been proposed to quantify thiodiglycol, a major breakdown product of mustard gas, in urine by gas chromatography-mass spectrometry (GC-MS) using heptafluorobutyric anhydride (HFBA) derivatization. Mustard gas was allegedly used during the Iran-Iraq conflict in 1984. Conclusive chemical verification was not possible at that time due to the presence of high levels of thiodiglycol in control urines.¹ Subsequent reports have indicated thiodiglycol levels in control urines may be low enough to be useful in verifying mustard gas exposure.^{2,3} Our objective was to develop a reliable, portable assay for thiodiglycol that would verify mustard gas exposure. Reliability was increased by maximizing analyte recovery during sample preparation, stabilizing the thiodiglycol against oxidation, and preventing against contamination. The assay was made more portable by using electron ionization on a benchtop instrument. Verification of mustard exposure using thiodiglycol would be possible only if control levels of thiodiglycol are shown to be very low. Therefore, a data bank of human urine control levels was started.

In the first phase of the study, spiked human, rat, or guinea pig urine (1 to 500 ng/mL) served as samples. Sample preparation consisted of incubation with glucuronidase, acidification to pH 2, evaporation with N₂ at 90°C, derivatization with an excess of HFBA, and then extraction into ethyl acetate. A Hewlett-Packard GC-MSD with a DB5 (30m) capillary column was used for separation and detection in the selected ion monitoring mode. Derivatization of thiodiglycol with HFBA produced the di-heptafluorobutyric acid ester (di-HFBA) in 95% yield. The molecular ion at m/z 514 of the thiodiglycol derivative was not used because of low abundance. Instead, the analyte ions at m/z 300 and 301 were used for quantification along with m/z 309 of the deuterated internal standard. These ions represented loss during fragmentation of one of the two HFBA substituents present on the molecule. The di-HFBA thiodipropanol standard was monitored using ions m/z 328 and 542. Standard curves (1, 5, 10, 50, 100, and 500 ng/mL thiodiglycol) were prepared using an internal standard approach. Both thiodipropanol and dg-thiodiglycol were used as internal standards.

The second phase of this study consisted of animal exposure to mustard gas by both subcutaneous injections and by vapor exposure. Rats were exposure subcutaneously at two doses. Each group of twelve rats received either 450 ug/kg or 750 ug/kg mustard with collection and analysis of the urine for thiodiglycol. A separate group of twelve rats served as a control. Urine was collected in 4 and 8 hour intervals from the rats for two weeks post-exposure. Several chemical and physical methods of stabilizing the urine were attempted during the rat study. Guinea pigs were exposed to a mustard saturated vapor over a small area of their back (4-6 cm²) for two to ten minutes. A single urine specimen was collected from the guinea pigs at 24 hr post-exposure.

Both internal standards yielded linear relationships over the entire concentration range. Precision using the deuterated internal standard ranged from 15% RSD (percent relative standard deviation) at 1 ng/mL to 2% RSD at 500 ng/mL of thiodiglycol in rat and human urine. Thiodipropanol (1 ug/mL sample) was found to prevent degradation of the analyte. Analyte recovery was better than 90% which included the 95% conversion of thiodiglycol to the di-HFBA derivative.

During the development of the assay, several other derivatives of

thiodiglycol were made such as the trifluoroacetic acetate derivative. In general, the molecular ions of thiodiglycol and its derivatized forms had very low relative abundances. Conversely, thiodipropanol and its derivatized forms yielded relatively stable molecular ions. For example, the M⁺ of underivatized thiodipropanol (m/z 150) represented 80% of the total ion abundance versus 4.5% in the case of thiodiglycol (m/z 122). One reaction that contributed to the lower abundance of molecular ion in the case of thiodiglycol was the elimination of water or its equivalent. Loss of water could have produced either 1,4-thioxane or 2-hydroxyethyl vinyl sulfide. If 1,4-thioxane was formed then the d₈-thiodiglycol under the same mass spectrometric conditions should retain all eight deuteriums. However, loss of one deuterium was noted which supported the formation of the vinyl analog of thiodiglycol. Furthermore, the relative abundance of the M⁺ for the deuterated thiodiglycol was 6.5 times that of the undeuterated species. This indicated a primary kinetic isotope effect which supported the breaking of a carbon hydrogen bond in the rate determining step. An E_{1cb} type of mechanism described the dehydration of underivatized thiodiglycol. A similar elimination reaction was observed when thiodiglycol was derivatized. However, the isotope effect dropped to 2.5 in the case of HFBA derivatives. The heptafluorobutyrate ion was a better leaving group and made a larger contribution to the elimination reaction than did the hydroxide ion.

Animal exposure to mustard has typically resulted in the production of many metabolites.^{4,5} Thiodiglycol has been one of the most accessible metabolites of mustard to quantify. Mustard injections in the rat were approximately 1/4 and 1/3 of an LD₅₀. In general, mustard at this level of exposure had no effect on the hematology or health of the animals. Determinations of thiodiglycol levels were possible for approximately a week after the subcutaneous injections. Collecting the samples over ice or the use of anti-oxidants such as nordihydroxyguairitic acid proved to be no better at stabilizing urine samples than the use of thiodipropanol alone. Thiodiglycol levels in rat urine post mustard exposure were 70.5±19.5 ng/mL (24hr) and 60.9±21.4 ng/mL (48hr) for the low dose. The higher dose of mustard produced levels of 196±109 ng/mL (24hr) and 113±58.1 ng/mL (48hr). Control levels of thiodiglycol were below detectable limits. Thiodiglycol levels in guinea pig urine after vapor exposure ranged from 34 to 185 ng/mL. Studies were also undertaken to develop a data base on human background levels of thiodiglycol in control groups. At present, background levels of thiodiglycol in urine collected from human volunteers (15 samples) have been 2 ng/mL or less. These results have indicated that thiodiglycol would be a suitable metabolite to verify and monitor mustard exposure. In man mustard metabolites are eliminated only half as fast as in rats.⁴ Therefore, detection and verification of mustard contamination should be possible for up to two weeks after exposure depending on degree of exposure.

Application of FAB and Thermospray Mass Spectrometry to the Identification of Two Glucuronide Metabolites of Methapyrilene

J. O. Lay, Jr., T. A. Getek, D. Kelly, W. Slikker Jr., and W. A. Korfmacher

Food And Drug Administration, National Center for Toxicological Research,
Jefferson, Arkansas 72079 USA

INTRODUCTION

Ethylenediamine antihistamines although once widely used, may have undesirable toxicological effects. Methapyrilene is reported to be a rat hepatocarcinogen (1). Pyrilamine induces unscheduled DNA synthesis (2). For this reason, we have developed mass spectral methods for the identification of metabolites of ethylenediamine antihistamines as well as metabolites from other less problematic compound classes (3-5).

We report the characterization of two glucuronide metabolites of methapyrilene, (from mouse-hepatocytes) using TS and FAB/MS. One metabolite was incompletely separated (HPLC) from more abundant components presumed to be from the biological matrix. This problem is typically encountered in the identification of radiolabeled metabolites in biological systems. Because of the complementary nature of the TS and FAB mass spectra it was possible to ascertain that the metabolites had the same molecular weight as likely glucuronide metabolites, that a glucuronide substituent was present, that the glucuronidation occurred remote from the dimethylamine moiety, and that the metabolites differed by the metabolic loss of a single methyl group.

EXPERIMENTAL

FAB mass spectra were obtained with a Kratos MS-50 equipped with an M-Scan fast atom source and gun. FAB ionization employed 10-keV xenon atoms. Approximately 0.5 μ g of sample was loaded on a copper target after 2-3 μ l of thioglycerol matrix liquid.

Thermospray mass spectra were obtained using a Delsi Ribermag RC10-10C equipped with a Vestec TS controller and a Delsi TS source. A liquid carrier composed of 80/20 methanol/0.5M aqueous ammonium acetate was used at a flow rate of 1.5 ml/min. The TS conditions were control temperature 118C, tip 207C, and block 237C. Approximately 5 μ g of sample was injected in 10 μ l.

Metabolites were generated from suspension-cultures of isolated mouse-hepatocytes dosed with methapyrilene hydrochloride (specific activity 50 mCi/mmol). The metabolites were isolated, purified and quantified according to previously published HPLC (6) and scintillation methods.

RESULTS AND DISCUSSION

Two methapyrilene metabolites had HPLC retention characteristics similar to those of other glucuronide metabolites. Prior to mass spectral analysis these HPLC fractions were further purified (C-18 SEP-PAK) to remove salts from the HPLC system. Signal levels in the FAB spectra of similar metabolites have been reduced when this step was omitted (3).

Methapyrilene glucuronide

Initial FAB/MS analysis of the major metabolite HPLC fraction, showed a series of cation adduct molecule ions at m/z 454, 476, 492, 498, 514, and 530 corresponding to $[MH]^+$, $[MNa]^+$, $[MK]^+$, $[MNa_2-H]^+$, $[MNaK-H]^+$, and $[MK_2-H]^+$. Major ions were also observed at m/z 409, and 278 and 233. The ion at 409 daltons corresponds to loss of dimethylamine, and has been shown to be a characteristic cleavage for ethylenediamine antihistamines (4). Based on this loss, glucuronidation of the antihistamine occurred remote from the dimethylamine moiety. The ion, at m/z 278 corresponds to loss of the glucuronide sugar (176 daltons), and is reported to be a primary and initial loss from the FAB produced protonated molecules of many glucuronide metabolites (7). The other ion, m/z 233, corresponds to loss of both the glucuronide sugar and dimethylamine moiety.

The TS mass spectrum also showed a protonated molecule, albeit much

weaker relative to m/z 278 (sugar loss). Loss of a dimethylamine moiety (45 daltons) was not observed using TS ionization. A weak ion at m/z 233 was also observed via TS/MS, suggesting sequential loss of the sugar and dimethylamine.

Desmethylmethapyrilene glucuronide

FAB and TS/MS analysis of the other HPLC fraction initially showed major ions at m/z 371 and 391 (FAB) or 388 (TS), not corresponding to a glucuronide or any other known metabolite. Closer examination of the TS spectra revealed weak ions at m/z 440 and 264 corresponding to the protonated molecule, and subsequent sugar loss from a glucuronide of desmethylmethapyrilene. Reexamination of the FAB spectrum also revealed an ion at m/z 440 whose time dependence in mass/time plots differed significantly from the more abundant ions at m/z 371 and 391. By selecting a scan so as to minimize the unwanted signals (m/z 371 and 391) with respect to the suspect protonated molecule (m/z 440), it was possible to produce a FAB spectrum with minimal contribution from the biological matrix. The protonated molecule, and a signal corresponding to the loss of methylamine (m/z 409) were then observed. A difference of 14 daltons relative to the major metabolite, as well as the loss of 45 daltons (methylamine) are very suggestive of demethylation of the major metabolite to produce the minor one. Thus the metabolite in this HPLC fraction appears to be desmethylmethapyrilene glucuronide. Although this compound was apparently not resolved from other major components even using two HPLC separation steps, structural assignment was possible because of the complementary nature of the fragmentation observed in the FAB and TS mass spectra.

CONCLUSION

The fragmentation observed in the thermospray and FAB mass spectra of the glucuronide metabolites of this ethylenediamine antihistamine were utilized advantageously for the identification of the metabolites. The complementary nature of the fragmentation was especially useful in samples showing high levels of extraneous unwanted signals, and we expect this phenomenon will apply to other metabolite identification problems as well. The two mouse-hepatocyte metabolites were identified as methapyrilene glucuronide, and desmethylmethapyrilene glucuronide. Finally, these results are consistent with previous reports that the characteristic fragmentation pathways in the FAB mass spectra of related antihistamines, including other ethylenediamines (3,4), behave more or less independent of either minor structural changes associated with metabolism or the small differences in molecular structure which occur between members of a given antihistamine class. The existence of these antihistamine class-specific fragments in FAB mass spectra significantly aid the interpretation of spectra obtained from metabolism studies, especially in studies such as this one where the presence of unwanted signals from the biological matrix may obscure analytically useful ions.

The haloalkane nematocide 1,2-dibromo-3-chloropropane (DBCP) was used extensively as a soil fumigant prior to the observation of oligospermia and infertility in male pesticide formulators exposed to DBCP. In experimental systems DBCP is a carcinogen, nephrotoxin, testicular-toxin and is mutagenic to *Salmonella typhimurium* TA100. Toxicology studies have inferred a role for glutathione (γ -glutamyl-cysteinylglycine; GSH) dependant metabolism in DBCP-related target-organ toxicities, however, the nature of the reactive intermediate(s) and their mechanism of biogenesis have not been well defined chemically.

Fast-Atom Bombardment Tandem Mass spectrometry (FAB/MS-MS), represents a powerful tool in the structural elucidation of GSH conjugates¹, and when combined with the use of stable isotopically-labelled substrates, the information thus derived provides a unique insight into the chemical nature of the reactive intermediate(s) and their mechanism of biogenesis. Here we report the identification of five GSH conjugates of DBCP by MS/MS techniques and employ a per-deutero- analog of DBCP (D₅-DBCP) as a mechanistic probe to address the metabolic events in the formation of these conjugates.

Experimental: GSH conjugates excreted in the bile of rats administered DBCP (80mg/kg), or D₅-DBCP were converted to their N-benzoyloxycarbonyl-dimethylester derivatives¹, separated by HPLC and examined by FAB/MS-MS. Collision-induced dissociation (CID) daughter ion spectra of the MH⁺ ions of metabolites were recorded on a VG 70 SEQ hybrid tandem instrument of EBQQ geometry, equipped with an Ion-Tech fast atom gun, and a VG11/250 data system. CID was performed in the first (rf-only) quadrupole employing argon as a collision gas (2×10^{-6} Torr) and collision energies of 20-30 eV. Daughter ion spectra were recorded via the data system in the multi-channel-analysis mode and subsequently mass measured.

Results and Discussion: Five biliary GSH conjugates derived from DBCP were identified as: S-(2,3-dihydroxypropyl)glutathione (**1**), S-(3-chloro-2-hydroxypropyl)-glutathione (**2**), 1,3-bis-(S-glutathionyl)-propan-2-ol (**3**), 1-(S-cysteinylglycine)-3-(S-glutathionyl)-propan-2-ol (**4**) and S-(2-hydroxypropyl)glutathione (**5**). Under CID conditions structurally informative fragment ions were observed for **1** - **5**, the origins of which are depicted in Figure 1 and 2. **1** (Figure 1), **2** and **5** displayed characteristic fragment ions arising from expulsion of methylglycine (-89u; ion **a**) or the derivatized γ -glutamyl moiety (-277u; ion **e**). Further fragmentation of ion **e** with elimination of HSX (where X represents the conjugated xenobiotic) afforded an ion at m/z 159 common to **1**, **2** and **5**. The identity of each of these conjugates was confirmed by reference to the CID spectra of authentic standards. For high mass glutathione conjugates **3** and **4**, collision gas pressures of 7×10^{-6} Torr were required to yield structurally informative fragment ions. In the case of **3** (Figure 2) ions arose from two losses of methylglycine (-89u) to afford ions at m/z 906 (ion **a**) and 817 (ion **a'**), or via elimination of the γ -glutamyl moiety (ion **e**). Significant fragmentation was also observed adjacent to either sulfur, and a number of ions at low mass (< 500u) were common to **1** and **3**. Upon administration of D₅-DBCP conjugates **1-4** displayed full deuterium retention. Conversely, **5** retained only three deuteriums indicating an oxidative step in its genesis. The results indicate that the bioactivation of DBCP to GSH conjugates proceeds almost exclusively by conjugative processes. The chemical nature of the conjugates and full deuterium retention in **1-4** implicates the intermediacy of a reactive episulfonium ion in the bioactivation of DBCP.

A SCREENING STRATEGY FOR THE DETECTION OF DERIVATIZED GLUTATHIONE CONJUGATES BY TANDEM MASS SPECTROMETRY (MS/MS).

Paul G. Pearson, William N. Howald, Sidney D. Nelson and Thomas A. Baillie.

Department of Medicinal Chemistry, School of Pharmacy, University of Washington,
Seattle WA 98195.

Conjugates of the endogenous tripeptide glutathione (γ -glutamyl-cysteinyl-glycine; GSH) may arise from the interaction of GSH with reactive electrophilic species, which are generated metabolically from drugs or other xenobiotics. Analytical strategies to isolate and characterize GSH conjugates are important as a knowledge of the structure of the conjugate provides a unique insight into the chemical nature of the transient electrophilic species from which it is derived. We have recently demonstrated the analytical utility of an aqueous phase derivatization procedure to confer excellent chromatographic and collision induced dissociation (CID) MS/MS properties upon GSH conjugates¹

The objective of the present investigation was to exploit a characteristic fragmentation pathway observed for derivatized GSH conjugates (loss of glycine methylester; -89u), to facilitate their identification by a class-specific constant neutral loss screening strategy. As model compounds for this investigation we chose GSH conjugate metabolites of acetaminophen, trichloroethene, N-methylformamide (NMF) and 1,2-dibromo-3-chloropropane (DBCP). The analytical utility of this approach was evaluated by identification of GSH conjugates of NMF and DBCP isolated from biological matrices.

Experimental: 1,2-Dichlorovinylglutathione (**1**), oxidized GSH (**2**) S-(N-methylcarbamoyl)glutathione (SMG; **3**), S-(2,3-dihydroxypropyl)glutathione (**4**), 3-(S-glutathionyl)acetaminophen (**5**) and 1,3-bis(S-glutathionyl)-propan-2-ol (**6**) were converted to N-benzyloxycarbonyldimethylester derivatives. Daughter ion spectra were recorded on a VG 70 SEQ tandem hybrid instrument (EBQQ geometry) as previously described¹. CID was performed in Q₁ and neutral loss screening undertaken by scanning B and Q₂ at a constant mass offset of 89u. NMF and a trideuteromethyl analog (400mg/kg) were co-administered to male BALB/c mice; SMG (**3**) and its trideutero-variant excreted as biliary metabolites were derivatized, purified by HPLC and examined by neutral loss scanning. In a similar experiment, **4** excreted in the bile of rats administered DBCP (80mg/kg) was identified by analogous MS/MS techniques.

Results and Discussion: The general applicability of this technique was established by characterising a total of six derivatized GSH conjugates of diverse chemical structure by MS/MS techniques. Structurally-informative fragment ions were observed in the CID spectra of **1** to **6**; in each case the most intense daughter ion arose by elimination of glycine methylester (-89u) as exemplified for **3** (Figure 1C). Constant neutral loss scanning, for this transition permitted identification of **3** (Figure 1B) and **4**, as biliary metabolites in mice or rats, administered NMF or DBCP respectively. The selectivity of this approach is illustrated by comparison of the conventional FAB spectra of **3** (Figure 1A) with that obtained by constant neutral loss scanning (Figure 1B). In conclusion, the conversion of GSH conjugates to their N-benzyloxycarbonyldimethylester derivatives conferred excellent chromatographic properties and induced characteristic MS/MS (CID) fragmentation pathways. These diagnostic fragments provided detailed structural information and facilitated class-specific neutral loss screening to identify derivatized GSH conjugates derived metabolically from xenobiotics of diverse chemical structure.

ANALYSIS OF BENZO(A)PYRENE METABOLITES BY
CONTINUOUS-FLOW FAB/MS

Teffer, Y., Baird, W.M., Smith, D.L.,
Purdue University, West Lafayette, IN 47907

The carcinogen benzo(a)pyrene requires metabolic activation to ultimate carcinogenic derivatives before it binds to macromolecules and causes cancer induction. The study of the multiple pathways of metabolism of benzo(a)pyrene is thus essential to understanding the mechanism of carcinogenesis. The metabolites of benzo(a)pyrene include phenols, diols, tetrols, and the water soluble glucuronic acid, sulfate and glutathione conjugates. Identification of the conjugates by electron impact or chemical ionization mass spectrometry has been difficult because these metabolites are involatile and thermally unstable. Although fast atom bombardment mass spectrometry (FAB/MS) has proven useful for analyzing a wide variety of involatile or thermally labile substances, detection limits are not low because of the characteristically high level of background signals. For this reason, we have investigated the potential of continuous-flow FAB/MS as a means of identifying metabolites of benzo(a)pyrene.

A Kratos MS-50 double focusing mass spectrometer was used for mass spectrometric analyses. An Applied Biosystems microbore pump was used to deliver 2 μ l/minute of a 5% aqueous glycerol solution through a 3 m, 0.075 mm id fused silica capillary tube. The continuous-flow probe tip, which was kept at 45-50°C for all measurements, was constructed in our machine-shop. The standard, benzo(a)pyrene-3-sulfate was dissolved in 5% aqueous glycerol and injected using a one microliter loop injector.

The continuous-flow FAB mass spectrum of the sulfate conjugate shows a strong signal at m/z 347, corresponding to the acid anion as well as another strong fragment ion signal at m/z 267 (Fig. 1). When 100 ng of this sulfate was injected, a signal to noise ratio (S/N) of 60 was achieved. In addition to giving substantially improved S/N, the continuous-flow probe also gives a significant increase in the absolute signal level.

Daughter ion MS/MS spectra have been used frequently to establish parent-daughter relationships which are very useful for determining molecular structures. In addition, MS/MS often give increased selectivity and reduced detection limits. A linked scan (E/B) of the parent ion m/z 347 of the sulfate conjugate gave a daughter ion at m/z 267 as the only daughter ion (Fig. 2). The other peaks in the daughter ion spectrum were background fragment ions from glycerol. The peak at m/z 267 is formed by cleavage of the oxygen-sulfur bond with charge retained on the hydrocarbon portion.

The present studies show that subnanomolar quantities of sulfate conjugates of benzo(a)pyrene can be detected easily by continuous-flow FAB/MS. This provides the sensitivity required for the analysis of these substances when isolated from cell culture. We have also shown that MS/MS can be used to establish definite relationships between fragment ions and parent ions. This feature will be important when we analyze complex mixtures, such as cell extracts. The presence of a strong molecular ion and a characteristic fragment ion enables us to use selected ion monitoring in our LC/MS work.

CHARACTERIZATION OF THE BILIARY METABOLITES OF THE HEPATOTOXIC MONOTERPENE PULEGONE BY TANDEM MASS SPECTROMETRY (MS/MS).

David Thomassen*, Paul G. Pearson, and Sidney D. Nelson.

Departments of Pharmaceutics* and Medicinal Chemistry, School of Pharmacy, University of Washington, Seattle, WA 98195.

Conjugation to the tripeptide glutathione (γ -glutamyl-cysteinyl-glycine; GSH) constitutes a major pathway for the detoxification of electrophilic metabolites of protoxic compounds. Thus, structural elucidation of GSH conjugates provides a unique approach to the identification of transient reactive species derived metabolically from foreign compounds.

Pulegone is a hepatotoxic monoterpene constituent of the folklore abortifacient Pennyroyal Oil. Significant hepatocellular GSH depletion is induced by pulegone in experimental systems and its toxicity can be enhanced by prior depletion of hepatic GSH (Gordon *et al*, 1982). Hence, the hepatotoxicity may be mediated by the metabolic generation of electrophilic intermediate(s), which become conjugated with GSH. The objectives of the present investigation was to isolate and characterize biliary GSH conjugates of pulegone by fast-atom bombardment tandem mass spectrometry (MS/MS).

Experimental: GSH conjugates excreted in the bile of rats, following co-administration of ^{14}C -pulegone and a $^2\text{H}_3$ analog (1:1) were converted to their N-benzoyloxycarbonyldimethyl ester derivatives, purified by preparative RP-HPLC and analyzed by FAB / MS (Pearson *et al*, 1988). Metabolites were identified from their MH^+ ion twin isotope clusters (derived from $^2\text{H}_0$ - and $^2\text{H}_3$ -pulegone) observed in their respective FAB mass spectra. Daughter ion spectra of the MH^+ ions were recorded on a VG 70 SEQ hybrid tandem instrument of EBQQ geometry, equipped with an Ion-Tech fast atom gun. Collisionally activated decomposition (CAD) was performed in the first (rf-only) quadrupole, with argon as a target gas (2×10^{-6} Torr) and collision energies of 20-40 eV.

Results and Discussion: Three distinct GSH conjugates were detected, based on HPLC mobility, molecular weights and CAD daughter ion spectra. Molecular species with weights of 617, 619, and 621, corresponded to GSH attached to the elements of oxidized, unchanged and reduced pulegone, respectively. These conjugates displayed uniform fragmentation characteristics, with principle pathways consisting of elimination of glycine methylester (-89u), or the xenobiotic moiety to afford protonated GSH (470u) (see example in figure 1).

In addition to these simple GSH conjugates several metabolites were identified which apparently contained structural elements of glucuronic acid (GLU) as well GSH; mixed diconjugates of this type have not previously been reported. A metabolite with $\text{MH}^+ = 812/815$ (corresponding with $^2\text{H}_0$ and $^2\text{H}_3$ label, respectively) displayed collisionally induced losses of glycine methylester (-89u) and methyl glucuronate (-190u, assignment confirmed by fragmentation of simple glucuronides of hydroxypulegone); ions at m/z 470 (GSH) and 154 (reduced pulegone) were present as well (figure 2). By the use of MS/MS, in conjunction with isotopic labeling, we have determined that pulegone is bioactivated to three distinct electrophilic intermediates, which may each contribute to the hepatic necrosis caused by this agent.

Figure 1. Daughter ion spectra of m/z 622 and 625. This twin ion cluster had been recognized in the regular FAB mass spectrum of a radioactive HPLC fraction obtained from bile of rats treated with $^2\text{H}_0$ - and $^2\text{H}_3$ -labeled pulegone. The moiety X (insert) contains the elements of reduced pulegone. Note that protonated GSH (m/z 470) is the most prominent daughter ion.

Figure 2. Daughter ion spectra of a diconjugate of $^2\text{H}_0$ (top) and $^2\text{H}_3$ pulegone (bottom), which was isolated from rat bile. The loss of 190u from the respective MH^+ ions is indicative of (methyl ester of) glucuronic acid, whereas m/z 470 corresponds to GSH. The origin of other diagnostic ions is indicated.

RAPID SCREENING OF NEONATAL WHOLE BLOOD FOR VARIOUS METABOLIC
DISORDERS BY FAB-MS/MS

Naoki Kodo, Daniel L. Norwood, and David S. Millington
Division of Pediatric Genetics and Metabolism
Duke University Medical Center
Box 3028, Durham, NC 27710

It is well documented that specific acylcarnitines increase in concentration in biological matrices as a result of inherited disorders of fatty acid and branched chain amino acid catabolism. In this study, a method was developed to obtain diagnostic acylcarnitine profiles from neonatal whole blood adsorbed onto filter paper (PKU cards) and from umbilical cord blood. We also investigated the feasibility of screening for inherited metabolic disorders in the neonatal period.

To recover acylcarnitines from "PKU cards", one dried blood circle, corresponding to approximately 50 μ l whole blood, was cut out, chopped and extracted ultrasonically for 20 minutes with methanol (1 ml). The extract was filtered onto a reverse-phase cartridge (C18, 0.1 g) and eluted with 2 ml methanol. The filtrate was evaporated and the residue treated with methanolic-HCl prior to analysis by FAB-MS/MS. Umbilical cord blood plasma (400 μ l) was mixed with methanol (400 μ l), centrifuged and the supernatant applied to a C18 cartridge (0.6 g) and treated as described for the blood-spot extracts.

Samples were analyzed by FAB-MS/MS using a triple-quadrupole (TRIO-3, VG Masslab, UK). Xenon gas was used for the primary atom beam, argon was employed as the collision gas (0.2 - 0.5 uBar) and the collision energy was 15eV. The instrument was set up to detect precursors of m/z 99; these are predominantly the molecular cations of acylcarnitine methyl ester¹. Thus, the new scan function generates a "metabolic profile" of acylcarnitines which would detect about 12 known inherited metabolic diseases and perhaps identify some new disorders.

Application of the method to neonatal blood spots is shown in Figure 1. Normal blood (Fig. 1A) and post-mortem blood from a child who died of unexplained causes ("SIDS", Fig. 1B) was spotted onto the PKU cards before extraction. The normal blood shows numerous interesting signals, with a weak signal at 218 corresponding to the normal metabolite, acetylcarnitine. The blood from the "SIDS" case showed a profile dominated by the M^+ ions of medium-chain length acylcarnitines, e.g. m/z 274 (hexanoyl) and 302 (octanoyl). This profile is diagnostic of medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, one of the most common metabolic diseases and frequently associated with SIDS. The profile in Fig. 1C is from the original PKU card of a child with a confirmed diagnosis of MCAD. A useful diagnostic profile was observed although the card had been stored 6 months at 20° C. The effect of storage on the recovery of acylcarnitines has not been determined.

Normal and diagnostic plasma acylcarnitine profiles of propionic acidemia and isovaleric acidemia are compared in Fig. 2. The profiles from the affected children are very clear. It would appear that FAB-MS/MS is a very efficient screening technique when neonatal blood is available. At present, PKU cards are the most readily available source. The preliminary results are encouraging and studies are in progress to optimize the recovery of acylcarnitines.

URINARY EXCRETION PATTERN OF DICARBOXYLIC ACID AND ACYLCARNITINES IN THE PATIENTS TREATED WITH CALCIUM HOPANTENATE.

Isamu Matsumoto, Masahiro Matsumoto, Tomiko Kuhara, Toshihiro Shinka, Yoshito Inoue and Takashi Ohkura

Department of Biochemistry, Institute of Human Genetics, Kanazawa Medical University, Uchinada, Ishikawa 920-02, Japan

Urine extracts from two patients who were suspected to exhibit acute toxicity of calcium hopantenate [calcium D-(+)-4-(2,4-dihydroxy-3,3-dimethyl-butyramido) butyrate hemihydrate] were analyzed by means of gas chromatography-mass spectrometry (GC/MS) and fast atom bombardment mass spectrometry (FAB/MS). The patients excreted a large amount of medium chain dicarboxylic acids and its carnitine esters, and they were presenting with an episode of Reye like syndrome.

Patient

Case 1. The patient was a 3-year-old boy . On the 2nd year of life, he was admitted to hospital because of his speech delay and hyperactivity, and diagnosed as Autism. He had been treated with 1.5g/day of calcium hopantenate. 3 Months later, he developed a fever and vomiting and further developed to coma in the next morning. He recovered with glucose and sodium bicarbonate treatment.

Case 2. The patient was a 10-year-old girl. At 9-year-old, she was admitted to hospital with abnormal emotion, and had been treated with 1.5g/day of calcium hopantenate. After 3 months, she had developed a fever, vomiting, convulsion and coma, and admitted to hospital. On the next morning, she had developed polypnea and hyperanmonemia (> 400µg/dl). She was doubted Reye's syndrome. After 10 days, her clinical abnormalities were recovered completely.

Methods

Analysis of urinary organic acids.

Urinary organic acids were extracted with diethylether at acidic condition. The organic layer was trimethylsilylated and analyzed using a JEOL DX-300 gas chromatograph-mass spectrometer assisted with a JMA 3500 data acquisition system. The chromatographic separation was carried out on a fused silica capillary gas chromatograph column (25 m x 0.32 mm i.d., 1.0µm film thickness), which was coated with methyl silicone (Quadrex Corporation, Conneticut, USA). The oven temperature was started from 100°C and raised at a rate of 8°C/min to 290°C. Electron impact mass spectra were recorded at an ionizing voltage of 70eV.

Analysis of acylcarnitines

To 1 ml urine was added 10µg D₉-Isovalerylcarnitine as an internal standard, which was mixed and applied to a 0.9 x 4 cm glass column of Bio Rad AG-1X8 (200-400 mesh, Cl⁻ form) anion exchange resin. Acylcarnitine fraction was eluted from the column with 6 ml deionized water. The effluent was collected in a glass test tube and the content was lyophilized. To the dry residue was added 100µl of the methanol and acetylchloride (7:3) mixture for methylation, which was then allowed to stand for 2 hours at room temperature. Sample aliquots of 2µl were analyzed by FAB mass spectrometry at low resolution.

FAB/MS was performed using a JEOL JMS-DX303 mass spectrometer and JMA-DA5000 data acquisition system. Argon was used for the reagent gas. The electron accelerating voltage was 3 KV, GUN voltage 6KV and ionization current was 20mA. Glycerol was used for matrix. Spectra were recorded between m/z80 and 800 at a scan speed of 10s decade⁻¹ and a resolution of 1500. Each ion intensity was calculated from an average of 10 scans.

Result

The excretion of adipic acid, suberic acid, sebacic acid, dodecanedioic acid and 3-hydroxydodecanedioic acid were substantial at clinical conditions, with a concomitant increase of 3-hydroxyhexanoic acid, 5-hydroxyhexanoic acid and dehydrosebacic acid. Lactic acid, 3-hydroxybutyric acid and acetoacetic acid were also excreted in large excess (Fig. 1), and huge amount of acetyl, dehydrosebacyl and sebacylcarnitine were excreted. Suberyl, octanoyl, butyrylcarnitine were also excreted in excessive amounts (Table 1). All the above unusual metabolites disappeared in urine extracts from the patients after recovery.

Discussion

Oxidation of fatty acids is an essential energy supply for cell, when glucose availability is decreased or an impairment of gluconeogenesis. In those hypoglycemic conditions, the massive concomitant excretion of dicarboxylic acids (dicarboxylic aciduria) are observed.

Seven inborn errors of fatty acid catabolism have been described to date:

- (1) systematic carnitine deficiency (SCD);
- (2) hepatic carnitine palmitoyl transferase deficiency (hepatic CPT deficiency);
- (3) long chain acyl-CoA dehydrogenase deficiency (LCAD deficiency);
- (4) medium chain acyl-CoA dehydrogenase deficiency (MCAD deficiency);
- (5) short chain acyl-CoA dehydrogenase deficiency (SCAD deficiency);
- (6) riboflavin responsive defects of β -oxidation;
- (7) multiple acyl-CoA dehydrogenase deficiency (MAD deficiency, GA II)

In our patients, large amount of acylcarnitines were excluded, so the possibility of (1) and (2) are eliminated. The possibility of (3)-(7) are also diminished, because large amount of medium chain monocarboxylic acid carnitine esters are excluded in those patients but not in our patients.

Possible explanation for the dicarboxylic aciduria in the patients treated with calcium hopantenate is the inhibition of coenzyme A synthesis, since calcium hopantenate is known to cause the pantothenic acid (a precursor of coenzyme A) deficiency in animals. The other explanation is the inhibition of mitochondrial acylcarnitine translocation system by hopantenate. In the block of translocation system, fatty acid is oxidized by microsomal α -oxidation system followed by peroxisomal β -oxidation to produce medium chain dicarboxylic acids. Since adipic and suberic acid could not be transport into mitochondria from cytosol. These dicarboxylic acid are accumulated in the cell in the patients. On the otherhand, sebacic acid (C_{10} dicarboxylic acid) can be transported from cytosol to mitochondria as carnitine ester and oxidized by mitochondrial β -oxidation. The disturbance of acylcarnitine translocation causes the accumulation of sebacylcarnitine.

CHARACTERIZATION OF ORGANIC NITROXIDE RADICALS BY MASS SPECTROMETRY

Brian J. Sweetman, P.S.R. Anjaneyulu, Albert H. Beth and James V. Staros
Departments of Pharmacology, Biochemistry, Molecular Physiology and Biophysics
Vanderbilt University, Nashville, TN 37232-6600

There are a plethora of stable organic free radical nitroxides available for studies of macromolecular systems of biological importance, such as membranes, for studying drug-receptor interactions in pharmacology and as contrast enhancers in medical NMR imaging applications. Structurally, these stable nitroxides are heterocyclic, secondary amine N-oxides which have no hydrogen atoms attached to the carbon atom α to the nitrogen. Because of this structural feature, disproportionation of the nitroxide to nitron and hydroxylamine is minimized and stability of the nitroxide is enhanced. Many of the stable nitroxides available commercially fall into a small number of structural classes, such as 2,2,6,6-tetramethylpiperidinoxyl nitroxides (TEMPO spin labels), the 4,4-dimethyl-2,2-disubstituted-oxazolidinoxyl nitroxides (DOXYL spin labels) and the 5,5-dimethyl-2,2-disubstituted-pyrrolidinoxyl nitroxides (PROXYL spin labels). There is a need to characterize adequately new spin labels which have been synthesized for specific applications in biochemistry, pharmacology and medicine. Little has been described concerning the mass spectrometry of such nitroxides.

Nitroxide spin labels are stable organic radicals which are detectable by EPR spectroscopy and have seen wide use in biochemistry as probes of the dynamic state of macromolecules or of molecular aggregates, e.g., membranes. Many substituted nitroxides are available to address a diversity of biological questions. We have been interested specifically in characterizing by mass spectrometry compounds containing the DOXYL moiety. Simple 1,1 dialkyl DOXYLS, under electron impact ionization, give spectra showing abundant structural information. Their FAB spectra also yield much structural information and show a unique molecular ion cluster pattern containing M^+ and MH_2^+ as the abundant species, which are attributed to the nitroso oxonium radical cation and the protonated hydroxylamine, respectively. We have also characterized using FAB-MS, several labile, very polar bifunctional bis (sulfosuccinimidyl) DOXYL derivatives as their di-sodium salts, and their stable isotope-labelled analogs. These polar, membrane-impermeant bifunctional spin-labelled DOXYLS, bis(sulfo-N-succinimidyl) doxyl-2-spiro-4'-pimelate (BSSDP), bis(sulfo-N-succinimidyl) DOXYL-2-spiro-5'-azelaate (BSSDA) and [^{15}N , $^2H_{16}$] BSSDP have been synthesized as probes to study the rotational dynamics of the anion-exchange channel in intact human erythrocytes using EPR spectroscopy. These polar di-sodium sulfonates have been characterized by FAB-MS using glycerol as matrix and yield meaningful molecular ion data in both the positive and negative ion modes. The isotopic distribution in the dicarboxylic acid precursor to BSSDP, [^{15}N , $^2H_{16}$]-2-spiro-4'-pimelic acid was determined using high resolution electron impact mass spectrometry. This was synthesized from 4-keto pimelic acid.

The positive ion FAB spectrum of BSSDP shows low abundance ions at m/z 660 (MH_2^+) (2 sodiums) and m/z 682 ($MHNa^+$) (3 sodiums) which apparently arise by conversion of the nitroxide to the hydroxylamine in the FAB process. The spectrum of the homologous azelaate BSSDA shows corresponding peaks. The corresponding negative ion FAB spectrum show peaks having m/z values at $[M-Na+H]^-$ (one sodium) and $[M-Na]^-$ (one sodium), attributed to hydroxylamine sulfonate and sulfonate anions, respectively. [^{15}N , $^2H_{16}$] BSSDP gave a negative ion FAB spectrum (not shown), showing the appropriate mass increment of 17 daltons, compared to BSSDP, with a major cluster of peaks centered at m/z 653.

We have acquired and studied the mass spectra of 3 isomeric DOXYL stearic acids substituted at the 5, 12, and 16 positions on the stearic acid chain. Spectra obtained using high resolution electron impact ionization or fast atom bombardment with positive or negative ion extraction were compared. The EI spectra are characterized by very low abundance molecular ions, ions arising by the loss of the elements of the DOXYL ring, and in each case, ions formed by cleavage of the carbon-carbon bond alpha to the ring junction with the loss of either sidechain and with substantial concomitant loss of the nitroxide oxygen. The corresponding FAB+ spectra obtained using 3-nitrobenzyl alcohol as matrix also show the same cleavages alpha to the ring junction as do the EI spectra, but loss of the nitroxide oxygen is not a major process. The base peak in each spectrum at m/z 88 was attributed to the C_4H_9NO cation. Each FAB spectrum showed a relatively abundant peak at MH_2^+ , attributed to the protonated hydroxylamine, together with a peak at M^+ , attributed to the nitroso oxonium radical cation. MH_2^+ increases substantially during the bombardment suggesting that the reduction of nitroxide radical occurs as a consequence of the FAB process. The negative ion FAB spectra show M^- and $[M-H]^-$ as the most abundant peaks with little or no structural information, except for ions at m/z 312 and 297 arising by the loss of C_4H_8O and C_4H_8O-O from M . Despite the formation of MH_2^+ , the FAB spectra are preferable to the EI spectra, since they do give clear molecular ion information and fragment ions are more easily related to the parent structure than in the EI spectra. These spectral features are illustrated below in the FAB+ spectrum of 5-DOXYL stearic acid using 3-NBA as matrix.

FAB-MS is the preferable ionization mode both for the characterization of more polar or polycyclic nitroxides, which are generally not amenable to EI-MS and for the characterization of small nitroxides which are amenable to EI-MS, because the peaks observed in FAB-MS relate more closely to the parent structure.

DETERMINATION OF INTACT STYRENE-7,8-OXIDE IN BLOOD USING AUTOMATED GAS CHROMATOGRAPHY-MASS SPECTROMETRY. PATRICK W. LANGVARDT and RICHARD J. NOLAN, The DOW CHEMICAL COMPANY, MIDLAND, MI., 48674.

Styrene-7,8-oxide (SO) is a putative metabolite of styrene, an important monomer used in the production of plastics and resins. Styrene is thought to undergo enzymatic oxidation to SO via microsomal cytochrome P-450. SO then reportedly undergoes spontaneous and enzymatic hydrolysis to phenylethylene glycol (PG) or is conjugated with glutathione. PG is then further oxidized, or conjugated with glucuronic acid. SO is not an excreted metabolite of styrene, but has been reported to have been measured in blood after exposure of individuals to styrene vapors.¹

A rapid, specific method for the determination of SO in rat blood was needed to support pharmacokinetic studies. These studies required sequential, small (~0.1 ml) blood samples from individual animals. This sampling regimen would allow the kinetics to be defined in individual animals and minimize the number of animals needed. In addition, the analytical method needed selectivity, particularly in regard to possible or known metabolites of styrene such as phenylacetaldehyde or PG. Previously reported methods either did not have the desired 10 ng/ml detection limit, required larger volumes of blood, or required time-consuming derivatization procedures, possibly compromising the specificity of the measurement (reported derivatization procedures call for liquid-liquid extraction of the minor metabolite, SO, from samples containing the major metabolite, PG, followed by conversion of SO to PG prior to derivatization).

The method described here involves a single extraction of SO from whole blood samples as small as 100 µg and subsequent analysis by gas chromatography/mass spectrometry. Whole blood is obtained from the animal through an indwelling silastic cannula and placed directly into a tared vial containing ~100 mg anhydrous sodium sulfate. Benzene containing 0.3 µg/ml 1-phenylpropylene oxide (PPO) as an internal standard is added immediately. Samples are mixed vigorously and centrifuged. The liquid is then transferred to autosampler vials for GC/MS analysis.

During method development studies SO was found to undergo some thermal rearrangement to phenylacetaldehyde when using conventional heated split or splitless injection techniques. The use of cold on-column injections (1 µl) eliminated that problem. A 4 m x 0.53 mm retention gap was used ahead of a 10 m x 0.25 mm DB-5 (1 µ film) analytical column. The column temperature was held at 35°C for 0.25 min, then programmed at 40°C/min to 220°C. SO eluted at 4.98 min and PPO at 5.17 min (see figure).

The 70 eV electron impact mass spectra of aromatic epoxides contain characteristic fragment ions at m/z 89 and 90 which have been attributed to the formation of ring expansion products.² The relatively unique and abundant fragment ion at m/z 89 was chosen for quantitation to improve the selectivity of the method. A Hewlett-Packard 5970B GC/MS system equipped with a 7673 autosampler and a reduced-pressure interface device was used.

² H. E. Audier et. al., *Tetrahedron Letters*, 2077-2082, (1966)

The internal standard response factors at m/z 89 were equivalent from 0.01 to 1.0 $\mu\text{g/ml}$. If possible, higher samples were diluted into that range, otherwise bracketing calculations were necessary. Recovery of SO spiked into whole blood was $91\% \pm 6\%$ (SD, $n=21$). The half-life of SO in whole rat blood at 22.5 and 37°C was 84 and 26 min, respectively., but SO concentrations in benzene extracts were unchanged after six days. SO was also found to be stable ($94\% \pm 2\%$) in corn oil dosing solutions under ambient conditions for 39 days. Recovery of SO in blood (1.0 $\mu\text{g/g}$) passed through silastic cannulae was $91\% \pm 4\%$.

CHARACTERIZATION OF AN INTERMEDIATE IN THE BIOSYNTHESIS OF CHOLESTEROL

Cholesterol is a precursor to important endocrine hormones as well as bile acid surfactants, and a component of cellular membranes. All the enzymes required for the synthesis of cholesterol from lanosterol, the first steroid intermediate, are bound to the endoplasmic reticulum. The net change from lanosterol to cholesterol encompasses the loss of three methyl groups at the 4 α , 14 α , and 14 β positions, the reduction of the side chain double bond and the isomerization of the nuclear double bond from carbon 8 to carbon 5. These five modifications to lanosterol are accomplished with molecular oxygen, NADPH, NADH and NAD⁺ as the required substrates and cofactors. A plausible 19-step sequence involving nine distinct enzymes can now be written as a result of organic synthesis of presumed intermediates, generation of intermediates in microsomes, further enzymatic conversion of these intermediates to cholesterol, solubilization and purification of membrane bound enzymes and reconstitution of groups of enzymes into artificial membranes.

The initial attack upon the lanosterol precursor is by a cytochrome P-450 mono-oxygenase enzyme complex that demethylates the 14 α -methyl group from lanosterol. The 14 α -methyl demethylation occurs in three consecutive oxidative steps first to a C-32 alcohol, then to a C-32 aldehyde and then to a final undefined intermediate which undergoes decarbonylation (see Figure 1). To study this mechanism of oxidation and elimination of the 14 α -methyl substituent of lanosterol a labeled substrate, 3 β -hydroxy-[3 α -(³H)]-5 α -lanost-8-en-32-al (3), was metabolized with a rat liver microsomal preparation of the lanosterol demethylase P-450 enzyme. The metabolism was stopped with methanol and the metabolite was extracted with petroleum ether and purified by a normal phase HPLC method. The chromatogram contained 4,4-dimethyl-5 α -cholest-8,14-dien-3 β -ol(Z) and an unknown polar peak.

Initial attempts to analyze the unknown intermediate by GC/MS was inconclusive because the material decomposed on the column. Direct probe EI analysis resulted in the spectrum shown in Figure 2C which is dramatically different from the spectrum for 4,4-dimethyl-5 α -cholest-8,14-dien-3 β -ol(Z) and the two synthetic standards (4) and (5), the postulated structures for the intermediate. The molecular ion was observed at m/z 458 for both synthetic standards (4) and (5) and at m/z 412 for (Z), but no molecular ion was apparent for the unknown. In addition, the fragmentation patterns are sufficiently different to indicate that the isolated intermediate has a different structure than those proposed.

For further verification of the structure, the polar intermediate was analyzed by an LC/MS interface, continuous flow fast atom bombardment (FAB) mass spectrometry (MS) interfaced to an LC. Continuous flow FAB was required because of its increased sensitivity (a factor of 10 over direct probe FAB). To further improve the sensitivity selected ion monitoring (SIM) was used to analyze significant ions [e.g. (M+H)⁺, (M+H-CH₄)⁺ and (M+H-H₂O-CH₄)⁺] (see Figure 3). The SIM experiment provided molecular weight information for the isolated intermediate.

Determination of Radiation Induced Cholesterol Oxides by On-Column²
Capillary GC-MS.² Thomas G. Hartman¹, Robert T. Rosen¹, Gerhard Maerker²
and Leon Lakritz²; Center for Advanced Food Technology¹, Cook College,
Rutgers University, New Brunswick, NJ 08903 and USDA Eastern Regional
Research Center², 600 East Mermaid Lane, Philadelphia, PA 19118.

The safety evaluation of food irradiation as an alternate means of sterilization or preservation has initiated a search for unique radiolytic products to act as indicator or tracer compounds. The search for such unknown compounds in an authentic food is extremely difficult due to its complex matrix. Therefore, model systems are being used to identify such compounds which can then be targeted in real foods.

¹³⁷Cs gamma source at a rate of .125 kGy/min. for 6-7 hours at 0-2°C. The cholesterol radiodecomposition products produced were then fractionated by TLC and analyzed using on-column injection capillary GC-MS with EI detection. This technique is the preferred method for the determination of underivitized sterol oxidation products since it is highly inert and results in library searchable EI spectra.

Compounds identified include various combinations of diol, triol, keto, epoxy and unsaturated analogues of cholesterol. The analytical data is summarized in table # 1. At least one of the compounds identified, cholesta-3,5-diene-7-one is produced by both radiolysis and as an artifact by dehydration of 7-ketocholesterol in the gas chromatograph. The use of cold on-column injection technique was shown to minimize the production of this artifact.

None of the compounds detected in this investigation were found to be useful as radiation induced "indicators" since they are also produced in foods through enzymatic or nonenzymatic lipid peroxidation pathways and in normal cooking. Apparently, the free radical reactions induced by irradiation fail to produce unique radiolytic products but rather are very similar to hydroxy radical propagation reactions which occur during lipid oxidation in foods.

¹Clinical Neurosciences Branch, NINDS, NIH and ²Section on Analytical Biochemistry, NIMH Bethesda, MD 20892 USA

INTRODUCTION

The high incidence of a variant of amyotrophic lateral sclerosis - Parkinsonism complex (ALS-PD) in three foci in the Pacific region (the Mariana island of Guam, the Kil peninsula of Japan and Irian Jaya) may be associated with consumption and/or medicinal use of cycads. β -methylamino-L-alanine (BMAA), a minor constituent of cycads, has recently been shown to cause a behavioral dysfunction, clinical signs of motor-neuron deficiency and, pathological changes consistent with those seen in the human disease (1). To examine the link between cycads and ALS-PD we have developed assays for the quantification of BMAA in a variety of samples including plant material, foods prepared from cycads, brain tissue, CSF and plasma. We have employed 1) GC/MS of the di-N-pentafluoroacyl derivative of BMAA *iso*-butyl ester and 2) continuous flow L-SIMS MS/MS of BMAA as the *iso*-butyl ester

MATERIALS AND METHODS

GC/MS ASSAY Formation of the *iso*-butyl ester of BMAA (*via* the methyl ester) before analysis permitted acid-base extraction as well as concentration of the sample prior to acylation. An Hewlett-Packard 5890 gas chromatograph and 5970 mass selective detector were used. Chromatography was performed with a split/splitless capillary inlet on a fused-silica capillary column (12 m X 0.22 mm i.d.) with a cross-linked methyl silicone stationary phase (HP1, 0.33 μ m film thickness). Samples were run in the selected-ion monitoring mode (SIM) with the base peak (m/z 190) and a second ion (m/z 365) used for quantification.. A representative SIM chromatogram for the analysis of a cycad flour extract is shown in figure 1.

Figure 1
Representative SIM chromatograms for the quantification of the di-N-pentafluoroacyl derivative of BMAA *iso*-butyl ester in a plant sample. Two ions (i.e. m/z 190 & 365) are monitored for BMAA while the others (i.e. m/z 193 & 368) correspond to the same fragments for the stable isotopomer added as standard.

L-SIMS ASSAY The *iso*-butyl ester of BMAA was formed and analyzed directly. Data were acquired on a Finnigan Mat TSQ-70 triple stage quadrupole mass spectrometer equipped with a Finnigan Mat prototype Bioprobe ion source and a Phrasor cesium ion gun. An HPLC pump with a microflow adaptor and pulse dampener was used to deliver mobile phase through a 0.5 μ L loop injector, through the vacuum manifold flange and into the ion source. Cesium ions (5-6 keV) were used to bombard the surface of the probe tip (where capillary tubing was continuously delivering mobile phase). A water/glycerol mobile phase (80/20) was used and delivered at a rate of $\approx$ 8 μ L/min. Argon was used as the collision gas with a pressure of 0.5 millitorr in the collision chamber. For quantification, the BMAA *iso*-butyl ester parent ion $[M+H]^+$ (i.e. m/z 175 for BMAA and m/z 178 for the deuteriated isotopomer) were selectively transmitted through the first quadrupole every 0.1 secs and the corresponding daughter fragments (m/z 44 & 47) were then alternatively monitored. Centroid data were collected and stored for analysis. Representative integrated ion currents (figure 2) were obtained by using routine chromatographic data processing techniques.

RESULTS AND CONCLUSIONS

Comparison of Assay Methods Comparison of the results show an excellent quantitative correlation ($r^2 > 0.98$). However, at this stage, GC/MS offers a significantly lower limit of detection (i.e. $\approx$ 10 pg injected on column) when compared with continuous flow L-SIMS MS/MS (maximum sensitivity for the detection of BMAA *iso*-butyl ester was approximately 1 ng injected). Recent findings from our laboratory suggest that the application of a focused cesium ion beam will result in a significant improvement in the detection limit of the L-SIMS approach. (See abstract by Wang T-C *et al.* - this meeting.)

BMAA in Cycads and ALS Although we have demonstrated the presence of BMAA in the seeds of cycads levels are relatively low. Processing of the seeds results in a fall in BMAA content to levels of 1-100 μ g/g of flour. Based on these data, consumption of 1 kg of processed flour would only deliver a maximum dose of about 1 mg/Kg. However, when demonstrating BMAA neurotoxicity in primates, oral administration of doses of 100-350 mg/kg were employed. We conclude that diet is unlikely to deliver neurotoxic quantities of this compound to the central nervous system. Further, studies with neurons in culture suggest that BMAA levels in toxic cycad extracts are orders of magnitude lower than those required to demonstrate toxicity when the pure compound is employed. If a causal link does exist between cycads and ALS-PD on Guam, other constituents are likely the key neurotoxic agent(s).

Figure 2: Quantification of BMAA as the *iso*-butyl ester in a plant sample by continuous flow L-SIMS selected reaction monitoring. Three repeat injections are shown. The parent ion $[M+H]^+$ (i.e. m/z 175 for BMAA and m/z 178 for the deuteriated isotopomer) were selectively transmitted through the first quadrupole every 0.1 secs and the corresponding daughter fragments (m/z 44 & 47) were then alternatively monitored.

Determination of Ethyl Carbamate (Urethane) in Commercial Protein Based Condiment Sauces (Soy Sauces) by Gas Chromatography-Mass Spectrometry.
Thomas G. Hartman, Robert T. Rosen and Joseph Lech
Center for Advanced Food Technology, Cook College, Rutgers University, New Brunswick, N.J. 08903

Commercial protein based condiments such as soy and teriyaki sauces are available as traditional fermented products or as synthetic nonfermented substitutes. Both types of products were analyzed for the presence of ethyl carbamate, a well known carcinogen, since the potential exists for its formation in the fermentation process. Initial attempts to analyze these products using GC with FID or nitrogen selective detection were unsuccessful due to the presence of interfering matrix derived compounds. Therefore, we have developed a mass spectrometric method for the determination of this compound in these matrices.

Samples were spiked with *t*-butyl carbamate internal standard, extracted with methylene chloride and concentrated prior to GC-MS analysis. Experiments were conducted using electron ionization and chemical ionization (methane and isobutane) modes. The characteristic ion masses from ethyl carbamate produced by electron ionization could not be reliably used for detection or quantitation due to the presence of matrix derived interferences. The methane CI spectrum of ethyl carbamate contained a protonated molecular ion at m/z 90 and a prominent fragment ion at mass 62. However, the mass chromatogram for m/z 62 contained numerous interferences and hence there was no advantage in monitoring this ion. Isobutane CI produced a strong protonated molecular ion exclusively and was interference free. Therefore, for quantitation, the ratio of the protonated molecular ions produced during isobutane chemical ionization for ethyl carbamate and *t*-butyl carbamate (m/z 118) were monitored. Samples testing positive were confirmed by EI. Table # 1 summarizes the analytical data obtained from several commercially obtained fermented and nonfermented products.

The analytical GC-MS methodology developed provides for rapid and reliable determination of ethyl carbamate in protein based condiment sauces. The method proved interference free in spite of the simple extraction procedure employed. A detection of ethyl carbamate at twice the signal to noise ratio in the m/z 90 mass chromatogram provides sensitivity down to at least 1 ppb. Confirmation limits in the EI mode are 10 ppb. Selected ion monitoring provides increased sensitivity over mass chromatography, but a limit of detection of 1 ppb was deemed adequate. The extraction efficiency, recovery of internal standard and response factors were determined. The extraction efficiencies for the *t*-butyl carbamate internal standard and ethyl carbamate averaged 87.6 % and 88.7 % respectively ($n=12$). Fermented products were found to contain ethyl carbamate at levels ranging from 36 ppb for a "lite" soy sauce to 102 ppb for a traditional soy sauce. No trace of ethyl carbamate was found in the nonfermented substitute condiments.

NJAES Publication No. J10535-1-89, Caft is an initiative of the New Jersey Commission on Science and Technology.

Table # 1 Analysis Results on Condiment Samples

<u>Sample</u>		<u>Conc. Ethyl Carbamate ppb</u>
Traditional Soy Sauce (fermented)	---	86 - 102
"Lite" Soy Sauce (fermented)	---	36 - 42
Teriyaki Sauce (fermented)	---	86 - 89
Nonfermented Soy Sauce	---	ND

AMMONIA CHEMICAL IONISATION GCMS ANALYSIS OF
POLYHYDROXY AMINES FROM PLANT SOURCES

Robin T. Aplin, Daniel P.M. Coffey, George W.J. Fleet,
The Dyson Perrins Laboratory, Oxford University, Oxford, U.K., and
Linda E. Fellows, The Royal Botanic Gardens, Kew, London, U.K.

A number of polyhydroxy cyclic amines e.g. castanospermine (I) have shown potential for the control of the AIDS virus.^{1,2} As part of an ongoing plant screening program based on both taxonomic considerations and enzyme inhibition studies a number of potential sources of natural polyhydroxy cyclic amines have been identified.

We have developed a routine procedure for the analysis of crude plant extracts for these compounds. Following ion-exchange chromatography the crude extract is silylated using Sigma Silyl A and the resulting O-trimethyl silyl ethers are analysed by ammonia chemical ionisation capillary GCMS on a VG Masslab TRIO 1 "Bench Top" mass spectrometer. In contrast to their EI mass spectra which fail to show the molecular ion the ammonia CI mass spectra show abundant MH⁺ ions together with three characteristic fragmentations corresponding to the type of substituent present.

- (i) MH⁺ - 90 Secondary hydroxyl group.
- (ii) MH⁺ - 104 CH₂OH alpha to nitrogen
- (iii) MH⁺ - 206 CHOCH₂OH alpha to nitrogen

Such fragmentations allow the ready identification of the common structural isomers: the pyrrolidines II and III; the hydroxy piperidines IV and V and the isomeric castanospermines VI and alexins VII as well as providing molecular weight and structural data on new compounds (e.g. VIII) obtained during the crystallisation of an alexin from Castanospermum australe.

DETERMINATION OF MONO (2-ETHYLHEXYL) PHTHALATE IN HUMAN SERUM ALBUMIN.
J. Zamecnik, J.-C. Ethier, D.B. Black, G.A. Neville, Health and Welfare
Canada, Bureau of Drug Research, Ottawa, Ontario, K1A 0L2.

The Canadian Red Cross Society requested the Health and Welfare Canada to determine levels of mono (2-ethylhexyl) phthalate (MEHP) and bis (2-ethylhexyl) phthalate (DEHP) in commercial preparations of Human Serum Albumin (HSA) [1-8]. HSA is prepared from blood plasma by either older precipitation fractionation or newer gel permeation chromatography. The latter products were suspected of having high concentrations of MEHP. Whole blood is usually collected into polyvinylchloride bags, which contain 30-40% by weight of DEHP (not very toxic) [5]. DEHP leaches into the collected blood and is enzymatically converted to more toxic MEHP [5]. A GC-MS assay was developed to confirm MEHP values, obtained through a published HPLC method.

GC-MS assay: Standards were prepared by spiking the phthalate free HSA solutions (1 mL) with MEHP at concentrations 0.2, 2, and 20 µg/mL. Phenobarbital (0.5 µg/mL) was used as an internal standard. The mixture was acidified with 0.1M citric acid buffer (pH 2) and extracted with 3 mL of toluene, spun at 2500 rpm to break an emulsion, dried under stream of nitrogen at 40°C. An excess amount of ethereal diazomethane was added and the mixture evaporated and reconstituted with methanol for injection in GC-MS. Samples were treated in a similar fashion, 1 mL of HSA was spiked with aqueous internal standard (0.5 µg of phenobarbital). The extraction and derivatization were done as described above. Finnigan 4610 B GC-MS was used. GLC: 15 m fused silica capillary column from J&W Scientific, 0.25 mm I.D., DB-5 0.25 µm thick stationary phase; helium as a carrier gas. The injector (split 1:30) was kept at 250°C, the interface oven was at 260°C. The GLC oven was programmed from 150°C at 10°C/min. to 260°C. MS: electron impact (EI) and multiple ion detection (MID) mode. Fragments 149, 163 and 181 m/z were monitored for MEHP methyl ester and 232 m/z for methylated phenobarbital (scanned 0.25 sec./mass; 45 eV; emission current of 0.32 mA). The ion source was kept at 150°C and manifold at 80°C. A ratio of areas under fragments 163 and 232 m/z was plotted against the standard concentrations. A typical curve was linear with an equation $Y = 1.849 X - 0.313$ with a correlation coefficient 0.99995. Samples were assayed for intra- (6.34 % C.V.; n=10) and inter- (8.4% C.V.; n=10) assay variation statistics.

The HPLC assay [1,4]: Standards were prepared in acetonitrile : 1% acetic acid (9:1), with 0.2, 2, 10 and 50 µg/mL standard points per a curve. Samples (1 mL) were extracted after addition of 2 mL of citrate buffer (pH 2) and 5 mL of toluene. The mixture was shaken, spun to break the emulsion and 3 mL aliquot was removed and dried under N₂ (@40°C). The sample was redissolved in 1 mL of acetonitrile : 1 % acetic acid (9:1). 20 µL of standard solutions and samples were injected onto a HPLC column (Dupont Zorbax ODS 4.6 mm x 15 cm). The UV detector (Milton Roy/LCD SpectroMonitor D) was set at 230 nm. The system was used in a isocratic mode with mobile phase flow of 1 mL/min. and mobile phase acetonitrile : 1% acetic acid (65:35).

The two assays for MEHP were plotted against each other (GC-MS - X and HPLC - Y). The resulting line had an equation $Y = 0.5341 X + 0.2455$ with a correlation coefficient 0.99646. The HPLC assay produced consistently lower results than GC-MS method over a tested range 0.1-50 µg/mL. A typical values found in the high MEHP content HSA ranged from 5-20 µg of MEHP per mL of HSA. The products obtained by older fraction precipitation techniques had values 10 times lower than contaminated HSA. This discrepancy has to be addressed before the HSA obtained by gel permeation technology can be released on the market.

ANALYSIS AND MASS SPECTROMETRIC IDENTIFICATION OF FOOD DYES AND THEIR SUBSIDIARY COLORED MATERIAL

Makoto Suzuki, Katsuyoshi Masuda, Hisao Oka and Ken-ichi Harada
Faculty of Pharmacy, Meijo University, Tempaku, Nagoya 468, Japan

Introduction

Many dyes are used for foods all over the world and the following eleven dyes are only permitted in Japan; Erythrosine, Phloxine, Rose Bengale, Acid Red, Tartrazine, Sunset Yellow, Amaranth, New Coccine, Brilliant Blue FCF, Fast Green FCF and Indigo Carmine. However, non-permitted dyes are also frequently detected in foods. Usually, food dyes are synthetically prepared and contain many similar components. Few mass spectrometric studies of food dyes has been reported to date because of their nonvolatility. Consequently, a combination of precise and simple chromatography and appropriate mass spectrometry is greatly required for identification of small amount of food dyes. In this paper we would like to describe the mass spectrometric features of these compounds under SIMS conditions and the optimization for TLC/MS.

Experimental

SIMS and TLC/SIMS were performed using a double focusing Hitachi M-80B mass spectrometer fitted with a M-0101 data system. Operation conditions were: primary ion, Xe^+ ; accelerating voltage, 8 kV (primary) and 3 kV (secondary). Samples were dissolved in a solution of water and each sample solution (1-5 μl) was loaded on a silver target. About 3 μl of matrix material was added to the sample on a target. Aluminum TLC precoated plates impregnated with 10% liquid paraffin in petroleum ether were used for TLC/SIMS. The employed mobile phase were methanol:methyl ethyl ketone:10% sodium sulphate (1:1:3.5) for xanthene dyes and methanol:acetonitrile:10% sodium sulphate (3:3:10) for triphenylmethane dyes. The TLC/SIMS were carried out as follows. Thioglycerol was applied around the developed spot on a TLC plate. After a few minutes magic bullet was dropped on the condensed sample zone. The plate was cut (0.6 x 0.5 cm) and introduced into ion source.

Results and Discussion

Synthetic food dyes are classified into three groups, xanthene, triphenylmethane and azo (Fig. 1). In general they have conjugated chromophores and highly polar functional groups such as carboxylic or sulphonic acid groups, as their sodium salts. Many matrices, glycerol, a mixture of dithioerythritol and dithiothreitol (magic bullet), 15-crown-5, sulfolane, diethanolamine and thioglycolic acid were attempted. Among them, magic bullet and glycerol were only effective and showed differently characteristic mass spectrometric behavior. Table 1 shows the molecular ion species of the three type food dyes using glycerol and magic bullet as the matrices under SIMS conditions. While sodium ion-eliminated ions such as $(\text{M}-2\text{Na}+3\text{H})^+$ and $(\text{M}-2\text{Na}+\text{H})^+$ were mainly formed using glycerol, normal protonated molecules $(\text{M}+\text{H})^+$ were found in magic bullet assisted spectra, which retain completely sodium ion and are very convenient for determination of their molecular weights. An additional and unfavorable feature that glycerol reduced the sample molecule to give the hydrogenated molecular ion species was observed in the spectra using glycerol as the matrix. As the results of these experiments magic bullet proved to be the most suitable for identification of these food dyes by SIMS.

TLC is the simplest chromatography and does not require special equipments. So TLC/SIMS has been widely and successfully applied to analysis of various nonvolatile and unstable compounds, and we also wished to use it. To effectively perform TLC/SIMS with good sensitivity, selection of suitable matrix, optimization of TLC conditions and prevention of diffusion of spots on TLC plate must be carried out. We have already made sure that magic bullet is suitable for ionization of food dyes under SIMS conditions and reversed phase TLC is quite effective for separation of food dyes using the two mobile phases described in Experimental section.¹⁾ Accordingly, we devised a method to reconcentrate the developed spot on TLC plate. For this purpose thioglycerol is most suitable because it has faster diffusion speed than other matrices such as glycerol and threitol. In our method thioglycerol was applied around the developed spot on TLC plate and after a few minutes the dyes was condensed to center of the spot in line with the penetration of thioglycerol. And then magic bullet was dropped on the condensed zone. The present method can provide satisfactory SIMS spectra of the above food dyes with good sensitivities (0.1-0.5 $\mu\text{g}/\text{spot}$).²⁾

Finally the established results and method were successfully applied to identification of the subsidiary colored materials of Brilliant Blue FCF and an unknown food dyes from an imported candy.

MASS SPECTROMETRIC ANALYSIS OF *IN VITRO* METABOLITES OF FLUORINATED HERBICIDES

Hideji Fujiwara*, R. Thomas Solsten, Robert C. Chott,
and Eugene W. Logusch

*Monsanto Company, Life Sciences Research Center
700 Chesterfield Village Parkway
Chesterfield, Missouri 63198*

The *in vitro* metabolism of herbicides with rat liver enzyme preparations yields important information on the types of metabolites that may be produced during *in vivo* metabolism studies. Such information can be obtained rapidly, since *in vitro* incubations can usually be completed within a few hours.

This study was focused on the *in vitro* transformation of two experimental Monsanto herbicides: dimethyl-2-(difluoromethyl)-4-(2-methylpropyl)-6-(trifluoromethyl)-3,5-pyridinedicarboxylate **1**; and 2-chloro-N-(ethoxymethyl)-N-[2-methyl-6-(trifluoromethyl)phenyl]acetamide **2**.

The *in vitro* incubations were carried out using S-9 rat liver enzymes in the presence of NADPH and glutathione. Radiolabeled substrate was used in the incubations to allow the progress of metabolism to be monitored by HPLC with radioactivity detection (HPLC/RAD). To facilitate identification, the substrate also contained an appropriate amount of ¹³C-label to provide ¹²C/¹³C "doublets" in the mass spectra of metabolites.

Metabolite structure elucidation was performed using both positive and negative ion liquid chromatography mass spectrometric (LC/MS) techniques, as well as static fast atom bombardment mass spectrometry (FAB/MS). Negative ion LC/MS can be a convenient analytical method for metabolites of fluorinated herbicides since many are readily ionized by electron capture. Most microsome constituents do not undergo electron capture and are essentially transparent to detection.

Although **1** and **2** both contain a fluorinated methyl group, their relative negative ion sensitivities were very different. Negative ion sensitivity was found to be excellent for **1** and its metabolites. Negative ion analysis of **2** and many of its metabolites provided very poor sensitivity. The latter compounds were therefore analyzed in positive ion mode. An HPLC injection typically contained 100ng-2μg of each metabolite. A simple, rapid sample clean-up and concentration greatly improved

the spectra obtained during the positive ion analyses of **2** and its metabolites.

The pyridine **1** was metabolized to six metabolites which were identified by LC/MS. The significant metabolic reactions were oxidation and ester hydrolysis of the substrate. There was no mass spectral evidence to suggest that glutathione conjugation had occurred. See Scheme 1.

The chloroacetanilide **2** was rapidly and extensively metabolized by rat liver S-9 enzymes to give nine metabolites. Seven of these were identified by LC/MS. FAB/MS was also used to confirm the structure of one of the metabolites. The significant metabolic reactions included glutathione conjugation and oxidation of the substrate. Many of the initial oxidation products underwent glutathione conjugation as the incubation progressed. See Scheme 2.

ANALYSES OF ACIDIC AND NEUTRAL CATECHOLAMINE METABOLITES IN BRAIN TISSUES,
CSF, PLASMA AND URINE.

S. Y. Chang, J. Reinhard, B. Cooper and L. C. E. Taylor, Burroughs
Wellcome Co., Research Triangle Park, NC 27709

A simple extraction method combined with high resolution EI SIR GC/MS was used to analyze homovanillic acid (HVA), 3-methoxy-4-hydroxyphenylethylene-glycol (MHPG) and 5-hydroxyindolacetic acid (5HIAA) in 1 to 10 mg of brain tissues, 200 μ l of plasma, 100 μ l of CSF or 50 μ l of urine samples.

Reagents and Chemicals - Buffer solution was 1 M sodium acetate (pH 6.0) containing 10 mM EDTA. $^{13}\text{C}_6$ -HVA (phenyl carbon) and $^{13}\text{C}_6$ -MHPG (phenyl carbon) were obtained from Cambridge Isotope Laboratories, Woburn, MA. The 5HIAA-d₂ (alpha H) was purchased from Merck Isotopes, St. Louis, MO.

Brain Tissue Homogenization - One to 30 mg of wet tissue was sonicated in 1 ml of sodium acetate buffer using an Ultrasonic Processor (W-375) at 3°C. The homogenate was centrifuged at 3,000 rpm (Servall, RT6000B) at 3° to remove tissue debris.

Extraction and Derivatization - Approximately 15 ng each of $^{13}\text{C}_6$ -HVA and $^{13}\text{C}_6$ -MHPG and 45 ng of 5HIAA-d₂ were added to brain homogenate (500 μ l), plasma (200 μ l plasma and 300 μ l sodium acetate buffer), CSF (100 μ l and 400 μ l sodium acetate buffer) or urine (50 μ l urine and 450 μ l sodium acetate buffer). To the sample mixture which contained IS and sodium acetate buffer, 60 μ l of 8 N HCl and 2 ml of 5% ethylacetate in hexane were added, mixed thoroughly, centrifuged and the organic layer was discarded. The organic solvent wash step was repeated. All neutral and acidic catecholamine metabolites (HVA, MHPG, 5HIAA and others) were extracted from this organic solvent (5% ethylacetate in hexane) washed aqueous layer with 2 ml of ethylacetate-hexane (3:2) mixture. The ethylacetate-hexane layer was transferred to 1 ml Reactivial and the solvent was removed in a nitrogen stream. The dried residue was reacted with 50 μ l of BSTFA-CH₃CN-CH₂Cl₂ (2:1:0.01) mixture at 100°C for 30 min.

Instrumentation - The instrument was operated in EI SIR mode at 6,000 resolution (10% valley). Ions were divided into 3 groups. HVA was monitored with m/z 326.14 (M⁺) and m/z 332.16 (M⁺, IS). MHPG was monitored with m/z 297.13 (M-TMSOCH₂) and m/z 303.15 (M-TMSOCH₂, IS). 5HIAA was monitored with m/z 407.18 (M⁺) and m/z 409.19 (M⁺, IS). The VG70S mass spectrometer was interface with a HP5890 GC equipped with a J&W on-column injector. The column used was DB5-30W (0.25 μ thickness).

Results - Twenty-five anatomically specific regions of cynomolgus monkey brain tissues were examined before and after 1-methyl-4-phenyl-1,2,4,5-tetrahydropyridine (MPTP) treatments. A significant change in the levels of HVA and MHPG were noted (Table 1). The method was also used to analyze brain levels of HVA, MHPG and 5HIAA in rats treated with the antidepressant bupropion which is undergoing clinical trials (Table 2).

Conclusions - A simple extraction method combined with high resolution EI SIR gave a reproducible and sensitive method for determining neutral and acidic metabolites of catecholamines in brain tissues, plasma, CSF, and urine. TMS derivatives are stable for 2 to 3 weeks and show no change in sensitivity. The method was successfully applied to numerous analyses of brain samples and other matrices.

QUANTIFICATION OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) AND THREE OF ITS METABOLITES IN RAT BRAIN BY GAS CHROMATOGRAPHY/ION TRAP MASS SPECTROMETRY.

H.K. Lim and R.L. Foltz; Center for Human Toxicology, Department of Pharmacology and Toxicology, University of Utah, Salt Lake City, Utah 84112

Introduction

MDMA (3,4-methylenedioxyamphetamine) is now known to be a serotonergic neurotoxin in several animal models such as mice, rat and nonhuman primates. We have recently reported the identification of several biotransformation pathways of MDMA in rat (1) and human (2). To further understand the contributory roles of metabolites of MDMA in MDMA-induced neurotoxicity, we now report a disposition study of MDMA in the rat brain.

Experimental

A capillary GC/PCI-MS assay for simultaneous quantification of MDMA, 3,4-methylenedioxyamphetamine (MDA), 4-hydroxy-3-methoxymethamphetamine (HMM) and 4-hydroxy-3-methoxyamphetamine (HMA) in brain tissue was developed. Isobutane was the PCI reagent gas. The assay was performed on an ion trap mass spectrometer by repetitively scanning a narrow mass range (m/z 275-290) which encompasses the ion currents for the MH^+ of the trifluoroacetyl derivatives of MDMA, MDA, HMM, HMA and the internal standard, 3,4-methylenedioxyethylamphetamine (MDE). A manifold temperature of 120°C was selected to minimize fragmentation of MH^+ ions of MDMA, MDA and MDE.

Results and Discussion

The mean recoveries of MDMA, MDA, HMM and HMA over the concentration range examined (5 and 250 ng/g) are 83.4, 86.0, 86.6 and 83.2, respectively. Calibration curves for MDMA, MDA, HMM and HMA are linear from 1 to 500 ng/g wet brain tissue (Figure 1 A-D). In each case, a correlation coefficient of 0.999 was obtained. The measured concentrations of MDMA, MDA, HMM and HMA in fortified brain tissues were within 10% of the target concentrations (Table 1). The mean coefficient of variation, both intra- and inter-assays, was less than 12% in each case. The limit of quantification of MDMA and metabolites is 1 ng/g.

Figure 2 shows ion current profiles from analysis of rat brain tissue at 3 hours after a subcutaneous dose of 10 mg/kg MDMA. The rat brain concentration-time profiles of MDMA and its metabolites are shown in Figure 3. Maximum brain concentrations of MDMA, MDA, HMM and HMA were obtained at 1, 3, 2 and 2 hours, respectively. The reported maximum decrease and recovery of the serotonergic markers following a subcutaneous dose of 10 mg/kg MDMA (3) correlate with the brain concentration-time profiles of HMM and HMA. This suggests that these phenolic amine metabolites may be responsible for MDMA neurotoxicity via oxidative stress.

INTRODUCTION

The site-specific action of the ketoxime analogs of several β -adrenergic antagonists (1) in the reduction of the intraocular pressure, which is a beneficial effect in glaucoma treatment, has recently been achieved by the topical administration of the compounds [1,2].

(1)

The mechanism of action appears to be ultimately connected to their metabolic properties, and relies on the biotransformation of these substances by enzymes present in the eye. More specifically, the iris-ciliary body is one of the major sites of the intraocular enzymatic processes [3] that may be responsible for the observed pharmacological effect of the title compounds. Propranolone oxime (Ar = 1-naphtyl, R = *i*-Pr) and alprenolone oxime (Ar = 2-allylphenyl, R = *i*-Pr) have been selected as models for more detailed studies, since these compounds have proved to be the most potent ones regarding the reduction of the intraocular pressure. The direct aim of our approach was to identify the principal route(s) of bioactivation by determination of the products of the proposed enzymatic reactions in the related ocular tissues. Mass spectrometry, especially in combination with on-line chromatographic methods of analysis such as gas chromatography (GC) and high-performance liquid chromatography (HPLC), appeared to be a sensitive and specific method that can provide means to assess the underlying metabolic processes.

Specific problems associated with the application of mass spectrometry to the identification and determination of the ketoximes and their metabolites *in vivo* include, however, the possible geometrical (E- and Z-) isomerism of the oximes, the low volatility of the compounds, and the chemical/thermal lability of certain possible intermediates. Therefore, GC-MS and thermospray (TSP) LC-MS methods have been developed and evaluated for these studies.

EXPERIMENTAL

The mass spectrometer used in the experiments was a KRATOS MS80RFA double focusing instrument (operated at 4 kV accelerating voltage), and the electron impact/chemical ionization (EI/CI) source was interfaced to a Carlo Erba MEGA Series GC (Model 5160) by direct coupling. 25 m x 0.22 mm i.d. DB-1 (bonded methylsilicon stationary phase, 25 μ m film thickness) fused silica capillary column was applied for separations. The column oven temperature was programmed during the GC-MS analyses, generally from 80 to 280 $^{\circ}$ C at 10-30 $^{\circ}$ C/min rate. On-column injections were made, and the mass spectrometer scan rate was selected to be 1 s/decade and the spectra were recorded in the *m/z* 50-500 mass range under the control of data system (DS90). Different derivatives of the analytes were prepared in order to improve their chromatographic properties and/or increase their chemical/thermal stabilities for GC. Trifluoroacetylations (TFA) were carried out with the anhydride or with N-methyl-bis(trifluoroacetamide) (MBTFA), trimethylsilylations (TMS) were achieved by the application of N,O-bis(trimethylsilyl) trifluoroacetamide (BSTFA). By carefully selecting the appropriate reaction conditions, the derivatization techniques could be used in combination, and even selective protection of the relevant functional groups was achieved. N-, and N,O-trifluoroacetyl, N,O-trimethylsilyl, and O-TMS-N-TFA derivatives were prepared and evaluated for practical applications.

The TSP LC-MS experiments were performed by the KRATOS Thermospray Option. The HPLC apparatus consisted of a Spectroflow 400 solvent delivery system and a Spectroflow 480 injector module (with 20 μ l loop). 5 cm x 4.6 mm i.d. SUPELCOSIL LC-18-DB column was applied for the separation of the analytes. The mobile phase contained an aqueous buffer solution (0.1 M ammonium acetate, 0.02 M acetic acid, and 0.02 % triethylamine), and acetonitrile (30 %, v/v) as an organic modifier. At 1.0 ml/min flow rate, optimal thermospray conditions were achieved by setting the probe, vaporizer, source, and jet temperature to 135,

165, 175, and 220 °C, respectively. The spectrometer was scanned at 3 s/decade, the calibrated mass range (PEG 600) was m/z 150-600.

In vivo experiments were carried out by topical administration of the solutions containing the ketoximes to rabbits. The animals were sacrificed 1-1.5 h after the treatment, the respective eye tissues were removed, homogenized in alkaline buffer (pH 10.0), and extracted with dichloromethane/diethyl ether.

RESULTS AND DISCUSSION

The developed GC-MS methods are useful for the identification and sensitive determination of the biotransformation product. However, separation of the oxime isomers has not been achieved under routine capillary GC conditions, although derivatives leaving the oxime hydroxyl groups intact for possible regiospecific interactions (i.e., N-TFA derivatives) have also been prepared (Fig. 1). On the other hand, both EI and CI give readily interpretable spectra. (Derivatization may even improve the fragmentation properties of these substances). TSP LC-MS provides, however, the separation of the E- and Z-isomers of the title oximes (application of a column packing material deactivated for the analysis of basic compounds is a must, and addition of a competing base to the mobile phase is advisable in order to achieve adequate chromatographic resolution), and it can also be used for the assay of the possible intraocular metabolites (Fig. 2), although (ca. an order of magnitude) lower sensitivities can be achieved, as compared to GC-MS.

The combined results have allowed the identification of the dominant intraocular enzymatic processes of the ketoxime analogs. Significant oxime isomerase activity of the tissues was found. The hydrolysis of the oximes, making the ketone (2) available to further metabolic process, and the subsequent reduction result in the formation of the aminoalcohol (3) which exerts the desired effect.

FAST ATOM BOMBARDMENT OF WARFARIN AND WARFARIN METABOLITES

D.R. Hilker, K.M. Aldous, D. Spink, F. Azzam and L. Kaminsky
New York State Department of Health
Wadsworth Center for Laboratories and Research
P.O. Box 509, Albany, New York 12201-0509

We have proposed that urinary analysis for warfarin metabolite profiles will provide information on hepatic cytochrome P-450 composition, and its susceptibility to environmental pollutants. This and other applications underscore the importance of the analysis of warfarin (I) and its metabolites, dehydrowarfarin (II), 4-hydroxywarfarin (III), 6-hydroxywarfarin (III), 7-hydroxywarfarin (V), 8-hydroxywarfarin (VI) and 10-hydroxywarfarin (VII).

WARFARIN AND WARFARIN METABOLITES

I. $R^1=R^2=R^3=H$

III. $R^1=R^2=H$, $R^3=4-OH$

IV. $R^1=5-OH$, $R^2=H$

V. $R^1=7-OH$, $R^2=H$

VI. $R^1=8-OH$, $R^2=H$

VII. $R^1=10-OH$, $R^2=H$

Current widely used methods involve GC/CIMS of the diazomethane derivatives of warfarin and its metabolites¹. A method utilizing multiple metastable peak monitoring of warfarin in plasma has been published². Recently we reported a Thermospray LC/MS method for (I) through (VII) which does not require derivatization with carcinogenic and explosive diazomethane. This method required only a two step separation before Thermospray ionization³.

In this work we show data on the FAB mass spectrometry of (I) and its metabolites on a high resolution mass spectrometer. These investigations were undertaken to provide a convenient means of confirming identifications by Thermospray LC/MS, to compare FAB analysis of warfarin with other currently used methods and to identify new or unusual metabolites.

The desorption of (I) and (II) was tested in triethanolamine, TEA, and glycerol. Both the oxygen content and the nearly completely conjugated structure of (I) and (II) suggested that these structures would stabilize a negative charge resulting from proton abstraction. The negative FAB spectra of (I) and (II) in TEA are shown in Figures 1 and 2. Both (I) and (II) gave relatively intense molecular ions. The only fragmentation is the loss of acetone from the warfarin molecule to give m/z 250. Dehydrowarfarin gives m/z 263 which represents a loss of acetyl from its molecular structure. The base peak in both Figs. 1 and 2 is due to the matrix, TEA, and this material gives an intense dimer ion at m/z 297. Other intense ions are due to a trace of CsI and RbI which remained on the probe tip after calibration. The spectra were taken on a Kratos MS-50 at 1000 RP (10X valley) scanning at 3 sec/dec from m/z 700 to n/z 30. Warfarin and dehydrowarfarin and TEA were dissolved in acetone, the acetone was evaporated and 2 μ l of the remaining TEA solutions were added to the probe. The FAB probe tip was bombarded by 5 keV Xe from a saddle field gun described in Reference 4. Data were collected as voltage readings into a Kratos DS-90 data system for subsequent processing.

Figure 1

Figure 2

Addition of a proton from glycerol or acidified glycerol to the generalized warfarin structure (I) or (II) produces a $[M+H]^+$ ion in positive ion mode. As in negative ion mode little fragmentation occurs. The ion at m/z 251 in the spectrum of warfarin represents loss of CH_3COCH_3 from the $[M+H]^+$ ion at m/z 309. The spectrum of (III) also shows a loss of CH_3COCH_3 from m/z 325, m/z 267. The ion at m/z 289 in the spectrum of (II) represents the loss of H_2O from the $[M+H]^+$ ion at m/z 307. This loss of water which also occurs to a very limited extent in the FAB spectrum of warfarin is observed in the spectra of all three compounds, (I), (II) and (III) in positive ion Thermospray³. The FAB conditions for the positive ion spectra were similar to those used for the negative ion spectra. Although no quantitative measurements were made (I) and (II) appear to desorb more efficiently as negative ions from TEA.

In order to push the detection limit of these compounds below a clinically significant level high resolution selected ion monitoring experiments were attempted. The mass range, m/z 261 to m/z 357 was calibrated using a saturated solution of CsI and RbI in glycerol. An ion at nominal mass 277, although weak occurs in both the mass calibrant and the glycerol matrix. Using the CsI/RbI calibration and m/z 277 as a lock mass 13.4 ng of warfarin were easily detected by desorption from a conventional FAB probe. The detected signal when compared against background in blank glycerol represented a detection limit of less than 2 ng of warfarin. Unfortunately this performance was not reproducible. The accurate mass of highly resolved (10,000 RP, 10% valley) m/z 305 ions of (II) was measured as 305.0818834 with 3 ppm rms error in a mixture with TEA, CsI and RbI. This measurement can be made on 2 μ g of (II) in a classical peak matching experiment. Data on further refinements in the accurate mass measurements of these compounds and on their analysis in mixtures will be presented at a later date.

Further work will involve investigating high resolution selected ion monitoring with continuous flow FAB in both positive and negative ion modes.

SIMULTANEOUS PREPARATION OF ACIDIC BASIC AND NEUTRAL URINARY CONSTITUENTS FOR GC/MS. Shoemaker, J.D., Elliott, W.H., E.A. Doisy Dept. of Biochemistry and Molecular Biology, St. Louis Univ., St. Louis, MO 63104

Urinary organic acids, amines, amino acids, sugars, purine and pyrimidine metabolites were prepared simultaneously for derivatization and gas chromatography. Urease was used to decrease the urea concentration below detectable levels. Samples were desiccated by azeotropic evaporation and triethylamine trifluoroacetate was used to maintain solubility in the anhydrous state. After derivatization with N-methyl-N-(trimethylsilyl) trifluoroacetamide, capillary GC-MS on DB-5 from 80 to 240°C with the VG Trio 2 in EI+ mode revealed creatinine tri-TMS to be a suitable internal standard. The creatinine-TMS derivative was identified by co-elution with the (methyl) tri-deuterated compound and by comparison of the mass spectra below. The d₃-creatinine was formed from d₃-creatine in the aqueous phase of the procedure as described by Edgar and Shiver (1). In contrast to their results, however, dehydration at pH 9-10 in the presence of trifluoroacetate and triethylammonium ions yielded creatinine exclusively. The method has been applied to urine samples from subjects with hydroxymethyl glutaric, propionic, methylmalonic, and 'medium chain' fatty aciduria, and generalized amino aciduria and confirmed these diagnoses. Software compatible with the multi-task RSX 11M Plus V3.0 Program supplied with the DEC Micro PDP 11/73 computer system was developed to identify peaks using the NBS Library during the 60-90 minute GC run, so that by the end of the run a printout is available of peak identities, heights and areas. Thus GC-MS metabolic screening required no more time than GC alone. Supported by NIH Training Grant HL-07050 and NIH Grant HL-07878.

SIMULTANEOUS DETERMINATION OF ACIDS AND AMINES BY GC-NCIMS.

Michael J. Avery and Gregor A. Junk
U.S.D.O.E., Ames Laboratory, Ames, IA 50011

Aliphatic amines have been successfully derivatized to imines directly in water using pentafluorobenzaldehyde (PFB) [1]; the imines were isolated using solid phase extraction and separated and measured using GC-MS [2]. This direct procedure can be extended by adding pentafluorobenzyl bromide (PFBzBr) to form esters directly of any aliphatic acids present in the water sample. Preliminary test data are presented to show that aliphatic amines and acids in water samples can be simultaneously determined with high sensitivity and selectivity.

EXPERIMENTAL

Derivatization Procedure. --A 0.5 mL aliquot of in situ oil shale retort water or test water in a 5 mL vial was spiked with 5 μ g each of CD_3NH_2 AND CD_3COOH and the pH adjusted to 8 with 0.5M borate. Then 300 μ L of acetonitrile containing 1.0 mg PFBzBr and 2.0 mg PFB was added to the vial and heated to 80°C and held at that temperature for 40 minutes. After cooling to ambient, the derivatives were isolated using a solid phase extraction cartridge containing 100 mg of C-18 bonded porous silica. The bonded silica was dried by aspirating room air through the cartridge for 5 minutes and the amine and acid derivatives eluted with 200 μ L hexane.

Instrumentation. --A Finnigan model 4000 combination GC-MS with an INCOS 2300 data system was used for all analyses of the hexane extracts. The GC-MS was operated in the negative chemical ionization (NCI) mode using methane as the buffer gas at 0.3 torr and an ion source temperature of 250°C. The acid and amine derivatives were measured using multiple-ion-monitoring and quantitated using response factors generated from the appropriate deuterated internal standard.

NCIMS behavior. -- The amine derivatives formed predominantly molecular anions under the NCI conditions of our instrument. These anions appear at m/z 209, 223 and 237 for methyl, ethyl and propylamines, respectively. The acid derivatives formed characteristic carboxylate anions. These anions appear at m/z 59, 73 and 87 for acetic, propionic and butyric acids, respectively. The deuterated internal standards produced anions three mass units higher than the respective unlabeled compounds.

RESULTS AND DISCUSSION

The sensitivity of the method for 50 ppb of ethylamine and propionic acid is illustrated in Figure 1. The high S/N and lack of any background peaks suggest that this procedure could be used at much lower concentrations.

The quantitative performance of the method was tested by spiking propionic acid and ethylamine into pure water. Deuterated acetic acid and methylamine were used as internal standards. For triplicate determinations, the precision was 3% RSD for the acid and 16% RSD for the amine. Accuracies were 11% and 26% respectively. These preliminary figures are promising and it is expected that fine-tuning of the reaction conditions can be used to improve the quantitative data.

The developed method was applied to a waste water from an in situ shale retorting process. This water sample contained aliphatic acids and amines as well as a complex variety of other compound classes, including pyridines, phenols, aldehydes, ketones and nitriles. Mass chromatograms for the derivatives of three acids and three amines are shown in Figure 2. The two peaks in the mass chromatogram labelled 'C4' correspond to the derivatives of iso- and n-butyric acids. The resolution of the fused silica capillary column used for the separation ensures that other isomeric acid and amine derivatives can be measured selectively. Quantitative values for selected acids and amines in the sample are listed in Table 1. These values are consistent with the reported composition of shale oil retort waters [3].

The demonstrated applicability of the method to low levels of aliphatic acids and amines present in waste waters and the high sensitivity and selectivity using GC-NCIMS suggest that successful application to biological fluids may be possible.

IDENTIFICATION OF MERCAPTURIC ACID METABOLITES OF ACRYLONITRILE BY TANDEM MASS SPECTROMETRY

Max J. Turner, Jr, Sara D. Held, Gregory L. Kedderis
Chemical Industry Institute of Toxicology
Research Triangle Park, NC 27709

Acrylonitrile (AN) is widely used in the manufacture of plastics, rubber, and acrylic fibers. Oral administration of AN to rats causes tumors of the brain, stomach, and Zymbal's gland. Current data on the metabolism and carcinogenicity of AN do not allow an accurate assessment of risk to exposed humans.

Metabolism studies of AN in rats and mice have demonstrated that most of the administered dose is excreted as urinary metabolites. The two major biotransformations are conjugation with hepatic glutathione resulting in excretion of N-acetyl-S-(2-cyanoethyl)cysteine, and a cytochrome P-450-mediated oxidation to 2-cyanoethylene oxide which is further metabolized to N-acetyl-S-(2-hydroxyethyl)cysteine. The epoxide metabolite 2-cyanoethylene oxide has been shown to alkylate DNA.

We are studying the metabolic disposition of AN in rats and mice and have identified the urinary metabolites of AN, quantitated these metabolites as a function of dose, and compared the metabolite profiles of the two species. The data presented here describe a method to identify the two major mercapturic acid metabolites of AN using minimal sample preparation and tandem mass spectrometry. It is hopeful that this method can be extended to monitoring these metabolites in occupationally exposed humans.

¹⁴C Male Fischer-344 rats and male B6C3F1 mice rats were administered [2,3-¹⁴C]acrylonitrile p.o. (rats 0.1-28 mg/kg, mice 0.1 - 11.7 mg/kg). Animals were placed in individual glass metabolism cages and urine and feces were collected for 72 hr. Urine was mixed with an equal volume of methanol and centrifuged to remove protein.

Mass spectral analysis was performed on a Kratos MS90MS hybrid mass spectrometer of geometry EBQQ. Pseudomolecular ions, MH^+ , were generated by methane positive ion chemical ionization. Sample introduction was by solids probe. Samples were prepared by evaporating 5 μ l aliquots of deproteinized urine in glass capillaries. The MH^+ ions were selected at 1000 resolving power by MS-I (EB), and focussed into the collision quadrupole containing xenon (2×10^{-5} torr). The daughter ions generated by CID (30 eV) were mass analyzed by scanning the analytical quadrupole from m/z 300-50 in 3 seconds. Multiple scans were acquired and combined/integrated using the raw data software facility in DS-90.

HPLC analysis of urine samples from AN dosed animals indicated the presence of four qualitatively similar metabolites in rats and mice. Peak 3 was identified as N-acetyl-S-(2-hydroxyethyl)cysteine and Peak 4 as N-acetyl-S-(2-cyanoethyl)cysteine, by comparison with spectra of authentic compounds. Figures 1 and 2 show the daughter ion spectra of the MH^+ ions of the respective hydroxyethyl and cyanoethyl mercapturic acid metabolites in mouse urine along with the spectra of the authentic compounds. The daughter ion spectra indicate that most of the ions produced by CID come from fragmentation of the cysteine portion of the molecule. Both compounds produce analogous ions from loss of H_2O (18), $COCH_2$ (42) from the N-acetyl group, $HCOOH$ (46), and $H_2NHC(O)CH_3$ (59), although the relative abundances of these ions are different in each compound.

Figure 1

Daughter ion spectra of the MH^+ ion from authentic N-acetyl-S-(2-hydroxyethyl)cysteine (lower) and from the m/z 208 ion in urine from a mouse given AN (upper).

Figure 2

Daughter ion spectra of the MH^+ ion from authentic N-acetyl-S-(2-cyanoethyl)cysteine (lower) and from the m/z 217 ion in urine from a mouse given AN (upper).

Conclusion: This method provides a rapid and specific means to screen urine for mercapturic acid metabolites of AN. By selectively monitoring one or two daughter ions from each metabolite, it should be possible to qualify/quantify these metabolites (if present) in the urine of occupationally exposed humans. Along with a better understanding of the disposition of acrylonitrile in other species, this method could provide a better assessment of exposure of people to acrylonitrile.

VINYL ANION FORMATION AND REACTIVITY:

Kraig Anderson and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

Strong bases such as alkyllithiums and lithium dialkylamides are common reagents for generating carbanions in solution.¹ In the gas phase, amide ion is the strongest base which can readily be prepared ($PA = 403.6 \text{ kcal mol}^{-1}$)², and it is frequently used to produce other ions by proton abstraction. Compounds which are less acidic than ammonia can not be readily deprotonated by NH_2^- and the formation of their conjugate bases presents a considerable synthetic challenge. Several ions of this type such as CH_3^- , $c\text{-}C_3H_5^-$, and $C_2H_3^-$ have been prepared but only one general method, decarboxylation by collision-induced dissociation has been reported to date.³

We have recently discovered a convenient chemical ionization procedure for the preparation of highly reactive vinyl anions in our flowing afterglow device. In particular, the reaction of OH^- and appropriately substituted diazirines (I), which are readily synthesized in two steps, leads to the elimination of molecular nitrogen and the formation of vinyl anions.

R, R', and R'' = H or alkyl

Using this this method we have prepared a number of mono and disubstituted vinyl anions. They are all exceedingly reactive and sufficiently basic to readily deprotonate ammonia. The

reactivity of these ions has been explored and the reactions with N_2O are given:

DETERMINATION OF THE FRAGMENTATION MECHANISMS OF ORGANOPHOSPHORUS IONS
BY H₂O AND D₂O ATMOSPHERIC PRESSURE CHEMICAL IONIZATION
TANDEM MASS SPECTROMETRY

A. Peter Snyder, C.C. Chou, and Charles S. Harden
U.S. Army Chemical Research, Development and Engineering Center
Aberdeen Proving Ground, MD 21010-5423

The literature relates that methyl phosphonates, phosphates and phosphites, e.g., dimethylmethylphosphonate (DMMP), trimethylphosphate (TMP) and trimethylphosphite (TMPI), produce fragments primarily by direct radical loss (-CH₃ and -OCH₃) from the M⁺ ion under conventional electron impact mass spectrometry (MS) or collision-induced dissociation (CID) MS/MS (1,2). Formaldehyde loss by a McLafferty-type rearrangement has also been reported (1,2,3). Isobutane chemical ionization (CI) of DMMP followed by CID has reportedly resulted in methanol, methyl and methoxy losses from the pseudomolecular ion, MH⁺ (1).

These observations have been compared with those of the daughter ion mass spectra (see Figure) of the MH⁺ from DMMP, dimethylphosphite (DMPI), TMPI and TMP. H₂O and D₂O atmospheric pressure CI tandem MS/MS of the MH⁺ and MD⁺ species show that the majority of the fragmentation mechanisms of parent ions can be described by stable molecule (not radical) loss events and a summary is presented in the Table, where H⁺ denotes the ionizing proton or deuteron.

All four species exhibit methanol and dimethylether losses from the MH⁺ and MD⁺ species; water loss is observed from DMPI. Methanol, ether, formaldehyde, and water losses were observed from various daughter ions. All four compounds form m/z 79 from MH⁺ and m/z 80 from MD⁺ in the MS/MS spectra. However, the MD⁺ MS/MS mass spectra of DMPI, TMPI and TMP also show m/z 79 indicating that there are two parallel mechanisms for the fragmentation of the pseudomolecular ions of these two species. The m/z 79 from the MH⁺ of TMP can be explained by a consecutive loss of MeOH⁺ and CH₂O. The other mechanism constitutes consecutive methoxy losses, the first being unobserved (an alternative mechanism might be a rearrangement and loss of CH₃OOCH₃) while retaining the source proton to yield either an m/z 79 or 80. From DMPI the formation of m/z 79 involves a methanol loss with either MeOH⁺ directly or MeOH by a rearrangement; the latter mechanism would not have been obvious without the D₂O experiment.

The daughter ion mass spectra showed that the m/z 47 ion was produced from the MH⁺ and MD⁺ species from all four compounds. In addition, the D₂O analysis showed the presence of m/z 48 from TMPI and TMP with intensities equal to that of m/z 47. High resolution Fourier Transform MS/MS mass spectra of (TMP)H⁺ produced two ions having a nominal mass of 47 amu with a Δm of 0.03 amu. The indications are that m/z can be PO⁺ and (HPCH₃)⁺; the mechanism(s) of the formation of the latter species are still under investigation.

MS/MS analyses of MD⁺ confirm that the ionizing proton is contained in other fragments, e.g., m/z 31, 33, 49, 65 (except TMPI) and 95 (except DMPI and TMPI). The ions at m/z 15, 29, 45 (DMMP and TMPI), 63, 93, and 109 (TMP) do not contain the ionizing proton. Methyl and methoxy neutral losses were not directly observed from the MH⁺/MD⁺ of the four compounds.

Qualitative comparison of isoelectronic molecules has provided a useful conceptual framework for the understanding of many species.¹ Indeed, a recent round of computational studies on noble gas fluoride cations^{2,3} made heavy use of isoelectronic reasoning, both "vertical" and "horizontal". In the current paper we wish to quantitate the use of isoelectronic comparisons to aid in the computational study of reaction enthalpies for isogyric and nonisogyric reactions involving HeF^+ , NeF^+ , ArF^+ , ArH^+ , HCl , HCl^+ , ClF , Cl_2 , HF , HF^+ , F_2 , H_2 and H_2^+ . We will provide a general conceptual framework and other studies, in progress, are designed to test the qualitative and quantitative utility of our approach.

The calculations were carried out ab initio using the Gaussian 82 and 86 programs.⁴ Fully optimized geometries were obtained utilizing the HF/6-31G*, MP2(fu)/6-31G** and CID(fu)/6-31G** approximations employing analytical gradients.⁴ The largest difference in the MP2/6-31G**³ and CID/6-31G** geometries is 0.044 Å; the smallest is 0.001 Å. Most of the calculated values are within 0.015 Å of the available experimental values.⁵

Normal mode vibrational frequencies were computed with the HF/6-31G* and MP2/6-31G** equilibrium structures. The MP2 and HF harmonic vibrational frequencies are larger than the experimental frequencies.⁵ The greatest overestimation is 322 cm^{-1} for F_2 ; the others are all within 250 cm^{-1} .

The CID and MP2 equilibrium structures were used to compute single - point energies with fourth (MP4SDTQ) order Møller-Plesset theory.⁴ Reaction energies were corrected for zero-point energies, basis-set superposition errors, the pressure-volume work term and temperature effects.⁴ The ZPEs were scaled by 0.89 (HF/6-31G*) and 0.93 (MP2/6-31G**) ⁴

Calculated and experimental⁶ reaction enthalpies for eight representative gas phase reactions are listed in Table I. Forty reactions were examined in all. The reactions have been divided into four categories. The reactions in category 1 (reactions 1 and 2) are isogyric *and* the reactant and product pairs are isoelectronic. In isogyric reactions the number of unpaired electrons is identical on both sides of the equation. The reactions in category 2 (reactions 3 and 4) are isogyric *and* the reactant and product pairs are valence isoelectronic. The reactions in category 3 (reactions 5 and 6) are *only* isogyric. The reactions in category 4 (reactions 7 and 8) are *not even* isogyric.

The deviations in the MP4/6-31G** and MP4/6-311G(2df,2pd) enthalpies of reaction for category 1 are generally small, ranging from about 0.5 - 3 kcal/mol. With two exceptions, both basis sets yield $\Delta H^\circ_{\text{calc}}$ values within 2.5 kcal/mol of $\Delta H^\circ_{\text{exp}}$. For the reactions in categories 2 and 3, the situation is less promising. The deviations in the MP4/6-31G** and MP4/6-311G(2df,2pd) enthalpies are as large as 11 kcal/mol. The MP4/6-311G(2df,2pd)

enthalpies of reaction are generally within 3.5 kcal/mol of the experimental enthalpies; the MP4/6-31G** values differ from the experimental values by up to 16 kcal/mol. The worst results are obtained for the nonisogyric reactions (category 4). The MP4/6-31G** enthalpies differ from the MP4/6-311G(2df,2pd) enthalpies by as much as 17 kcal/mol. The deviations in the experimental and MP4/6-311G(2df,2pd) and MP4/6-31G** enthalpies of reaction are as large as 10 and 25 kcal/mol, respectively.

CROSSED-BEAM INVESTIGATIONS OF $\text{Ar}^+ (2P_{3/2}) / \text{O}_2 (X^3\Sigma_g^-, v=0)$ CHARGE TRANSFER AT 2.75 AND 5.70 eV CM COLLISION ENERGY: Julie A. Biggerstaff and Jean H. Futrell, Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware 19716

INTRODUCTION

Crossed beam experiments performed at 2.75 and 5.70 eV CM (center of mass) collision energy on the Ar^+/O_2 charge transfer system show that the coupled complex reaction surfaces result in behavior anomalous to most other charge exchange reactions previously studied. The O_2^+ formed at 2.75 eV, found in all three available product surfaces, is produced by both long and short range collisions. At the higher energy the most exothermic product channel disappears. The role of Frank-Condon factors, energy resonance principles, and direct and intimate collision mechanisms in Ar^+/O_2 charge transfer and the effect of translational energy on these parameters is examined.

EXPERIMENTAL

The crossed beam instrument used here has been described in great detail elsewhere.¹

DISCUSSION

Our experiments at 2.75 and 5.70 eV demonstrate that charge exchange in the $(\text{Ar}-\text{O}_2)^+$ system is rather complex. This system differs from many previously-studied charge transfer systems in that there are five potential energy surfaces (neglecting vibrational states) to provide multiple reaction pathways. Clearly this plays a most significant role in the $(\text{Ar}-\text{O}_2)^+$ system. Specifically, the $\text{Ar}^+ (2P_{3/2}, 2P_{1/2})$ surfaces are capable of interacting with both the quartet ($a^4\Pi_u$) and doublet ($X^2\Pi_g$ and $A^2\Pi_u$) O_2^+ product surfaces of the reactant $\text{O}_2 (X^3\Sigma_g^-, v=0)$ ground state surface. As is seen from the scattering diagrams O_2^+ is formed along all three product surfaces.

The mechanisms responsible for the formation of O_2^+ in these product states cannot be rationalized on the basis of any simple theory. Concepts of energy resonance (or energy defect), the Frank-Condon (FC) principle and elements of both long range and intimate collision processes all appear to play a role in Ar^+/O_2 charge transfer.

Figure 1 represents the scattered O_2^+ product from charge transfer with argon at 2.75 eV CM collision energy. Within the ground potential surface ($X^2\Pi_g$) the O_2^+ product is found scattered at large angles and in highly excited vibrational levels (ie., found predominantly in $v \geq 12$). The $v=19$ to $v=22$ level of the X^2_g state are nearly energy resonant with the $\text{Ar}^+ (2P_{3/2})$ state. However, the FC overlap probability of the $\text{O}_2 (X^3\Sigma_g^-, v=0)$ with these levels is on the order of $10^{-22.2}$. Such a poor overlap implies that an electron jump from the $\text{O}_2 (X^3\Sigma_g^-)$ ground state is highly unlikely. A small impact parameter collision is inferred from the large scattering angles, indicative of large angular momentum exchanges.

Kato suggests that the doublet potential product surfaces ($X^2\Pi_g$ and $A^2\Pi_u$) of O_2 interact and stabilize the $\text{Ar}^+ (2P_{3/2}$ and $2P_{1/2})$ until small internuclear distance typical of intimate collisions are reached. At this point a non adiabatic transition (ie. a Landau-Zener type transition) occurs at an avoided curve crossing.² He concludes that FC overlap and energy resonance principles should not influence the outcome of these intimate collisions since at small internuclear separations these curves are highly perturbed. This interpretation is supported by the observation of Marx et. al. They found from ICR experiments that O_2^+ is formed predominantly in the $v=9$ level in the ground state for near thermal collision energies.³ In contrast with these predictions, our results demonstrate a definite preference for forming the $X^2\Pi_g$ product in vibrational levels nearly resonant with the $2P_{3/2}$ state even though the $v=0$ level is exothermic by ≈ 3.7 eV.

The $\text{O}_2^+ a^4\Pi_u$ product formed in 2.75 eV collisions has a maximum in intensity on the relative velocity vector at $v=0$ and again in $v \approx 4 - 5$. In addition, a significant amount of intensity is found scattered at large CM angles (Θ). After considering the $\sin(\Theta)$ factor in the conversion of

the plotted differential cross sections into total reaction probabilities, it is clear that the dominant reaction channel is formation of O_2^+ ($a^4\Pi_u$). This surface lies closer in energy to the $Ar^+(^2P_{3/2})$ than any other electronic surface. Thus it has the smallest energy defect and is the most probable surface for formation of O_2^+ product. The FC factor for the $v=0$ level is about 8×10^{-3} , rising to a maximum of 0.35 at the $v=5$ level.⁴ Since the product is formed with both zero and a range of scattering angles we infer it is formed over a large range of impact parameters and is a result of both short and long range interactions.

The O_2^+ ($A^2\Pi_u$) channel exhibits scattering behavior very similar to that seen for the O_2^+ ($a^4\Pi_u$). However, the $A^2\Pi_u$ product is both lower in intensity and formed predominantly in the $v=0$ state. These differences can be rationalized on the basis of both reduced overlap and by the larger energy defect for this product surface relative to that for the O_2^+ ($a^4\Pi_u$).

At 5.7 eV CM collision energy (figure 2) the scattered O_2^+ product exhibits mechanistic behavior similar to that observed for both the $a^4\Pi_u$ and $A^2\Pi_u$ product surfaces at 2.75 eV, with the exception that product scattered from the relative velocity vector is more structured and of somewhat lower intensity. Additionally there is very little, if any, O_2^+ ($X^2\Pi_g$) product. Clearly translational energy is a very important variable in the Ar^+/O_2 charge transfer system.

For Ar^+/O_2 charge transfer it can be concluded that the extent of FC overlap and the size of the energy gap play an important role in both short- and long-range collisions. The extent of influence these variables have on intimate collisions is clearly related to the relative translational energy of the collision. It appears that the greater the interaction time available the more probable it is to yield product from more highly perturbed surfaces. Therefore the lower the relative translational energy, the less influence FC factors and energy resonance will have on the outcome of small impact parameter collisions.

CROSS-SECTION FOR PROTON TRANSFER FROM LARGE BIOLOGICAL IONS TO SMALL MOLECULES IN THE GAS PHASE

S C Davis, University of New South Wales, Australia, presently at Kratos Analytical

P J Derrick, Warwick Institute for Mass Spectrometry, University of Warwick, UK

The enormous body of literature on the subject of ion-molecule reactions concerns almost exclusively ions of relatively low masses [1,2]. We report results of a study of proton transfer between ions of the cyclic peptide valinomycin (relative molecular mass 1110.6) and ammonia molecules. The ion beam set up used in this work is shown in Figure 1. Collisions of valinomycin ions with ammonia molecules were carried out in the source region of a large-scale reverse-geometry mass spectrometer. Valinomycin ions were produced by field desorption (FD). Collisions of these ions were carried out without prior mass selection. The electrostatic lens system designed especially for these experiments [3] is shown in Figure 1. The performance of the lens system was evaluated from a detailed study of the well characterised reaction between $[\text{NH}_3]^+$ and NH_3 [4-11].

The rates of reaction were determined as a function of incident $[\text{NH}_3]^+$ energy, and from comparison with literature data used to draw up a correction curve accounting for the transmission characteristics of the lens system. The structure of the correction curve can be explained in terms of ion-optical effects [3].

An initial difficulty in the valinomycin experiments was interference from $[\text{NH}_3]^+$ generated in the FD source from a background pressure of NH_3 . The problem was alleviated by using ND_3 instead of NH_3 . In this case, $[\text{ND}_4]^+$ will be formed from $[\text{ND}_3]^+$, whereas $[\text{ND}_3\text{H}]^+$ will be formed by proton transfer from valinomycin ions. The yields of $[\text{ND}_3]^+$ and $[\text{ND}_3\text{H}]^+$ from the collision cell were monitored using ion counting techniques. The collision cell pressure of ND_3 was 1.3×10^{-3} torr.

RESULTS

Results are shown in Figure 2 for the percentage yields of $[\text{ND}_3\text{H}]^+$ as a function of incident valinomycin ion energy. There is a maximum yield of $[\text{ND}_3\text{H}]^+$ of 0.07 + or - 0.015% at an ion kinetic energy of about 1500 eV (cell voltage 6500). After correcting for losses of $[\text{ND}_3\text{H}]^+$ ions due to extraction at the front of the collision cell (i.e. in the reverse direction to the source slit) and losses due to the reaction $[\text{ND}_3\text{H}]^+ + \text{ND}_3 \rightarrow [\text{ND}_4]^+ + \text{NHD}_2$ in the time taken for extraction out of the cell, this figure becomes 0.13 + or - 0.03%. The cross-section for proton transfer from valinomycin to ammonia calculated using this value is $3.0 + \text{or} - 0.5 \times 10^{-17} \text{ cm}^2 \text{ molecule}^{-1}$. The measured cross-section for proton transfer from the $[\text{NH}_3]^+/\text{NH}_3$ experiments was $4.9 + \text{or} - 0.6 \times 10^{-18} \text{ cm}^2 \text{ molecule}^{-1}$ (for ion energy 1 eV). The measured cross-section for collision induced dissociation (CID) of the valinomycin ion was $1.5 \times 10^{-14} \text{ cm}^2 \text{ molecule}^{-1}$.

DISCUSSION

It has been assumed that the proton transfer observed has been due to the $[\text{M} + \text{H}]^+$ ion of valinomycin. It is possible that transfer also occurs from the $[\text{M}]^+$ ion of valinomycin. Since $[\text{M} + \text{H}]^+$ and $[\text{M}]^+$ are produced in about equal intensities, the experimental cross-section would then represent an average of the cross-sections for these ions.

In order for a proton transfer reaction to occur, it could be argued that the ND_3 molecule would have to interact with a specific part of the valinomycin ion where the proton is situated. Interaction with other parts of the ion structure could be expected to be more likely to result in CID processes. The measured cross-section for proton transfer from $[\text{NH}_3]^+$ to NH_3 ($4.9 + \text{or} - 0.6 \times 10^{-18} \text{ cm}^2 \text{ molecule}^{-1}$) is much larger than the measured cross-section for proton transfer from valinomycin ions to ND_3 ($3.0 + \text{or} - 0.5 \times 10^{-17} \text{ cm}^2 \text{ molecule}^{-1}$). The greater momentum in the case of a valinomycin ion (a factor of 8 larger than the momentum of an ammonia ion with the same translational energy) would inhibit orbiting and complex formation. Shielding effects from other parts of the ion structure would also be larger in the case of valinomycin ions.

Apart from the differences in magnitudes of the cross-sections for proton transfer from valinomycin and from ammonia, a major difference arises in the ion kinetic energies at which the cross-sections attain their maximum values. For ammonia the maximum occurs at room temperature. The cross-section at 1 eV ion kinetic energy is lower by a factor of about 0.85. For valinomycin the maximum cross-section occurs at 1500 eV ion energy. Consider an $[\text{NH}_3]^+$ ion travelling with 0.1 eV kinetic energy and interacting with an NH_3 molecule. The maximum amount of energy available for conversion into internal energy is 0.05 eV. Since $[\text{NH}_3]^+$ has 6 vibrational modes the maximum amount of energy available per vibrational mode is 0.008 eV. As some indication of the interaction time, the time taken for the $[\text{NH}_3]^+$ ion to travel 3 Å can be calculated i.e. a distance equal to the size of the ion. At 0.1 eV kinetic energy, $[\text{NH}_3]^+$ takes 3×10^{-13} seconds to travel 3 Å. Consider now an $[\text{M} + \text{H}]^+$ ion of valinomycin travelling with 1500 eV kinetic energy and interacting with an ND_3 molecule. The maximum amount of energy available for conversion into internal energy is 26.5 eV. $[\text{M} + \text{H}]^+$ of valinomycin has 501 vibrational modes, giving a maximum amount of energy available per mode of 0.05 eV. This is a similar magnitude to a typical vibrational quantum (0.1 eV). The interaction time with an amine group of $[\text{M} + \text{H}]^+$ of valinomycin can be estimated by calculating the time taken for the ion to travel 3 Å (1×10^{-14} seconds). This interaction time is of the same order of magnitude as a typical vibrational period (10^{-14} seconds).

CONCLUSION

In view of the results for proton transfer from valinomycin to ammonia, it would seem that the cross-sections for ion-molecule reactions between large ions and small molecules are very small. A "clean" interaction at the position necessary for reaction is apparently required, otherwise the ion will tend to fragment. The maximum amount of energy available per vibrational mode, at the ion energy giving the maximum cross-section for proton transfer to ammonia was found to be greater for valinomycin ions than for ammonia ions. The amount of this energy actually converted into internal energy of the ion would be expected to depend on the structure of the ion as a whole. In the case of valinomycin the interaction time is very short, and sufficient energy would need to be available in the appropriate vibrational modes in the collision. The ion kinetic energy giving the maximum cross-section for an ion-molecule reaction between a large multiatomic ion and a small molecule presumably reflects balancing conditions where there is both sufficient energy for conversion into internal energy in the appropriate bonds of the ion and a sufficiently long interaction time. This being the case, it might be expected that the larger is the ion, the smaller would be the cross-section for an ion-molecule reaction.

FAB INDUCED CONDENSATION OF GLYCEROL WITH TETRAALKYL AMMONIUM SURFACTANTS.

A. Tuinman* and K. D. Cook,
Department of Chemistry, University of Tennessee, Knoxville, TN 37996.

INTRODUCTION

The FAB spectrum of the tetraalkyl ammonium cation "D0" (structure below), from a glycerol matrix shows numerous peaks at higher mass than the naked analyte at m/z 256. These result from the reaction of radical glycerol artifacts with the analyte in the liquid phase or in the selvedge. An understanding of the reaction mechanism governing formation of these adducts may provide insight into the mechanism of the FAB process itself.

Keough¹ has concluded that $[M+14]^+$ of cetyl pyridinium chloride is formed by methylation at the para-position of the aromatic "head" following primary hydrogen atom abstraction from that site.

RESULTS AND DISCUSSION

The abundant oxygen-containing adducts of "D0", and its deuterium labelled analogues "D29" and "D35" were examined to detect possible regio-selectivity of glycerol (G) adduct formation.

For the chain labelled surfactant (D29), the most abundant adduct peak (m/z 374) represents the addition of 89 Daltons, indicating loss of one deuterium, and predominant attack at the long chain of the surfactant. The adduct therefore has the composition D29+G-HD. The abundance of m/z 375 (58% of 374) is more than twice that expected for ^{13}C of m/z 374. This indicates competitive attack at N-CH₃ (producing D29+G-2H).

Low energy CID (10 eV collision with Argon on a hybrid VG-ZAB-EQ) of the glycerol adducts for all three products produced daughter spectra interpretable because of the known original position of the isotopes. Two of the prominent daughter masses derive from glycerol attack at the long chain, as illustrated by reactions A and B for the D29 adduct (D29+G-HD). The excess of hydrogen migration over deuterium (60>61 for D29 and 69>70 for D35) indicates attachment close to N (possibly at the alpha carbon).

Reactions C and D below indicate parents with glycerol attached at an N-methyl group, as illustrated for the D35+G-HD parent.

Abundant daughter peaks at M-92 in all three spectra cannot be explained as the loss of neutral glycerol from the adducts mentioned above, since the D35 product would have to lose 93 Daltons. Instead, decomposition of complexes formed between neutral glycerol and surfactant radical or olefin are invoked. These complexes are isobaric or isomeric with the "normal" adducts.

D28 and D34 refer to surfactant with imperfect labelling; e.g. $(\text{CH}_3)_3\text{N}^+\text{C}_{14}\text{D}_{28}\text{H}$. These account for up to 30% of the surfactant present. The mislabelling is known² to be random.

Adduct formation is TIME DEPENDENT:

- 1) Relative intensities of certain daughter ions vary dramatically with FAB irradiation time (Fig. 1). This reflects a change in the relative abundances of different isobaric and isomeric parents with FAB irradiation time.
- 2) When the FAB target is loaded with a thin film of D0 plus glycerol, the intensity of adduct ions passes through a maximum over time (Fig. 2). This effect is less pronounced or not observed when the mixture is applied as a thicker film or as a convex droplet.

CONCLUSIONS

1. Adduct formation is not regio-specific, and ions at the nominal masses representing the adducts are not homogenous.
2. The relative abundance of different glycerol adducts varies as a function of FAB irradiation time.

FT-ICR Determination of the Ionization Potentials
of Carbon Clusters via Charge Transfer

Stephan B.H. Bach and John R. Eyler
Department of Chemistry, University of Florida
Gainesville, Florida 32611

Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry is an ideal method for studying the reactivity of cluster ions. These ions can either be formed externally and injected into the FT-ICR analyzer cell, or formed directly in the cell by laser ablation from suitable solids. In either case, the use of a pulsed valve to introduce a burst of unreactive collision gas (argon, 7.5×10^{-7} torr peak pressure) to remove excess translational and/or internal energy in the cluster ions is desirable. We have begun our FT-ICR studies of the properties of cluster ions by examining charge transfer reactions of carbon cluster cations in order to determine the ionization potentials of neutral carbon clusters. An accurate determination of the I.P.'s of the clusters may also lead to a better understanding of the structures of these species and may help resolve the question as to the cluster size at which the transition from cyclic to linear structure occurs. Previous photoionization work by Kaldor and co-workers led to I.P.'s for carbon clusters with up to seven atoms in the range 12.84 to 9.98 eV and between 12.84 and 6.42 eV for clusters with up to 30 atoms¹.

A variety of compounds have been employed, for charge transfer reactions, with I.P.'s ranging from 7.50 to 11.00 eV². Most of these neutrals are substituted benzenes. These molecules ionize via one of the delocalized electrons in the aromatic cloud, and often do not rearrange structurally upon ionization. This means that the ionization energy of the neutral does not need to be corrected because of structural changes between the neutral and the ion. These compounds are leaked into the system at a pressure of $1-2 \times 10^{-8}$ torr above the background pressure. By observing the occurrence or non-occurrence of charge transfer reactions with the neutral molecules of known ionization potential, the ionization potentials of carbon clusters containing from 6 to 24 atoms have been determined to an uncertainty of only a few tenths of an eV. This has substantially lowered the uncertainties in the I.P.'s of the carbon clusters.

The accompanying graph shows (black bars) the ionization potential range determined for each carbon cluster. The area above this (light hash marks) is where no charge transfer occurs and therefore the ionization potential of the carbon cluster is lower than that of the neutral species being leaked in. The area below the black bars (heavy hash marks) is where charge transfer between the carbon cation and the neutral charge transfer agent is observed and the ionization potential of the cluster is then greater than that of the neutral being leaked in. A general decrease of the carbon cluster ionization potential with increasing number of atoms in the cluster is seen, but pronounced differences from one cluster to the

next are also apparent. These differences could be the result of significant structural variation between the clusters.

The lower ionization potentials seen for clusters with 7 and 11 atoms relative to the I.P.s for clusters with 6, 8, and 10 atoms supports earlier speculation³ that the former have cyclic structures, while the latter have linear structures. The low ionization potentials seen for clusters with 11, 15, 19, and 23 atoms suggest that the higher intensities of these clusters ("magic numbers") found in earlier experiments¹ by other groups may not be due to any special stability of these particular size clusters, but rather is due to the ease of ionizing these clusters relative to those with more or fewer carbon atoms. The relatively lower I.P. of these cluster may also indicate that these species are aromatic.

A CHARGE TRANSFER REACTION OF EXCITED CH_5^+

Hung Yu Lin and Douglas P. Ridge,
Department of Chemistry, University of Delaware,
Newark, Delaware 19716.

David Herold,
Department of Pathology, University of Virginia Medical Center,
Charlottesville, Virginia 22908,

CH_5^+ is used extensively as a proton transfer chemical ionization reagent, but it is energetically possible for CH_5^+ to undergo charge transfer with some molecules. Since CH_5 neutral does not have a significant bond energy the overall reaction would be

The enthalpy change for either process would be $\text{IP}(\text{A}) - 7.89\text{eV}$. Thus species with low IP might undergo charge transfer with CH_5^+ . It is of interest to know how successfully charge transfer competes with proton transfer.

The para magnesium bromide of anisole effectively immobilizes active H and D substituents and can be used to determine the extent of D for H exchange in solution. Detecting D substituted anisole is therefore important. This led us to a particular interest in the methane CI mass spectrum of anisole. Anisole has a relatively low ionization potential, and if charge transfer competes with proton transfer that would complicate the analysis of mixtures of anisole and D-anisole. Another problem is that proton transfer from CH_5^+ to D-anisole accompanied by H for D exchange would be indistinguishable from charge transfer except with very high mass resolution.

We report here that charge transfer is the dominant product where A is anisole. Furthermore this reaction is observed only for CH_5^+ that has not suffered collisions after it has been formed in the reaction of CH_4^+ and CH_4 . This is a reaction of excited CH_5^+ and is not observed for collisionally cooled species. Indeed the reaction is only exothermic for excited reactants since $\text{IP}(\text{anisole}) = 8.20\text{ eV}$. The reaction was identified using labelled species and a Nicolet FTMS-2000 ion cyclotron resonance spectrometer. This makes it possible to do a kinetic analysis of the effect of collisional cooling on the competition between charge transfer and proton transfer.

The reactions of CD_5^+ with anisole produce anisole parent ion (m/z 108) and deuterated parent (m/z 110). If isotopic exchange accompanied deutron transfer and ion at m/z 111 would be expected. The m/z 111 intensity is just that appropriate for the ^{13}C peak of the deuterated parent. Any exchange must be less than 1% of the deutron transfer process.

To monitor the effect of collisional relaxation of CD_5^+ on its chemistry with anisole a two cell experiment was done. Methane was admitted to the source cell at a nominal pressure of 2×10^{-7} Torr. A 5 ms electron beam pulse formed CD_4^+ which reacts for time T_1 with methane. The resulting CD_5^+ is transferred to the analyzer cell which has a nominal background pressure of 3×10^{-9} Torr. All ions but m/z 22 are ejected and anisole is admitted through a computer controlled valve. After a delay of 1 s a mass spectrum is acquired. Plotted in the figure is the relative

intensity of the observed anisole parent ion as a function of T_1 . At short time the parent ion is the only product of reaction between CD_5^+ and anisole indicating that nearly all the CD_5^+ has enough energy (0.3 eV) to undergo charge transfer. At long times after the CD_5^+ has had an opportunity to collide before it is transferred to the analyzer, charge transfer disappears in favor of proton transfer.

FIGURE 1

ON THE USE OF NEGATIVE ION CLUSTERING BY DMSO FOR
THE ANALYSIS OF SUBSTITUTED NITROBENZENES BY APIMS:

D. R. Zook and E. P. Grimsrud

Department of Chemistry, Montana State University
Bozeman, MT. 59717

The use of electron capture (EC) reactions in the ion source of an Atmospheric Pressure Ionization Mass Spectrometer (APIMS) provides the basis for the sensitive detection of numerous environmentally interesting compounds, including the nitroaromatic hydrocarbons. The mass spectra thereby obtained are very simple, often consisting of the molecular anion, only, of the compound of interest.

In many cases, however, it would be desirable to have spectra which are more complex and contain more information concerning the identity of the analyte. In this study we have explored the use of dimethylsulfoxide (DMSO) in the buffer gas of an APIMS in order to cluster with the molecular anion, as shown in reaction 2.

Along with the initial electron capture product formed by reaction 1, the cluster ion has been shown to be a potential source of additional information.

Chowdhury and coworkers have recently reported a collection of thermodynamic parameters for clustering processes involving several isomeric sets of substituted nitrobenzenes. That study showed that a particular structural isomer may exhibit a unique, distinguishing propensity for clustering with a given solvent. (see Ref. 1)

We likewise investigated the majority of compounds studied by Chowdhury et al which had been found to cluster most favorably with DMSO. We found that, despite the free jet expansion conditions associated with ion sampling from our APIMS that with use of He buffer gas and a 50 um sampling orifice, the clustering chemistry clearly followed known trends characteristic of the electron affinity of the compound tested. Those APIMS results are shown in Figure 1.

APIMS Ion Source

continued

Through the course of our study we found generally that the pre-sampling isotopic stability patterns were mirrored at a standard condition of 150°C, and 0.4 Torr DMSO. An exception appeared to exist for the fluoronitrobenzenes. This non-equilibrium isotopic pattern was however quite reproducible, and was found to be invariant with changes in the partial pressure of DMSO. The effect of temperature was also found to be ineffective at altering the APIMS isotopic pattern for the fluoronitrobenzenes, from 125 to 225°C. The effect of temperature must be more carefully examined prior to making generalizations, however.

Use of a 50um aperture with He appeared to result in enhancement of the cluster ion while providing the same isotopic pattern. Due to the very temperature sensitive "DMSO" this enhancement attributed to adiabatic cooling was apparently insufficient to greatly increase cluster ion signal at higher temperatures, although significant enhancement is achieved at temperatures below 100°C.

The use of negative ion clustering appears to be of a controllable nature under carefully controlled conditions, and may be of analytical utility for providing additional information for isomer identification in APIMS.

OBSERVED CLUSTERING RATIO VS. EA

PROTON TRANSFER AND HYDROGEN HALIDE ELIMINATION
REACTIONS OF HALOGENATED BENZENES

Mark R A Falcini and Keith R Jennings
University of Warwick, Department of Chemistry
COVENTRY CV4 7AL, U.K.

In the study of proton transfer equilibria of the type

in a pulsed electron beam high pressure ion source, it is essential to ensure that competing reactions do not interfere with the establishment of equilibrium. In systems containing partly halogenated benzenes the major competing reaction is loss of HX (X = halogen) from the protonated species. The mechanism of this reaction has been determined by Harrison and co-workers¹:

This reaction has been studied as a function of temperature over the range 350 - 600 K. No HF is lost from $[\text{o-C}_6\text{H}_4\text{F}_2]\text{H}^+$ but HF loss from the meta and para isomers increases with temperature. This may be rationalised in terms of site of protonation. In the ortho isomer, the proton is bound between the two fluorine atoms to form a stable ion. In the meta and para isomers, protonation occurs at one of the fluorine atoms or directly on the ring and as the temperature rises, HF loss becomes more favourable. For the dichlorobenzenes, no HCl loss was observed, due to unfavourable energetics. For the chlorofluorobenzenes, HF loss is preferred over HCl loss. The ortho isomer shows greatest loss and increases with temperature for all isomers. Proton affinities of four dihalogenated benzenes were determined from the following systems:

	$\Delta H^\circ/\text{kJ mol}^{-1}$	$\text{PA(B)}/\text{kJ mol}^{-1}$	$\Delta S^\circ/\text{JK}^{-1} \text{ mol}^{-1}$	$\Delta S_{\text{calc}}/\text{JK}^{-1} \text{ mol}^{-1}$
(I)	-2.24 $\pm$ 1.0	756.3	-13.09	-14.9
(II)	-5.2 $\pm$ 0.9	751.3	-11.85	- 3.37
(III)	-1.5 $\pm$ 0.5	754.8	- 0.2	0
(IV)	-10.6 $\pm$ 1.8	740.6	-18.5	0

Absolute proton affinities were determined from $\text{PA}(\text{benzene}) = 758.5 \text{ kJ mol}^{-1}$.
Entropy changes were calculated using the relationship

$$\Delta S_{\text{calc}} = R \ln \frac{\sigma_A \sigma_{\text{BH}^+}}{\sigma_B \sigma_{\text{AH}^+}} \text{ where } \sigma_x = \text{symmetry number}$$

of species X. The entropy changes determined constitute supporting evidence for the dynamic protonated arene ion model, in which the proton has a degree of mobility within the plane of the ring, proposed by Fernandez et al². The results indicate that in meta disubstituted compounds, protonation occurs at a specific site ortho to one substituent and para to the other. For ortho and para disubstituted compounds there is no specific site of protonation.

DIFFERENTIATION OF OLEFINS AND NAPHTHENES USING
ION-MOLECULE REACTIONS IN THE COLLISION CELL OF A
HYBRID MASS SPECTROMETER

S.R. Missler, E & P Technology Division,
Texaco Inc, Bellaire, Texas 77401
and

M. Vassiliadou, Department of Chemistry,
University of Houston, Houston, Texas 77004

Collisionally activated reactions between selected parent ions and isoprene were used to distinguish olefins and naphthenes commonly found in petroleum products. Parent ions selected by the EB analyzer of a hybrid mass spectrometer (EBQQ configuration) were introduced into the quadrupole collision cell at low energy and subjected to collisional activation with isoprene target gas. The addition products thus formed were subsequently mass separated in the quadrupole analyzer. A substantial increase in the slope of the ion energy ramp was required to detect addition products, due to the relatively low velocity that these compounds possess following collision (Figure 1). Previous studies (1) with vinylethyl ether and butadiene suggested that the reaction between an olefin and diene proceeds via a gas phase Diels - Alder mechanism.

Figure 1. Ion energy program ramps required for
detection of collision products

Both olefinic and naphthenic hydrocarbons were found to produce addition products with isoprene. Naphthenes such as cyclohexane are known to undergo ring opening upon ionization in the source and produce radical-ions similar to olefins. Parent ions thus formed would be expected to have different internal energies than those formed by olefins, and could be expected to yield dissimilar reaction spectra. Figure 2 clearly shows the marked differences between relative ion intensities of major reaction products formed by isomeric olefins and naphthenes.

Figure 2. Major addition product fragment ions from collisional reaction with isoprene. Intensities normalized to [A-57] ion.

Discriminant analysis was used to determine if sufficient differences exist between reaction spectra to enable differentiation of olefins and naphthenes (Figure 3). Of the compounds examined, only the C-7 isomers were difficult to distinguish. All olefins examined were grouped in a narrow region of the graph, while naphthenic isomers tended to be widely distributed. Additional studies will need to be performed to determine the reactivity of other chemical species such as tetralins and polynuclear aromatic hydrocarbons.

Figure 3. Discriminant analysis of addition product spectra from olefins and naphthenes.

GAS PHASE ION-MOLECULE REACTIONS OF CARBOCATIONS:
RADIATIVE ASSOCIATION REACTIONS.

Thomas C. Pentecost and Lucia M. Babcock
Department of Chemistry, Louisiana State University,
Baton Rouge, La. 70803 and Geophysics Laboratory
Hanscom AFB, MA. 01731.

Radiative association reactions are of central importance in models of interstellar chemistry due to the low number densities that preclude synthesis of large ions by three-body association. The amount of experimental evidence supporting radiative association is, at best, minimal due to the low temperatures and pressures that are required experimentally to allow the ruling out of three-body association. The general ion-molecule association is given by:

where k_a is the rate coefficient for association, k_d is the rate coefficient for unimolecular decay, k_s is the rate coefficient for collisional stabilization, and k_r is the rate coefficient for radiative stabilization. Recently halide ion additions to the boron trihalides^{1,3} have been shown to possess a radiative stabilization component that competes with the three-body process and unimolecular decay back to reactants even at the relatively high pressures of the flowing afterglow and SIFT experiments. While BX_3 is not an important interstellar species it is interesting to note that CX_3^+ is isoelectronic with BX_3 and carbocations are some of the most important species found in space. We have studied the pressure and temperature dependencies of the reactions of CX_3^+ ($X=H,D,F,Cl$) with SO_2 and NO . The energetics of the reactions calculated from ionization potentials⁴ are given in table I.

Table I. Energetics of Reactions Studied

	A^+	$CH_3^+ + B$	$CD_3^+ + B$	$CF_3^+ + A$	$CCl_3^+ + A$
B					
NO		-0.58	-0.59	+0.09	+0.48
SO_2		+2.48	+2.49	+2.61	+3.54

The goals of the present study are:

- 1) to find and characterize carbocation systems which proceed via a radiative association mechanism
- 2) to examine reactions where charge transfer is near thermo-neutral or energetically unfavorable (eg. NO with CF_3^+ and CCl_3^+ and all SO_2 reactions) to see whether association will occur when no bimolecular channel is available
- 3) to calculate the temperature dependence of k_d and compare the results with theory
- 4) to gain information about the magnitude of k_r with the hope of gaining insight into the type of transition involved.

We have studied the reactions of CX_3^+ ($X=H,D,F,Cl$) with SO_2 and NO in helium buffer gas over a temperature and pressure range of 191 K to 468 K and 0.25 torr to 0.9 torr respectively in a Selected Ion Flow Tube (SIFT). The reactions of CH_3^+ and CD_3^+ demonstrated a positive pressure dependence and a negative temperature dependence. The presence of a non-zero intercept suggests the possibility of a radiative stabilization pathway in both reactions, as has been seen in the BX_3 work^{1,3}. The data for CH_3^+ is quantitatively similar to the CD_3^+ data shown below in figure 1, but in general k_{obs} for CD_3^+ is larger than the corresponding k_{obs} for CH_3^+ by a factor of two.

Figure 1. Temperature and pressure dependence of SO_2 association with CD_3^+

The reaction of CF_3^+ with SO_2 was found to be anomalously slow and CCl_3^+ did not appear to react with SO_2 . The temperature dependence of k_d was determined for both the CH_3^+ and CD_3^+ reactions with SO_2 , using the method developed previously⁵, and the values obtained were compared with the predictions based upon the theories of Herbst and Bates^{5,7}. The experimentally obtained temperature dependences are given in table II.

Table II. Temperature dependence of unimolecular decay rate coefficient: $k_d(T) = A \cdot T^n$

Reaction	n
$\text{CD}_3^+ + \text{SO}_2$	2.71
$\text{CH}_3^+ + \text{SO}_2$	1.79

The reactions of CD_3^+ , CH_3^+ , and CF_3^+ with NO produced only charge transfer products and again the CF_3^+ reaction appeared to be anomalously slow. No reaction was observed between CCl_3^+ and NO . Although table I indicates that charge transfer will not occur, no association product was observed even under the most favorable conditions (i.e. low temperature and high pressure) for ion-molecule association.

In summary the possibility exists for radiative association in CH_3^+ and CD_3^+ association reactions with SO_2 . The data are quantitatively similar to the isovalent BX_3 systems where we have good evidence for such a process, and the values of k_r are consistent with such a mechanism. When charge transfer is not energetically feasible association does not occur in the reactions of CCl_3^+ and CF_3^+ with NO . We determined the temperature dependence of k_d and k_{obs} in the reactions of CH_3^+ and CD_3^+ with SO_2 . Estimates of k_r for association of SO_2 with CH_3^+ ($k_r = 2.3 \times 10^6 \text{ s}^{-1}$) and with CD_3^+ ($k_r = 3.4 \times 10^6 \text{ s}^{-1}$) with SO_2 have been determined as well.

Neutralization-Reionization Studies of Isomeric Ions and Neutrals

M.-Y. Zhang, C. Wesdemiotis, D.E. Drinkwater, F. Turecek
and F.W. McLafferty
Chemistry Department, Cornell University, Ithaca, NY 14853-1301.

Neutralization-Reionization ($^+NR^+$) combined with collisionally activated dissociation of fast neutral species ($^+NCR^+$) has been used to differentiate isomers. CAD of neutral cyclobutadiene induces ring cleavage to give C_2H_2 as the most abundant product. The biradical $^{\bullet}HC=CH-CH=CH^{\bullet}$ is proposed as a common intermediate for dehydrogenation and ring cleavage to acetylene. Concerted cycloreversion to acetylene is disfavored. CAD of neutral vinylacetylene produces $C_4H_2 + H_2$ as major products, though the fragmentation is less abundant than with the less stable cyclobutadiene. Isomerization of cyclobutadiene to vinylacetylene is disfavored against dissociation to C_2H_2 .

Phenol and its less-stable keto-form, cyclohexa-2,4-dienone [1,2], are distinguished by CAD and $^+NR^+$ mass spectra. CAD spectra obtained at unit mass resolution allow for accurate quantification of $C_6H_6O^+$ isomers formed from phenyl alkyl ethers. The main products of neutral dissociations are $C_5H_5^+$, $C_5H_3^+$, $C_4H_2^+$, $C_3H_2^+$, CO and $C_2H_2^+$ for both isomers (Figure 1). The differences are preserved in $^+NCR^+$ spectra, suggesting that phenol and cyclohexa-2,4-dienone neutrals are separated by a significant energy barrier.

Loss of acetaldehyde from benzyl ethyl ether cation radical (1) has been re-examined [3,4]. A distonic-ion intermediate (2) pertinent to a step-wise route is generated independently by dissociative ionization of 3-methyl-2,4-dioxaspiro[5.5]undeca-8,10-diene (3) and by reaction of the methylenecyclohexa-2,4-diene cation radical (4) with acetaldehyde. The $C_7H_8^+$ (4) produced apparently isomerizes to the more stable toluene cation radical through an ion-molecule complex with acetaldehyde via reversible hydrogen transfer involving the acetaldehyde oxygen atom.

A new pc data system has been completed which controls the spectrometer scanning functions and provides integrated intensities of precursor and daughter ions.

A PHOTOIONIZATION STUDY OF $C_4H_7^+$ IONS IN THE GAS PHASE

John C. Traeger

Department of Chemistry, La Trobe University,
Bundoora, Victoria 3083, AUSTRALIA.

Dissociative photoionization mass spectrometry has been used to measure the $C_4H_7^+$ appearance energies for several C_4H_7Cl and C_4H_7Br precursors. The major difficulty in obtaining accurate thermochemical information from these measurements (Table 1) is the absence of any experimental data for the neutral molecule heats of formation. In most cases calculated values based on the Benson group equivalent scheme¹ were sufficiently accurate for the purposes of this study. For some molecules it was possible to use the thermochemistry associated with other fragmentation processes to modify or substantiate these estimates.

No threshold ion was observed with a heat of formation corresponding to the *trans*-1-methylallyl cation (1a).² The $C_4H_7^+$ ion formed from 3-chloro-1-butene and 1-chloro-2-butene was found to have a heat of formation close to that calculated (Table 2) for the *cis*-1-methylallyl cation (1b). This ion, which is 14 kJ mol⁻¹ less stable than its *trans* isomer, was also found from *ab initio* molecular orbital calculations to be the structure to which the homoallyl cation (3) collapsed. Photoionization of 3-chloro-2-methylpropene produced a $C_4H_7^+$ ion with a heat of formation in close agreement with experimental³ and theoretical⁴ results for the 2-methylallyl cation (2).

The $C_4H_7^+$ ion from (chloromethyl)cyclopropane had a heat of formation of 871 kJ mol⁻¹ which was assigned to the cyclopropylcarbinyl cation (5). A higher value of 886 kJ mol⁻¹ was derived for the cyclobutyl cation (4) on the basis of the chlorocyclobutane results. While the latter value is in good agreement with *ab initio* calculations, the lower value obtained here for the cyclopropylcarbinyl cation suggests that, even at the MP4/6-311G** level of theory, the relative stability is overestimated. Due to the relatively high ionization energies of the precursor molecules, the $C_4H_7^+$ ions from (bromomethyl)cyclopropane and bromocyclobutane were found to be formed with excess energy at threshold. The observation of significant molecular ion peaks in both photoionization mass spectra is evidence that the thermochemical $C_4H_7^+$ heats of formation are not significantly lower than the calculated upper limits in Table 1. The similarity between the CA spectra for these two ions⁵ is consistent with the small activation energy calculated for their interconversion.⁴

Threshold formation of 3 was not observed for 4-bromo-1-butene. Based on its CA spectrum and the calculated heat of formation, it is proposed that the $C_4H_7^+$ ion has a cyclopropylcarbinyl cation structure.

The 2-butenyl cation (6) and the isobutenyl cation (7) were calculated to have respective energies of 101 kJ mol⁻¹ and 159 kJ mol⁻¹ relative to 1a. Threshold formation was not observed for either ion. The 2-butenyl cation precursors, 2-chloro-2-butene and 2-bromo-2-butene, both had a calculated $\Delta H_f^\circ(\text{C}_4\text{H}_7^+)$ consistent with formation of 5. On the other hand, 1-chloro-2-methyl-propene and 1-bromo-2-methyl-propene, precursors for 7, had essentially the same C_4H_7^+ heat of formation, which may be interpreted as the result of formation of either 2 or 4 at threshold.

Table 1. Thermochemistry for the Gas-Phase Reaction at 298 K

DETERMINATION OF RADIATIVE ASSOCIATION RATE CONSTANTS BY FOURIER TRANSFORM ION CYCLOTRON RESONANCE SPECTROMETRY.

J.J. Fisher and T.B. McMahon

Department of Chemistry and Guelph-Waterloo Centre
for Graduate Work in Chemistry
University of Waterloo
Waterloo, Ontario, N2L 3G1
CANADA

The process of radiative association has been proposed to be an important mechanism in the formation of interstellar polyatomic molecules. In the experimentally achievable low vacua of the Fourier Transform Ion Cyclotron Resonance Spectrometer (FT-ICR), the products of association reactions have been observed. The stabilization of chemically activated intermediate species can occur by two mechanisms, radiative stabilization (reaction [1]) or collisional stabilization (reaction [2]).

The long trapping times achieved by the FT-ICR increase the statistical probability of observing an ion that will be stabilized by collision or the emission of photon, before it will undergo unimolecular decomposition. The low pressures which can be obtained the FT-ICR spectrometer will reduce the process of collisional stabilization and allow the radiative association process to be observed without interference from collisional stabilization.

The technique of FT-ICR has been used to determine the rate of formation of the proton-bound dimer of dimethyl ether, diethyl ether and acetonitrile from protonated species (reaction [3]) in the pressure range 5×10^{-6} mbar to 3×10^{-6} mbar.

By plotting the observed apparent rate constant as a function of pressure, the radiative association and the unimolecular decomposition rate constants may be extracted from the graphical analysis of the plot. Table 1 summarizes the radiative association and unimolecular decomposition rate constants and lifetimes obtained from FT-ICR experiments for dimethyl ether, diethyl ether and acetonitrile.

FT-ICR Variable Reaction Delay Experiment

DOUBLE IONIZATION ENERGIES OF FLUOROETHANE
MOLECULES MEASURED BY DOUBLE-CHARGE-TRANSFER SPECTROSCOPY

W.J. Griffiths, Chemistry Department
University of the West Indies, Mona Campus,
Kingston 7, Jamaica.

F.M. Harris, Mass Spectrometry Research Unit,
University College of Swansea, Singleton Park
Swansea SA2 8PP, U.K.

Double-charge-transfer spectroscopy [1] has been used to measure the double ionization energies of the fluoroethane molecules $\text{CH}_3\text{CH}_2\text{F}$, CH_3CHF_2 , CH_2FCHF_2 , CH_3CF_3 , CHF_2CF_3 and CF_3CF_3 .

OH^+ ions generated in the source of a ZAB spectrometer were accelerated to 6keV and underwent charge-inversion reactions in collisions with chosen fluoroethane molecules contained in the collision gas cell situated at the focal point between the magnet and electric sector of the spectrometer OH^- ions can be formed in two ways:-

- i) as a result of a single collision reaction

- ii) as a result of two sequential reactions

The reactions by which OH^- ions are formed are readily identified by observing the variation of OH^- ion signal with collision

gas pressure. In addition the translational energies of the ions formed by reactions (1) and [(2a) (2b)] are different. For reaction (1) the translational energy loss where OH^+ ions are converted to OH^- ions is given by $\Delta T_1 = \text{IE}_2(\text{C}_2\text{H}_x\text{F}_y) - \text{IE}_1(\text{OH}) - \text{EA}(\text{OH})$ (3)

while for reactions [(2a) (2b)].

$$\Delta T_2 = \text{IE}_1(\text{C}_2\text{H}_x\text{F}_y) + \text{IE}_1^1(\text{C}_2\text{H}_x\text{F}_y) - \text{IE}(\text{OH})_1 - \text{EA}(\text{OH}) \quad (4)$$

Once ΔT_1 and ΔT_2 are measured single and double ionization $\text{C}_2\text{H}_x\text{F}_y$ molecules can be obtained from Eqs (3) and (4) since $\text{IE}_1(\text{OH})$ and $\text{EA}(\text{OH})$ are known [3], [4].

Table 1 shows the values of IE_1 and IE_2 obtained for the fluoroethanes studies. This work provides the first determination of fluoroethane molecules double ionization energies and also the single ionization energies of CH_2FCHF_2 and CHF_2CF_3 have been determined for the first time.

Table 1. Double ionization energies of fluoroethane molecules.

	CH_3CF_3	CH_3CHF_2	CH_3CF_3	CH_2FCHF_2	CHF_2CF_3	CF_3CF_3
IE_2	32.5	35.0	36.4	33.3	35.8	38.7
IE_1	12.4	12.8	13.8	12.7	13.6	14.5
IE_2/IE_1	2.6	2.7	2.6	2.6	2.6	2.7

Gas-Phase Dehydrogenation of Cycloalkanes to Aromatic Hydrocarbons by Os^+ , Os_2^+ , and Os_3^+

Fernando R. Tollens and Alan G. Marshall

Departments of Chemistry and Biochemistry, The Ohio State University,
120 West 18th Avenue, Columbus, Ohio 43210

Transition metals have previously been reported to react with hydrocarbons to produce alkane elimination and dehydrogenation. Both C-H and C-C insertion mechanisms have been observed. For Fe^+ and Co^+ , for example, C-C insertion is the predominant mechanism for reaction with straight-chain hydrocarbons, whereas C-H insertion is preferred for cyclic hydrocarbons.¹ From its location below Fe^+ in the periodic table, the reaction of Os^+ with cycloalkanes should occur even more exclusively as C-H insertion; the absence of competing C-C insertion should facilitate the analysis of the stereoselectivity of the dehydrogenation reaction.

By a combination of collision-induced removal of ligand and selective ejection of all other ions, we have succeeded in isolating Os^+ , Os_2^+ , or Os_3^+ in high abundance from an electron-ionized sample of $Os_3(CO)_{12}$. Cycloalkanes exposed to Os_n^+ then undergo dehydrogenation until the 18-electron rule is satisfied for the corresponding neutral complex with Os_n . In contrast to the homologous reactions with other transition metals (e.g., Fe^+ or Co^+), cleavage of the carbon skeleton by Os_n^+ was seldom observed and need not occur by C-C insertion. Because the carbon skeleton is left intact, it is possible to devise tests for the stereochemistry of dehydrogenation. The structures and formation mechanisms of the various reaction products will now be discussed.

We find that Os_n^+ reacts with cycloalkanes in a concerted process to produce principally aromatic derivatives. Once the aromatic adduct has been formed, no more dehydrogenation occurs in that ring. If additional ligands are added to the metal center(s), dehydrogenation continues until the 18-electron limit is reached. For example, the reactions of Os^+ and Os_2^+ with cyclopentane give the results shown below:

In the absence of rf excitation, no fragmentation products were observed. Low-energy CID (Os_n^+ excited to ~50 eV) shows nothing but $C_5H_5Os^+$, but high-energy CID (~120-140 eV) produced the following products in minor yield (~10%):

Although these fragmentations occur from the high-energy collision-induced processes, we were able to identify the following products from the corresponding products of thermal reactions of Os^+ with cyclopentene and methylenecyclopentane, by the same reasoning previously demonstrated for the homologous Fe^+ and Co^+ reactions.¹

Finally, the quality of our experimental data is illustrated by the FT/ICR mass spectrum (see below) of isolated Os^+ ions which have been incubated with a mixture of C_5H_{10} and C_6H_{12} .

Diamine Basicities: A New Maximum Gas-Phase Basicity

**Fernando R. Tollens, Vaidyanathan Balasubramanian,
Gideon Fraenkel, and Alan G. Marshall**

Department of Chemistry and Department of Biochemistry, The Ohio State University,
120 West 18th Avenue, Columbus, Ohio 43210

cis-vicinal diamines, a functionality hitherto neglected due to the absence of efficient methods for making them, are potentially important ligands for Li^+ , Mg^{2+} , Zn^{2+} , and Pt^{2+} . These diamines catalyze the reactions of organolithium compounds. Of significant interest is the high basicity of such diamines in H_2O -ethanol: pK_a 's of ~10 and 3, due to intramolecular H-bonding within the monoprotonated species, **1**. We have measured gas-phase basicities of several such diamines (including compounds **2**, **3**, **4**, and **6** synthesized by us) in an attempt to discover the structural determinants (e.g., cis-trans geometry, axial-equatorial conformation) of basicity and cation affinity. In the course of those experiments, we have discovered that compound **2** has the highest gas-phase basicity yet reported.

Starting from the previous maximum gas-phase basicity as a reference, we have extended the scale of gas-phase basicities. The high basicities of the diamines can be explained by intramolecular H-bonding in the monoprotonated amine. We can now report some experimental evidence as to the effect of structure on gas-phase basicity.

H-bonding is favored in compounds **2**, **3**, and **4**, for two reasons: the short distance between the two nitrogens and restricted internal rotation. The high basicity for compound **5** can also be explained by an intramolecular H-bond, because the two nitrogen groups can achieve an entropy-favored (because of the high probability that the two ends of the molecule can come together) six-membered ring conformation, **8**, which is essentially strain-free. In compound **6**, the two nitrogens are axial and equatorial (see **9**) and are thus too far apart to form a favorable intramolecular H-bond. Compound **7**, also known as "proton sponge" due to its high basicity, is in fact much *less* basic than the above-mentioned diamines.

Experiments were then performed to investigate attachment of Li^+ to these amines. Lithium ions were generated by laser desorption from LiCl . Compounds **2**, **3**, and **4** form mono-lithium complexes (e.g., **10**), whereas compound **6** forms a di-lithium complex, **11**. (The corresponding diprotonated complex of **6** has also been observed.) These experiments offer an unparalleled opportunity to compare the electrophilicities of H^+ and Li^+ . For reaction with these amines, Li^+ is found to be more electrophilic than H^+ . The formation of lithium adducts further corroborates the proposed intramolecular hydrogen bond as the basis for the high gas-phase basicities of diamines.

THE MEASUREMENT OF ONSET POTENTIALS FOR EXOTHERMIC AS WELL AS ENDOTHERMIC
PROTON TRANSFER REACTIONS WITH A TRIPLE QUADRUPOLE INSTRUMENT

M. M. Bursey, T. R. Blackburn, W. J. Meyerhoffer, and W. A. Mattson
Department of Chemistry, University of North Carolina, Chapel Hill, N. C.

Slightly exothermic and endothermic proton transfer reactions were investigated with a triple quadrupole mass spectrometer in an effort:

- 1) to develop a new method for determining onset potentials for exothermic reactions and
- 2) to determine optimum conditions for measuring onset potentials for both exothermic and endothermic reactions.

Both daughter ion (D^+) and parent ion (P^+) intensities were monitored with respect to instrument P^+ ion kinetic energy settings (IKE(lab eV)). Inherent problems which could bias results and which could easily be overlooked were discovered:

- 1) P^+ (and D^+) intensity changes with time. Monitoring P^+ intensity with time revealed that the intensity could decrease by an order of magnitude during the first 15 minutes after initiation of source ionization. As our data showed, a plot of D^+ vs. IKE(lab eV) is greatly influenced by such a long term drift. Monitoring P^+ intensity before collecting data is recommended. A plot of D^+/P^+ vs. IKE(lab eV) is preferred--the D^+/P^+ ratio is less subject to long term drift since both D^+ and P^+ intensities are expected to change together.
- 2) P^+ (and D^+) intensity changes with IKE(lab eV). P^+ intensity increases with increasing IKE(lab eV) from 0 at 0 eV to high values around 10 eV. At low IKE(lab eV) P^+ intensity is low; D^+ intensity must therefore also be low, even for slightly exothermic and slightly endothermic reactions. Plots of D^+ vs. IKE(lab eV) for slightly exothermic reactions should erroneously give onset potentials at a slightly positive IKE(lab eV). But poor P^+ energy resolution might allow the more energetic P^+ 's to create D^+ 's at even negative IKE(lab eV) values, giving the misleading appearance of "good" results. A plot of D^+/P^+ vs. IKE(lab eV) is preferred; using extrapolation, such a plot can be used to measure onset potentials for slightly exothermic as well as endothermic reactions.
- 3) D^+/P^+ intensity tends to increase with decreasing IKE(lab eV) at low values of IKE(lab eV), thus distorting the D^+/P^+ plot in this important region. At low IKE(lab eV) values the intensities of D^+ 's (and P^+ 's) for slightly endothermic and exothermic reactions are low; using the ratio of such small imprecise values is questionable. The trend of increasing D^+/P^+ with decreasing IKE(lab eV) might be explained with the hypothesis that at low IKE(lab eV) P^+ 's having higher IKE's are more likely to be extracted leading to a greater % of D^+ 's and to a higher D^+/P^+ ratio than expected. To measure onset potentials ignore points having small D^+ relative intensities (e.g., < 0.1) and extrapolate the remaining points on the rising portion of the D^+/P^+ curve to 0 intensity. Evidently the D^+/P^+ curve will rise before the accepted onset potential, the amount perhaps depending on the energy distribution of P^+ .

Using plots of D^+/P^+ vs. IKE(lab eV), reasonable estimates for onset potentials for slightly exothermic as well as endothermic proton transfer reactions were obtained, generally in good agreement with values expected from data obtained by other methods.

MOLECULAR ORBITAL STUDY OF REACTION PROCESSES IN THE THERMOSPRAY MASS SPECTRA OF DEUTERATED PENICILLINS

Marshall M. Siegel*, Norman B. Colthup, Grant Kenion

American Cyanamid Company, Medical Research Division
Lederle Laboratories, Pearl River, NY 10965

When beta-lactam containing penicillin compounds were studied by thermospray mass spectrometry in a deuterium enriched solvent system, a number of characteristic ions were observed in which greater than 95% of all acidic hydrogen atoms were exchanged for deuterium atoms. These results are summarized in Table I. The abundant ions observed include the deuterium-adduct molecular ion (I) and the cycloreversion reaction products, namely, a deuterium-adduct substituted ketene product (III) and a deuterium-adduct substituted thiazoline product (IV). An unexpected reaction product was ion II, corresponding to ion III but with an additional exchange of a hydrogen atom for a deuterium atom.

Semi-empirical restricted Hartree-Fock molecular orbital (MO) calculations were performed in order to gain an understanding of the structures and energetics necessary for the formation of ions I-IV. All calculations were for the ground state so as to mimic thermal decomposition and chemical ionization processes. Ampicillin and penicillin V were used as the model compounds in the calculations of beta-lactam containing antibiotics.

BINDING SITE OF DEUTERON-ADDUCT IN IONS I-IV

From the computed proton affinities for ions I-IV, listed in Table II, the most likely sites for the deuterium-adducts can be deduced, viz.,

Ion I - amide oxygen O_p , beta-lactam carbonyl oxygen O_α or (if present, as in ampicillin) the amino group nitrogen. The beta-lactam nitrogen N_α is a very likely deuterium site but deuterium initiates the cycloreversion reaction.

Ions II and III - ketene carbon C_α (cyclic isomer), ketene oxygen O_α (cyclic isomer), amide carbonyl oxygen O_p .

Ion IV - beta-lactam nitrogen N_α .

ENERGETICS OF THE BETA-LACTAM CYCLOREVERSION REACTION

The results of the MO calculations for the concerted cleavage of the $C_\beta-N_\alpha$ and $C_\alpha-C_\gamma$ bonds in the beta-lactam ring, when the two bonds were stretched equally and the molecule deuterated at different sites, indicated that the reaction with the lowest activation energy (31.4 kcal/mol) occurred when nitrogen N_α was deuterated. (The same process for the neutral molecule was 61.5 kcal/mol.) Consecutive bond cleavages of the beta-lactam ring when nitrogen N_α is protonated was also investigated. The beta-lactam $C_\beta-N_\alpha$ bond cleaves first with an activation energy of only 6.6 kcal/mol. The remaining $C_\alpha-C_\gamma$ bond is then cleaved with an activation energy of 31.2 kcal/mol. These calculations show that when the beta-lactam nitrogen N_α is protonated, the substituted ketene and thiazoline products can form either in a concerted or consecutive manner with nearly the same total energy requirements. These results tend to indicate that ion I is probably less likely to be deuterated at nitrogen N_α because when this species is formed, the penicillin molecule cleaves into smaller fragments.

CH-CD HYDROGEN-DEUTERIUM EXCHANGE IN ION II

Only the exchange of a CH hydrogen atom, not normally considered labile, for a deuterium atom, can explain the additional H to D exchange in ion II. MO calculations were performed with ampicillin for the following cases:

- Tautomerization of the side-chain amide group: $CHCOND$ to $C=C(OH)ND$ followed by H to D exchange of the vinyl alcohol hydrogen.
- Exchange of aromatic CH's for CD's.
- Addition of D_2O to ketene group followed by HDO dehydration.
- Direct deuterium of ketene carbon C_α followed by deprotonation.
- Deuterium of a site followed by CH hydrogen bonding with D_2O and the release of HDO.

The most likely process was found to be "e" where the ketene carbon C_α was deuterated producing a $C_\alpha HD^+$ group. The exchange process took place as illustrated in the Figure with an activation energy of 47 kcal/mol.

RAPID DETECTION AND CHARACTERIZATION OF FOSSIL-DERIVED
FUELS IN WATER AND SOIL USING DIRECT PURGE ION TRAP
MASS SPECTROMETRY*

Marcus B. Wise, Michelle V. Buchanan, and Michael R. Guerin
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6120

We have recently developed a method for the rapid detection and characterization of fossil-derived fuels in environmental samples. This method uses direct purge of the volatile materials from the fuels into an ion trap mass spectrometer (ITMS), with little or no sample preparation. The entire analysis requires less than five minutes and detection limits are as good or lower than conventional methods (extraction and analysis by GC), which require much longer times.

Several types of fossil-derived fuels, including a jet fuel, an unleaded gasoline, and a diesel fuel, have been detected and characterized in water at the low ppb level using direct purge ion trap mass spectrometry. The sample (either 15 mL of water or 5 g of soil with 15 mL of distilled water added) is contained in a sealed 40 mL VOA vial. Helium is used to purge the volatiles from the sample at flow rates between 20 and 100 mL/minute. The purged materials pass through an open/split interface into the ITMS. Water is used as a proton transfer reagent, and a 50 msec reaction time is used with the ITMS. Detection limits of about 1 ppm are achieved using these conditions.

Figure 1 shows the spectrum of unleaded gasoline in water at a concentration of 200 ppb. The molecular weight distribution from m/z 79 to m/z 163 and the relative abundance of aromatic to aliphatic components is useful for characterizing fuel type. For example, the aromatic content in the unleaded gasoline is greater than that of the jet fuel, which is greater than the diesel fuel.

In addition to the water samples studied, a set of 4 soil samples contaminated with jet fuel were analyzed using direct purge ITMS. Previous analysis using conventional GC methods determined that the concentrations of the jet fuel in the soils ranged <10 ppm $\mu\text{g/g}$ to 5700 $\mu\text{g/g}$ (total organics). The conventional method included ultrasonic extraction with solvents (3 hours), followed by gas chromatography (1 hour). For the direct purge ITMS approach, the soil samples (with 15 mL of water added, see above) were slowly stirred in capped VOA vials for 2 minutes. The samples were then purged into the ITMS, requiring less than 5 minutes per sample for the entire analysis. It was demonstrated that the direct purge ITMS method has detection limits below the 10 $\mu\text{g/g}$ limit obtainable by conventional GC analysis (Figure 2).

Direct purge ITMS can rapidly detect and quantitatively determine fuels in soils and water, requiring 5 minutes or less for total analysis time, compared to 3 or more hours using conventional GC methods. Further, this technique has potential for being a field portable device.

**PARALLEL COLUMN CHROMATOGRAPHY-MASS SPECTROMETRY
FOR THE ANALYSIS OF COMPLEX MIXTURES***

M.A. Quilliam, J. Visentini¹ and J.C. Marr¹

Atlantic Research Laboratory, National Research Council of Canada,
1411 Oxford St., Halifax, N.S., Canada; B3H 3Z1;

¹Dept. Chemistry, McMaster University, Hamilton, Ontario, Canada.

The analysis of polycyclic aromatic compounds (PAC) in the environment is of considerable importance due to the established mutagenicity and carcinogenicity of many of these compounds. The main difficulty associated with PAC determinations is the extreme complexity of environmental matrices. Even after extensive fractionation, the PAC fraction may contain several hundred compounds. In order to detect, identify and quantify compounds in such mixtures, methods that offer combinations of good chromatographic resolving power and detection selectivity are required. We have found that the mass spectrometer in conjunction with high resolution chromatographic separation methods (GC-MS, HPLC-MS or SFC-MS) provides the best selectivity and sensitivity for the provision of reliable quantitative data.^{1,2} One of the objectives of our work was to determine as many compounds as possible in environmental reference materials (i.e., "broad spectrum" analysis). It quickly became clear to us that no single chromatographic technique, even one as powerful as capillary column GC, could provide sufficient resolution of the complex mixtures. Therefore, we began to investigate complementary methods of separation, either in series or in parallel, followed by mass spectrometry.

The acquisition and multivariate analysis of data produced with parallel chromatographic columns (of different separation selectivity) coupled with multi-channel detectors has been termed "third order chromatography".³ Data collected as a function of time, column and detector channel allow the enhanced resolution of complex mixtures. This paper reports on the application of parallel column GC-MS and LC-MS methods to the analysis of PAC in environmental samples.

Extremely complex mixtures of PAC extracted from various samples (marine sediments, urban airborne particulates and steel foundry dusts) have been analyzed by GC/MS using DB-1 and DB-5 capillary columns and by reversed phase LC/MS (moving belt interface) using Vydac-201TP and Zorbax-ODS packed columns. For each sample, the four separate data sets have been examined by a preliminary semi-automated data processing procedure. The key steps are: (a) detection and measurement of chromatographic peaks in all mass chromatograms; (b) organization of the data with a "spreadsheet" program (Lotus 123); (c) identification of molecular ions; and (d) calculation of retention indices. Over 350 compounds have been detected in the NRCC HS-3 marine sediment reference material with 53 identified positively from retention indices and mass spectra. The most complementary data sets are provided by the DB-5 GC-MS and the Vydac-201TP LC-MS analyses, due to the very different separation selectivities. An interesting variation possible with LC-MS is to perform two analyses with the same column, but with a change in either column temperature or type of mobile phase organic modifier. Both of these parameters cause sufficient change in separation selectivity to be useful. The major problem that we faced in interpreting the data was the lack of standard compounds for matching spectra and retention indices.

THE ROLE OF MASS SPECTROMETRY IN THE CLEAN-UP OF THE SYDNEY TAR PONDS

P.G. Sim, M.A. Quilliam, H. Perreault and C.M. Elson
Atlantic Research Laboratory, National Research Council of Canada
1411 Oxford St., Halifax, N.S., Canada, B3H 3Z1.

The Sydney Tar Ponds are the product of over 80 years of pollution from the Sydney (Nova Scotia) steel mill coke ovens. The production of metallurgical coke has as byproducts, coal tar, coal dust and coke fines, the latter liberated when the hot coke is quenched with water at the end of the process. The resultant sludge has been allowed to collect in an arm of Sydney harbour, which has formed the area known as the Sydney Tar Pond. Leachate from this lagoon has led to widespread contamination of the rest of the harbour and its biota. The local lobster fishery has been terminated as a consequence of the pollution.

A multi-million dollar clean-up of this grossly contaminated site is now starting. The progress of such work depends upon reliable analytical data for polycyclic aromatic compounds (PAC) in dredged sediment samples. Major engineering decisions on the materials to be disposed of rest solely on the results of chemical analyses. The main difficulty in the analytical work is the extreme complexity of the samples. The PAC fraction of the organic burden of the material contains a large proportion of alkylated or otherwise substituted PAC. A great number of heterocyclic compounds are also present.

The use of simple, non-selective detectors, such as GC or HPLC with flame ionization and ultraviolet absorption or fluorescence detectors does not provide sufficient specificity for reliable determinations and provides inadequate information on compound structures. We have belaboured this point elsewhere (1-4). Our thesis, now as then, is that only the mass spectrometer has the right combination of sensitivity, selectivity and wide dynamic range needed for reliable analysis of such complex mixtures.

This paper will report on our use of mass spectrometry combined with various chromatographic techniques to provide detailed analyses on sediment samples. The techniques applied to date include capillary column GC and SFC and packed column HPLC and SFC. The first two were directly interfaced to the mass spectrometer, while the packed columns were interfaced through the moving belt interface. All of these methods provide complementary data leading to more reliable determination of hundreds of compounds. The availability of UV absorption spectra generated by a diode array detector during HPLC-MS analyses helps to distinguish the various isomeric ring structures present in the sample (5). Several mass spectral techniques such as negative ion chemical ionization with carbon dioxide as reagent gas (6) and selected ion monitoring at half masses (7,8), which help to increase detection selectivity, will also be applied to this problem.

To date, we have applied a modification of the technique outlined in a previous paper (9). In that work, Quilliam and co-workers, considering the analytical challenge posed by the determination of PAC in complex environmental matrices, were led to the development of a multi-dimensional chromatographic/mass spectrometric technique. In this approach, data are acquired as a function of time, column and detector channel. In the work of the present project, their approach has been modified. The detector channels have been restricted to the mass spectrometer (with the diode array as an adjunct), but the column variable has been further expanded, with the incorporation of SFC separations (both capillary and packed column). The variable selectivity of the differing separations employed is essential for complete characterisation of the PAC mixture in these samples. For example, the limited dynamic range of the capillary techniques is complemented by the relatively high column loadings possible in HPLC and packed column SFC; whereas the lower efficiency of the latter is compensated by the higher resolution capillary techniques.

At the present time, the presence of more than 500 compounds has been demonstrated in the PAC extracts from various tar pond samples. Work is proceeding along two fronts: the identification of the suite of

compounds currently found and the search for further compounds. Identification is hampered by the relative paucity of authentic standards and spectroscopic techniques are being used as an aid. Both optical (diode array) and mass (particularly chemical ionization) spectral approaches are being used. The identification of the minor components, particularly the substituted species, is heavily dependent upon the application of such data.

Of the presently identified Superfund sites, a significant number are the result of contamination by wood preserving processes. Creosote constitutes one of the principal complex environmental contaminants at many of these sites. This abstract describes current efforts to characterize the environmental occurrence of creosote contamination using samples obtained from Eagle Harbor, Puget Sound. Full scan EI MS has been accomplished using a VG70EQ with two internal standards (d_8 -naphthalene and d_{10} -phenanthrene). Capillary chromatography is carried out with an oncolumn injector using a 30 m SPB5 column. In addition to polynuclear aromatic hydrocarbons (PNA's) such as phenanthrene, pyrene, and chrysene, nitrogen containing aromatic compounds (NCAC's) are also of interest. Initially, 9 NCAC's including carbazole, acridine and benzonitrile and 12 PNA's were targeted for identification and quantitation by GC/MS total ion current (Figure 1). Rapid screening of samples has made use of GC/NPD and element specific GC/microwave induced plasma emission spectroscopy which can be an important adjunct to GC/MS (Figure 2). GC/FTIR data has also been obtained to aid in identifications (Figure 3). The use of MS/MS daughter ions is currently being investigated to locate compounds of interest (Figure 4).

INTRODUCTION

Nitro-polycyclic aromatic hydrocarbons (Nitro-PAHs) are a class of genotoxic contaminants. They have been found in diesel exhaust, urban air, carbon blacks, aluminum smelters, and coal fly ash (1-5). Many techniques such as thin layer chromatography, high performance liquid chromatography, and gas chromatography have been used for the separation and identification of this class of compounds (1,6,4). Mass spectrometry (MS) has also proven to be a valuable analytical technique for the analysis of nitro-PAHs found in environmental samples (6). Since the mutagenic potency of these compounds varies considerably, even among isomers, the ability to differentiate isomers by mass spectral techniques will help for the analysis of environmental samples which might contain these compounds. This work reports the EI, API and methane NICI mass spectra of a series of five- and six-ring nitro-PAHs, including 5-nitropicene, 7-hydroxy-6-nitro-7,8,9,10-tetrahydrobenzo[a]pyrene and nitrotetrahydrobenzo[a]pyrene isomers.

EXPERIMENTAL

Nitro-PAHs

5-Nitropicene (5-NPN) was synthesized by Chemsyn Science Laboratories (Lenexa, Kansas) for N.C.T.R. The 1,3,6-nitro-7,8,9,10-tetrahydrobenzo[a]pyrene (1,3,6-NHBaP), 1,3-nitro-8,9,10,11-tetrahydrobenzo[e]pyrene (1,3-NHBaP) and 7-hydroxy-6-nitro-7,8,9,10-tetrahydrobenzo[a]pyrene (7-HY-6-NBaP) were synthesized by P.P. Fu (N.C.T.R.). All compounds were diluted in toluene.

Atmospheric Pressure Ionization MS

API was performed using a DB-5 fused silica capillary column connected directly to the APIMS source. All analyses were conducted in the negative ion mode. The source was maintained at 350°C and purged continuously with 40-60 cm³ per min of ultra high purity nitrogen. The mass spectrometer was scanned from m/z 50 to m/z 500 with a scan time of 1.5 s.

Electron Impact and Negative Ion Chemical Ionization MS

NICI and EI mass spectra were obtained on a Finnigan 4023 Automated Gas Chromatograph/EI-CI mass spectrometer. Ions were monitored using a 1.5 s scan from m/z 50 to m/z 550. The electron energy and electron multiplier were set at 70 eV and 1300V, respectively. For NICIMS, methane was adjusted to a source pressure of 0.25 torr. The source temperature was set at 250°C while for EIMS it was 270°C.

RESULTS AND DISCUSSION

The API mass spectrum showed the M⁻ for 3-NHBaP whereas the M⁻ and [M-O]⁻ were observed under NICI conditions. The EI fragmentation pattern was composed of ions at m/z 301, m/z 271 and m/z 255 for 1-NHBaP. These ions represent the M⁻, [M-NO]⁻ and [M-NO₂]⁻. For 7-HY-6-NBaP, the M⁻ was observed under API conditions. Ions at m/z 317, m/z 301 and m/z 287 observed in the NICI spectrum represent the M⁻, [M-O]⁻ and [M-NO]⁻. Also, a low-counts ion was observed at m/z 257. Under EI conditions (figure 1), ions at m/z 317, m/z 301, m/z 299, m/z 285, m/z 269, m/z 254 and m/z 252 were monitored. 5-NPN showed only the M⁻ ion under API, whereas the M⁻, [M-O]⁻ and [M-O₂]⁻ ions were observed under NICI conditions. The EI mass spectrum showed the M⁻, [M-NO]⁻, [M-CN₂O]⁻, and [M-HNO₂]⁻. Overall, the most sensitive technique was NICI. For example, a limit of detection of 80 pg was observed for 5-NPN via NICI compared to 1.4 ng with EI.

Figure 1. EI mass spectrum of 7-HY-6-NHBaP.

CONCLUSIONS

The three ionization methods provided different results for the individual compounds. Even though isomer differentiation was not possible for the nitrotetrahydrobenzo[a]pyrene and nitrotetrahydrobenzo[e]pyrene isomers, mass spectral characterization will help for further identification of these compounds that might be found in real samples.

INTRODUCTION

Fluff is the ground-up material remaining after bulk metals have been extracted from shredded vehicles and consumer appliances. In the US alone, a total of 3 million tons of fluff is created annually at over 200 shredding sites. Fluff is not presently classified as hazardous waste and is sometimes used as landfill at construction sites. Polychlorobiphenyls (PCB) in fluff from several states have been reported at concentrations of up to 1600 ppm. The purpose of this study was to determine if other classes of environmentally significant organics were present.

EXTRACTION

To facilitate identification of halogenated, neutral, aromatic classes of compounds, 10 g of fluff was extracted by a modified RCRA 8280 method. This method is used to prepare environmental samples for halogenated dioxin and furan analyses.

GC/MS ANALYSIS - FULL SCAN DATA

A total ion current chromatogram of the fluff extract is presented in Figure 1. Numerous compounds identified are labeled, including the 3 classes of compounds that were most abundant: polychlorinated naphthalenes (PCN), PCB, and polychlorinated terphenyls (PCT).

SELECTED ION RECORDING DATA

To provide greater sensitivity, selected ion recording (SIR) was used to search for polychlorodibenzodioxins (PCDD), polychlorodibenzofurans (PCDF), and the polybrominated analogs (PBDD and PBDF).

CONFIRMATION CRITERIA

Several confirmation criteria were met before a peak was attributed to one of these types of compound:

- 1) The retention time was within the time window established by standards.
- 2) A signal-to-noise ratio 2.5 was obtained for the molecular ions.
- 3) A prominent and characteristic fragment ion was observed.
- 4) The ratio of the molecular ion abundances was within 20% of the theoretical value.
- 5) For furans, no coeluting ether peak was observed containing 1 or 2 additional halogen atoms relative to the target compound.
- 6) The peak did not appear in the method blank.

Displayed in Figure 2a-c are the ion chromatograms used to identify HpCDD, HpCDF, and TBDF respectively.

COMPARISON OF MS/MS AND SELECTED ION RECORDINGS (SIR) IN
ANALYSIS OF TCDD AND TCDF

Y. Tondeur, Triangle Labs Inc., 4915F Prospectus Dr. Durham,

Orla Weir, D. Wood M. Clench, VG Tritech Limited, Crewe Road,
Wythenshawe, Manchester., UK.

INTRODUCTION

High resolution gas chromatography/high resolution mass spectrometry is the traditional method for TCDD and TCDF analysis. The high resolution (10000) is necessary to resolve the TCDD and TCDF from interfering ions in the molecular ion region. An alternative approach is to use the MS/MS facilities afforded by a HRGC coupled to a hybrid mass spectrometer.

The objective of this work is to compare the linearity, sensitivity, selectivity and reproducibility of HRGC/MS/MS with HRGC/LRMS and HRGC/HRMS.

EXPERIMENTAL

HP5890 GC's were interfaced to the different mass spectrometers. A Grob type split/splitless injector was heated to 280°C. The column used was a 50m DB5. This was held at 150°C for 1 minute, then was heated at 30°C to 190°C and at 3°C to 300°C. The GC/MS interface was heated to 250°C.

The LRMS selected ion recording (SIR) and the MS/MS were performed on a VG TRIBRID. LRMS was 2000 RP. HRMS SIR was carried out on a VG 70E at 10000RP. MS/MS was achieved by monitoring the transitions between the m/z 320 and m/z 322 peaks to m/z 257. This transition corresponds to the loss of CO^{35}Cl and CO^{35}Cl respectively from TCDD. The parent ion was selected by the magnetic sector at 500 RP.

Selectivity of the three techniques was compared using a smoke stack sample containing TCDD's and TCDF's. The dioxin and furan traces exhibited interferences at 2000 and 10,000RP which were removed by MS/MS. The furan traces show the improved selectivity of HRMS over LRMS SIR.

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

Sensitivity was derived from the S/N of m/z 320 molecular ion of TCDD. S/N of 500 fg TCDD at 2000RP was 10:1 S/N on 1 pg at 10,000RP was 20:1 S/N on the transition peak (10 pg) was 6:1.

500fg TCDD 2000RP SIR

10pg TCDD QUAD SRM

Linearity was established by acquiring two replicate injections of 5, 50, 100, 1000 pg TCDD and TCDF standards. The molecular ions of TCDF and TCDD were ratioed to their ¹³C internal standards. Calibration curves yield a coefficient of correlation in all cases at 2000 and 10,000RP greater than 0.999.

Reproducibility was determined from four replicate injections of TCDD standard. The ratios of the areas of the 322:320 peaks were calculated.

	2000RP	10,000RP	500RP MS/MS
mean	0.78	0.77	0.29
theoretical ratio	0.77	0.77	0.32
standard deviation	0.009	0.037	0.009
relative standard deviation	1%	1%	3%

ANALYSIS OF MONOBROMINATED PCDD AND PCDF IN MUNICIPAL INCINERATOR FLYASH

H.Y. Tong, S.J. Monson, and M.L. Gross, *Midwest Center for Mass Spectrometry, University of Nebraska, Lincoln, NE 68588-0304*

To reduce the levels of polychlorodibenzo-*p*-dioxins and -dibenzofurans (PCDD/Fs) in flyash generated from municipal waste incinerators (MWI), it is important to understand the mechanism and identify the precursors for PCDD/F formation during the incineration process. The information released about this, so far, is fragmentary and often controversial. The formation mechanism remains unknown. Recent findings of brominated PCDD/Fs (BPCDD/Fs) in flyash by HRGC/HRMS analysis may facilitate such studies^{1,2}.

The flyash sample preparation procedure employed for BPCDD/F analysis consisted of Soxhlet extraction, acid wash, and multi-column chromatographic clean-up. The subsequent HRGC/HRMS analysis was performed on a Carlo-Erba GC/Kratos MS-50 mass spectrometer with 70 eV EI and 10,000 resolving power. Selected ions of the target analytes were monitored at a 300 ppm mass span. A 30 and 60 meter DB-5 column were used for GC separation. The details of this analytical method were reported previously³.

Identification of BPCDD/Fs in flyash was discussed elsewhere¹. Figure 1 shows the mass chromatograms for selected BPCDD/Fs and their PCDD/F counterparts found in the same sample. Some examples of mass profile data obtained for BPCDD/Fs are also illustrated in this figure. All observed isotope ratios of those BPCDD/F ions monitored are in the acceptable deviation range (± 0.10) of the theoretical values. As observed for tetra- to penta-halogenated dibenzo-*p*-dioxin (DD) and dibenzofurans (DF) previously¹, each pair of BrCl_n-DD (or DF) and Cl_{n+1}-DD (or DF) exhibits very similar isomer profiles on a 30 meter DB-5 column. However, when the GC separation power is increased by using a 60 meter column, BPCDD/F peaks are "split", namely, more BPCDD/F isomers are recognized. Some examples are illustrated in Figure 2 as a comparison with PCDD/Fs analyzed under the same conditions. When a bromine atom is placed on PCDD/F, the degree of structural symmetry is degraded and more isomers become possible. For those compounds illustrated, the theoretical number of possible isomers is given in Figure 2. Apparently, the observed number of BPCDD/F isomers is not as many as the theoretical number. In contrast, all possible isomers of PCDD/Fs are present in MWI flyash.⁴

The data presented here indicate that BPCDD/Fs and PCDD/Fs in flyash are closely related. Those data also suggest that bromination of PCDD/F, chlorination of polybromo-DD/F, or simple Br/Cl exchange are not the main pathways for BPCDD/F formation in MWI. Laboratory experiments^{5,6} reported extensive isomers of BPCDD/Fs to be obtained under those mechanisms. Thus, BPCDD/F possibly undergoes the formation mechanism similar to their PCDD/F counterparts in MWI process. This provides many advantages of using BPCDD/Fs to study the formation mechanism of PCDD/Fs. For example, rationalization of the highly characteristic patterns of BPCDD/F isomers can give additional mechanistic information such as cyclization routes, substitution preferences, and the sequence of reaction steps. More importantly, the bromine atom in BPCDD/Fs serves as a "label" element and participates in the formation mechanism under the real conditions of MWI that cannot be easily simulated in a laboratory study.

ACKNOWLEDGMENT

We thank Drs. R.E. Clement, G.W. Sovocool, R.K. Mitchum and J.R. Donnelly for supplying the flyash sample and synthetic brominated PCDD/Fs.

EI AND NEGATIVE ION CIMS OF
POLYBROMINATED FURANS IN PLASTICS

William C. Brumley, Andrew H. Grange,* Nathan J. Nunn,*
Joseph R. Donnelly,* George M. Brilis, and G. Wayne Sovocool

U.S. EPA, EMSL-Las Vegas, NV 89193-3478
*LESC, Las Vegas, NV 89119

Polybrominated dibenzofurans (PBDF) have been identified and quantitated in flame retardant concentrate pellets and in plastic resins impregnated with the flame retardant materials. The flame retardant employed was usually decabromodiphenyl ether (DBDPE). Mass spectrometric techniques used in the analysis of cleaned up extracts for tetra through octa BDF congeners included EIMS in the selected ion recording mode (SIR) at both low resolution (LR) (1,000, baseline) and high resolution (HR) (10,000, 10 % valley). In addition, negative ion chemical ionization mass spectrometry (NICIMS) has also been explored as a complementary tool. Clean up of extracts followed RCRA method 8080 (SW846) after dissolution of the sample in toluene or trichloroethane/phenol.

Table 1 gives a brief tabulation of some results obtained based on two internal standards, $^{13}\text{C}_{12}$ - 2,3,7,8-TBDF and $^{13}\text{C}_{12}$ - 1,2,3,7,8-PBDF uncorrected for response factors. Reasonable agreement is obtained between the various instruments and between LR and HR SIR. By far, the pyrolysate materials contained the highest levels of PBDF.

Confirmation of identity was based on the three most abundant ions of both the M^+ cluster and the $(\text{M}-\text{COBr})^+$ cluster. In addition, one ion from each M^+ cluster of the brominated DPE one and two bromines higher than the corresponding furan was also monitored. Chromatographic separation was achieved using either an SPB5 or DB5 column of 30m (.25 mm ID, .25micron film) programmed from 150-320 at 5°C/min. On column injection used a 1 m retention gap uncoated column (.53 mm ID) and provided an independent assessment of the role of hot injections in producing PBDF during analysis.

NICIMS of PBDF revealed that M^- and $(\text{M}-\text{Br})^-$ ions were usually base peaks. SIR in the NI mode was also pursued at LR and HR employing a lock mass. Brominated diphenyl ether responses were noted by monitoring phenoxide ions derived from the corresponding DPE.

An example chromatogram of the M^+ cluster HpBDF is shown in Fig. 1 for a PBT resin treated under extreme extrusion conditions.

An example of NI responses for a similar chromatographic window is shown in Fig. 2

GC/MS METHODS UTILIZED IN A SURVEY OF SELECTED XENOBIOTIC
CONTAMINANTS IN FISH FROM SITES ACROSS THE UNITED STATES.

B.C. Butterworth(1), D.W. Kuehl(1), P.J. Marquis(2), M.L. Larsen(2), A.E. Mozol(2), and L.G. Holland(2); 1. U.S. Environmental Protection Agency, Environmental Research Laboratory, Duluth, MN 55804. 2. The University of Wisconsin-Superior, Center for Lake Superior Environmental Studies, Superior, WI 54880.

Concern that bioaccumulation in the aquatic food chain may represent a major route of human exposure to a number of toxic environmental contaminants prompted the Environmental Protection Agency's Office of Water Regulations and Standards to initiate the Bioaccumulation Study in 1986. The objective of the study was to broaden the base of information on anthropogenic chemical residues found in fish. Specifically, the study measured the levels of polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs), and 36 other pesticides and industrial chemicals. Residues of selected samples were further characterized via spectral library matching, and additional analytical effort. The data has been entered into a data base (the BIOACC data base) at EPA's National Computer Center at Research Triangle Park, NC, and is accessible by modem from any location in the nation. It will be used to identify potential risks to human health or aquatic life, identify correlations with contaminant sources, and initiate further investigations or remedial actions.

The study focused on fish because they provide a good indicator of contamination in aquatic systems, and represent a direct route of exposure to humans through consumption. EPA regional offices, and state and local agencies cooperated in collecting samples from over 400 sites. Sampling was done in both heavily polluted areas, and areas relatively unaffected by the activities of man. Target analytes were selected from among known contaminants of aquatic environments on the basis of their bioaccumulation potential, potential for human health effects, and feasibility of analysis.

The analytical methods utilized ¹³C isotope dilution techniques for quantitation of PCDDs and PCDFs. Other analytes were quantified by measuring relative responses to deuterated surrogate internal standards. Sample preparation involved a number of contaminant isolation and enrichment steps including soxhlet extraction, gel permeation chromatography, and partitioning on silica gel, potassium silicate, florisil, and carbon particulates. High resolution GC, scanning MS, and high resolution/multiple ion selection MS were utilized. Quality assurance criteria were developed for all aspects of the analyses including GC column performance, MS response, method efficiency, accuracy, and precision.

While a detailed analysis of the data is not yet complete some general observations can be made. The data indicate that PCBs continue to be a widespread contaminant in fish. Nearly 90% of the samples had PCB levels at or above the limit of detection of 1 ppb, with mean concentrations in some regions as high as 5 ppm. Over 90% of the samples contained measurable amounts of p,p'-DDE, some reaching part per million levels. Other chemicals found frequently include nonachlor, oxychlordane, chlordane, dieldrin, pentachloroanisole, hexachlorobenzene, and lindane, generally in the range of 1 to 100 ppb. PCDDs and PCDFs were detected in 3 out of 4 samples. The mean 2,3,7,8-TCDD toxic equivalency concentration (TEC) of PCDDs and PCDFs was 6.8 ppt. In 95% of the positive samples, over 70% of the TEC is attributable to 2,3,7,8-TCDD, 2,3,7,8-TCDF, and 1,2,3,7,8-PCDD.

GC/MS Analysis of Halogenated Organic Compounds in Water, Fish, and
Sediment Samples Collected Near an Industrial Outfall in the
Calcasieu River Estuary

Thomas J. Leiker, Wilfred E. Pereira, and
Colleen E. Rostad

U.S. Geological Survey
P.O. Box 25046, Mail Stop 408
Denver Federal Center
Denver, Colorado 80225

Studies conducted in the vicinity of an industrial outfall near the Calcasieu River estuary, Louisiana indicate that the area is impacted by environmental contamination. The study to date has shown that water, fish, and sediment samples collected at the outfall, above and below the outfall are contaminated with a variety of chlorinated, brominated, and mixed chlorinated and brominated organic compounds.

The analytical methodology that was used to extract and analyze the samples was matrix dependent. The one liter water samples were extracted with methylene chloride (3x50 ml) using conventional liquid/liquid extraction. The extract was dried over sodium sulfate and concentrated via Kuderna-Danish (K-D) to a volume of 1.0 ml and further concentrated under a gentle stream of nitrogen to 100 μ l and analyzed by GC/MS.

The 10 gram wet weight sediment samples were extracted with methanol (100 ml), and methylene chloride (2x75 ml). The actual extraction was accomplished with a tissuemizer. After extraction, the extracts were partitioned with 250 ml of 2% Na_2SO_4 . The aqueous phase was reextracted with methylene chloride (2x25 ml). The extract was concentrated to 1.0 ml by K-D. After solvent exchange into hexane, the extract was purified by passage through a microflorisil column. The purified extract was concentrated to 5 ml by K-D and further concentrated to 100 μ l under a gentle stream of nitrogen and analyzed by GC/MS.

The 10 gram wet weight fish samples were extracted with 20% acetone-hexane (3x75 ml). The extract was concentrated to 1.0 ml by K-D, and purified by passage of the extract through a 5 gram florisil column. The purified extract was concentrated to 5.0 ml by K-D and further concentrated to 100 μ l under a gently stream of nitrogen and analyzed by GC/MS.

The extracts were analyzed by GC/MS under the following conditions. An HP-5890 gas chromatograph was directly interfaced to a VG-7035 double-focussing mass spectrometer. The gas chromatographic separations were achieved on a 30m x 0.2mm i.d. DB-5 fused silica capillary column. The oven temperature was held at 50°C for 3 min. and then temperature programmed at 7°C/min up to a final temperature of 310°C. Splitless injections of 1 µl were made with the injection port temperature at 275°C. Transfer line temperature was 280°C. The mass spectral analysis were conducted under the following conditions. Low resolution mass analysis was conducted at a resolution of 1000 over a mass range of 50-500 daltons. The magnet was scanned at rate of 1 sec/decade, and the accelerating potential was 4Kv. High resolution mass spectral analysis was conducted at a resolution of 5000 over a mass range of 200-500 daltons. The magnet was scanned at a rate of 2 sec/decade, and the accelerating potential was 4Kv. All analysis were conducted at an electron-ionization energy of 70 eV.

Quantitation was achieved through the use of response factors for standards that were readily available. Semi-quantitation of compounds without authentic standards was achieved through an average response factor value as determined from the response factors of authentic standards from each class of compound reported. Confirmation of structures was achieved by comparison of authentic standards when available or by accurate mass measurement mass spectrometry when authentic standards were not available.

The results of this study to date indicate that the estuary is contaminated with a series of chlorinated, brominated, and mixed chlorinated and brominated organic compounds. The analyte concentrations in the water samples ranged from non-detectable up to 6 µg/l. The analyte concentrations in the sediment samples ranged from non-detectable up to 25 µg/g dry wet. The analyte concentrations in fish ranged non-detectable up to 300 µg/g lipid wet. The data suggests that there is a wide distribution of the contaminants in the study area. The contaminants detected in the fish tissue at Buoy 130 (control area), Lake Charles indicates that contamination is not limited to the area in the immediate vicinity of the industrial outfall.

GC/MS IDENTIFICATION OF TRICHLOROPHENYL ETHANOL IN IMPORTED PEPPERS:
POTENTIAL MISIDENTIFICATION AS A TRICHLORO METHYL METHOXY BENZENE.

Thomas Barry¹, Glenn Petzinger¹, Thomas Cairns², and Emil Siegmund²;
U.S. Food & Drug Admin., ¹B'klyn, N.Y. 11232 & ²Los Angeles CA. 90015

The FDA routinely monitors various domestic and imported foods for insecticide residues. GC/MS is used to confirm the presence of those insecticides or industrial chemicals found and to identify unknown analytical responses (UAR's) in these products. A UAR was encountered during analyses of a number of red and yellow peppers imported from the Netherlands. The UAR appeared in both the Luke extract and in the 15% eluate (1). The GC RRT's relative to Chlorpyrifos on three columns were: 5% OV-101, 0.34; 3% OV-17, 0.25; and 4% SE-30/6% SP2401, 0.35. GC/MS indicated the UAR had a molecular weight of 224 contained three chlorine atoms and produced a good match using the NBS library for a trichloromethyl methoxy benzene (Anisole) compound (Fig.1). The fragment ions m/z 209, [M-15] and 181, [M-43] were consistent with an anisole compound representing $[M-CH_3]^+$ and $[M-COCH_3]^+$, respectively.

PICI confirmed the molecular weight (224) but also produced a three chlorine cluster at m/z 207, indicating loss of H_2O from the protonated molecular ion suggesting the presence of an [OH] on the molecule.

Deuterium studies confirmed one exchangeable proton on the molecule by the shift in the molecular ion cluster to 225. In addition, m/z 209 and 181 each shifted up one mass unit indicating that the deuterium was retained on these fragment ions (Fig.2).

The FDA Mass Spectral Compilation of Pesticides and Industrial Chemicals (2) listed Trichlorophenyl Ethanol (TCPE) as the only other compound meeting all the criteria. TCPE is both an animal and environmental metabolite of the insecticide Tetrachlorovinphos(3,4). Reference material was obtained and the UAR was positively identified as TCPE.

Therefore, m/z 181 or the [M-43] ion in the EI spectrum represents a trichloro benzenium ion derived by loss of CH_3 and CO from the molecular ion with a two hydrogen rearrangement. This type of rearrangement was reported for benzyl alcohol and related compounds based on deuterium labeling and meta stable data (5).

A similar fragmentation mechanism is proposed for TCPE and is supported by CAD MS/MS analyses. The CAD daughter ion spectrum of the molecular ion m/z 224, shows that it dissociates to m/z 209 $[M-CH_3]^+$, m/z 181 $[M-COCH_3]^+$, 145 $[M-COCH_2Cl]^+$, and m/z 109 $[M-COCH_2Cl_2]^+$. The parent ion spectrum of m/z 181 indicates that it is derived from m/z 209 by loss of CO and from m/z 224 by loss of CO and CH_3 with a two hydrogen rearrangement (Fig.3). The deuteration experiment also shows that one of the hydrogens which rearrange onto the ring is from the [OH] moiety.

DIRECT ON-SITE VAPOR MONITORING BY TRANSFER LINE GC/MS

Neil S. Arnold, Kenneth A. Roberts, William H. McClennen, and
Henk L.C. Meuzelaar
Center for Micro Analysis & Reaction Chemistry, University of Utah
Salt Lake City, Utah 84112

A direct atmospheric vapor sampling inlet has been used for on-line monitoring of vapors in laboratory scale reactors. The inlet (Fig. 1) consists of three concentric tubes with appropriate flow control plumbing and electronics. This inlet provides for direct introduction of a pulse of air (.5 to 2 s) into a short (1 m) coated fused silica capillary column enclosed in the heated transfer line housing of a Finnigan-MAT ITD. Effluent from the column emerges directly into the ion trap.

Data presented here were obtained by sampling from a bed-characterization reactor (for waste disposal studies) using the MINITMASS, a modified mobile Ion Trap Mass Spectrometer [1] (Fig. 2). (Alternate sampling environments have included a coal combustor, an open air chemical release, a micro-scale laser pyrolysis chamber [2], and in-building ambient atmospheres.) Vapor samples were obtained repetitively at 60 s intervals, allowing for an isothermal GC separation of various components (Figs. 3 & 4). A ~1.5 s vapor sample allowed up to 100 μ l (@STP) of reactor atmosphere to enter the transfer line for chromatographic separation. A .18 mm ID transfer line with a .4 μ m DB-5 coating (J+W Scientific) was operated isothermally at either 25, 80 or 125 C. Carrier gas (helium) velocity was ~2.7 m/s (at column temp=25 C and 4400 ft elevation). All analyses were performed using electron impact ionization.

Detection limits have been established near the 1 ppb level for various substituted aromatic compounds using this (MINITMASS) system and taking advantage of the Axial Modulation* and Selective Mass Storage* features to improve sensitivity [3]. Estimations of concentration in this presentation are provided from the calibration data obtained on toluene, ethylbenzene, o-, m-, and p-xylene [4] and general sensitivity characteristics of ion trap mass spectrometers for the compounds of interest.

In the present analyses, halogen- and oxygen-substituted aromatics have been detected at < 100 ppb (Fig. 5). Various column temperatures allowed for analysis of compounds with atmospheric boiling points from 80 (benzene) to 350 C (anthracene) present in reactor vapors (Fig. 6). To date, test analyses of high boiling compounds than these have required the reactor be run under nitrogen to prevent rapid column degradation, though compounds as involatile as dibenzanthracenes (bp 550 C) have been detected under test conditions.

ACKNOWLEDGEMENTS

The authors are indebted to JoAnn Lighty, Geoff Silcox, Eric Eddings and David Pershing for providing the soil desorber samples. Financial support of the work reported here was provided by the Advanced Combustion Engineering Research Center (funded by NSF, the State of Utah, 23 industrial participants, and US DOE), the DOD Chemical Research Development Engineering Center (CRDEC) and Finnigan-MAT Corporation.

INLET SYSTEM FOR AUTOMATED GC/MS ANALYSIS OF COMPOUNDS IN
AMBIENT AIR AS COLLECTED IN STEEL CANISTERS

D. B. Cardin, C. C. Lin, D. B. Jacobs, M. Lev-on;
C-E Environmental, Camarillo, CA 93010

The use of SUMMA Passivated stainless steel canisters in ambient air monitoring is becoming increasingly popular because of the relatively good compound stability and recovery it affords. Presently, however, methodology for the quantitative analysis of canister samples by GC/MS has not been fully developed.

An automated inlet system has been developed which has been demonstrated to provide quantitative transfer of sample to a cryogenic trapping system at pressures above 0 psig (atmospheric pressure). The system incorporates a 16-position sampling valve where odd positions are plumbed to a zero air source to allow system purging. Sample is drawn into a modified Tekmar 5010 cryotrap/desorber using a vacuum system located downstream. Sample volumes are obtained by integrating the signal from a precision dual sensor mass flow controller also located downstream of the cryotrap. Internal standard is introduced via a 3-way solenoid valve located next to the 16-port valve.

The system is controlled using a PC/XT computer. External control is accomplished using an interface card developed in-house which contains a 12-bit A/D to digitize data received from the mass flow controller and 4 thermocouples. A D/A is also used to control a valve internal to the mass flow controller to obtain optimum sample flow rates at variable canister pressures. A separate relay board allows the operation of up to 7 valve solenoids and 3 heaters for closed loop temperature control. Additional relays allow the sample canisters to be heated individually if necessary to boost recovery of polar compounds.

The system operates under the control of "descriptor files" which control the sequence of events during analysis. Descriptor files can also be generated to perform multiple canister background testing in a single analytical run using a combined effluent technique, or to perform automated leak checking. The control software saves all of the runtime parameters at the end of each sequence as well as sequence and run termination events to increase the level of QA/QC and decrease the occurrences of the "what happened?" scenario.

Preliminary data shown on the following page indicates that the system does provide quantitative sampling of canisters with differing pressures. The first aliquot of 200 mls was taken while the canister pressure was 20 psig. After the final 1000 ml aliquot was removed, the pressure was about 13.3 psig and yet the last data point was within $\pm 5\%$ of theoretical for a linear curve. Data obtained for subatmospheric canister sampling yielded a non-linear curve after multiple samplings. This curve differs for different manifold positions so it is assumed that our 16-port valve leaks under vacuum. A solution to this problem is being investigated.

**REAL-TIME, IN-SITU POINT MONITORING
BY ION TRAP MASS SPECTROMETRY**

C. P. Leibman, T. M. Cannon, M. A. Wolf, and P. H. Hemberger
Analytical Chemistry and Instrumentation Groups
Los Alamos National Laboratory, Los Alamos, NM 87545

A transportable GC/ion trap mass spectrometer has been developed at Los Alamos National Laboratory to (1) identify and quantify hazardous organic compounds at chemical waste sites, (2) determine site boundaries, (3) document remedial activities, and (4) monitor the site after remediation. The instrument analyzes air, water, or soil samples for volatile organic compounds (VOCs) from part-per-billion (ppb) to part-per-million (ppm) levels and has been designed to mount in a 4x4 vehicle.

The transportable instrument consists of specialized sampling modules for air, soil, or water samples; a separations module containing sorbent traps and a megabore capillary column; and a detection module -- the Finnigan Ion Trap Detector. Different compound classes are accessed by selection of the appropriate separations module. Two sampling loops, which include a field interchangeable sampling module and sorbent trap, minimize dead-time between analyses by providing continuous sampling. Soil or water samples are purged with helium and the evolved organics are concentrated on a sorbent resin. A sampling pump is incorporated for air samples. After sample collection, the sorbent trap is ballistically heated and backflushed with helium to inject the organics onto the capillary column. The GC column is contained within a temperature programmed oven; carrier gas velocity is regulated with a mass flow controller. The sampling module, separations module, and associated hardware occupy a 18" x 18" x 5" box mounted on the top of ITD cover. All components are easily accessed for field maintenance. Heaters, valves, oven cooling fan, and mass flow controller are controlled through the ITD data system from an auxiliary microprocessor using FORTH and machine language.

A Finnigan MAT Ion Trap Detector was modified by removing the teflon RF ring spacers and replacing the standard 50 L/s turbomolecular pump with a 240 L/s turbomolecular pump. The fused silica capillary column was directly coupled to the ITD. Electron impact ionization was used with Automatic Gain Control (AGC). The Finnigan software was modified through the addition of key-stroke sequences and other FORTH routines. Instrument tuning, calibration, data acquisition and analysis are automated. The turn-key operating system allows the instrument to be used by minimally trained personnel.

The 24 priority pollutants in Purgeable Standards A and B can be correctly identified, quantified, and reported in a 10 minute automated sequence. A total ion chromatogram from 5 mLs water containing 50 ppb by weight A&B purgeables is shown in Figure 1. The mass chromatogram of trichloroethylene (m/z 130) obtained from 5 mLs water containing 10 parts-per-trillion A&B purgeables is shown in Figure 2. The corresponding sample mass spectrum and the library reference spectrum for trichloroethylene are shown in Figure 3.

APPLICATION OF MASS SPECTROMETRY TO
INDUSTRIAL CENTRAL ATMOSPHERIC MONITORING

M.E.Koslin, M.Rotheram and R.A.Heppner - Perkin-Elmer Corporation
Applied Science Division, Pomona, CA 91767

INTRODUCTION

Several techniques are available for near real-time detection of ppm and sub-ppm levels of hazardous vapors in air. However, mass spectrometry provides nearly universal detection capability, high sensitivity and wide dynamic range in one instrument. Mass spectrometry is utilized in the recently developed Industrial Central Atmosphere Monitoring System (ICAMS). This paper describes two areas important to its development: sample acquisition and sample introduction and ionization.

SAMPLE ACQUISITION SYSTEM (SAS)

Mass spectrometric instrumentation is typically used in central analyzer applications not only for technical reasons but also for economic reasons. A central analyzer requires sample transport from the multiple sampling locations. The process of providing a cost effective detection system begins with the development of a sample acquisition system that can: 1) sample many locations, 2) minimize sample transport time to the central analyzer by providing continuous flow on all sample lines, and 3) minimize the probability of interaction between sample molecules and sample lines.

A rotary valve with a novel sampling arrangement has been developed. It permits continuous flow on 50 sample lines and minimizes interactions between the gas sample and valve components. The rotary valve provides several advantages over manifolded solenoid valves: 1) reduced hardware and labor costs, 2) reduced maintenance costs, 3) improved reliability, 4) decreased space requirements, and 5) decreased system response time. Figure 1 is an illustration of the 50 port rotary valve and Figure 2 is a detailed illustration of the rotary valve/sample line interface. Only the central portion of the sample stream is selected for analysis. This minimizes channel cross-talk.

The use of teflon sample lines and filters minimizes sample molecule - sample line interactions throughout the system.

Figure 1. Rotary Valve

Figure 2. Rotary Valve Interface

SAMPLE INTRODUCTION and IONIZATION

Sample conversion, decomposition, and absorption can also occur in the mass spectrometer inlet and ion source. The probability of these processes occurring is decreased by minimizing the opportunity for gas molecule surface reactions in the analyzer. Increased mean free path and decreased surface area reduces these interactions.

The dual capillary inlet, Figure 3, ensures that the gas molecules "see" only teflon until within the ion source. The first capillary provides a pressure reduction from atmospheric to between 4 and 100 Torr and maintains a high gas flow rate for rapid equilibration of adsorbed species. The second capillary reduces the pressure and admits gas directly into the ionization region.

The "open" ion source configuration, Figure 4, eliminates the effects of surface interactions. Gas leaving the dual capillary inlet enters in a forward directed beam with high molecular density compensates for the loss of sensitivity associated with open or not differentially pumped source configurations. The probability of a gas molecule reacting with part of the ion source structure and returning to the ionization region is virtually eliminated. Thus, surface reaction products are minimized.

Figure 3. Dual Capillary Inlet

Figure 4. Open Ion Source

CONCLUSION

The rotary valve, dual capillary inlet and an open ion source in a high performance mass spectrometer based system enables the creation of a central atmospheric monitor for a variety of industrial environments. Over 200 chemicals are detectable by ICAMS. The system is configured to monitor 26 chemicals for any one application. Table I illustrates some of those chemicals.

Table I - Selected Chemicals

MASS SPECTROMETRIC ANALYSIS OF
SOME CHLOROALKYL PHOSPHATE
FLAME RETARDANTS

COLLEEN E. ROSTAD, WILFRED E. PEREIRA, AND THOMAS J. LEIKER
U.S. Geological Survey, Denver, Colorado 80225

During a study of the lower Mississippi River and its major tributaries, several chloroalkyl phosphate flame retardants were identified in surface water samples using gas chromatography (GC) electron impact (EI) ion trap mass spectrometry. The identifications were confirmed by matching the GC retention time (on a 30 meter, 0.25 mm i.d., 0.25 μ m film DB-5 J & W capillary column with helium at 35 cm/sec as the carrier gas) and the EI mass spectra (with electron energy, 70 eV and emission current, 0.25 μ A) with authentic standards analyzed under identical conditions on both the ion trap detector and TSQ-46 mass spectrometer. The selected compounds included tris(2-chloroethyl) phosphate, tris (chloroisopropyl) phosphate, and tris (dichloropropyl) phosphate.

The standards were reanalyzed in order to develop a rapid analysis utilizing tandem mass spectrometry. When analyzed by the traditional technique of electron ionization, no molecular ion was observed. Except tris(2-chloroethyl) phosphate, listed in the NBS Library as "ethanol, 2-chloro-, phosphate (3:1)", the spectra of these selected compounds were not present in the NBS Library of EI reference spectra. The selected compounds were ionized by positive ion chemical ionization with methane as the reagent gas at 0.25 torr. Although a protonated molecule was produced, some fragmentation occurred. For tandem mass spectrometry analysis based on the molecular ion, maximum sensitivity requires maximum production of the molecular ion. The compounds were then ionized by positive ion chemical ionization by using isobutane as the reagent gas. Under these conditions, only the protonated molecule was produced, ideal for tandem mass spectrometry analysis.

The protonated molecules, containing the ^{35}Cl isotope only, were subjected to collision activated decomposition by using argon as the collision gas. The resulting daughter spectra were produced at 15 eV collision energy and 1.5 mTorr collision gas pressure. The daughter ion spectra included sequential losses of the intact constituents from the phosphate ion. For example, the protonated molecule of tris (chloroisopropyl) phosphate, at mass 327, lost sequential chloroisopropyl units of 76 daltons, to produce strong daughter ions at masses 251, 175, and finally 99.

Variations of collision energy from 15 to 30 eV and collision gas pressure from 1.0 to 2.5 mTorr were not effective in producing one prevalent neutral loss from each protonated molecule, which would have enabled a very sensitive, specific analysis utilizing simple neutral loss scans. It was also not possible to maximize the generation of the final daughter ion at mass 99, which would have been an excellent analysis utilizing parent scans for this compound class of chloroalkyl phosphates. Therefore, a technique for the analysis of these flame retardant compounds by using isobutane positive ion chemical ionization followed by tandem mass spectrometry utilizing a neutral loss analysis was not sensitive.

DETECTION OF TRACE ORGANICS IN AIR USING THERMAL DESORPTION ITMS

Marcus B. Wise, Michelle V. Buchanan, and Ralph H. Ilgner
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6120

Introduction

A thermal desorption apparatus has been interfaced directly with a Finnigan ion trap mass spectrometer (ITMS) for the rapid detection and quantification of trace organics in air. No chromatographic separation of components is performed prior to introduction into the mass spectrometer. Instead, target compounds are ionized by chemical ionization (CI) and selective mass storage is used to isolate the $(M+H)^+$ ion for subsequent fragmentation by collision induced dissociation. Quantification is performed by integration of the thermal desorption profile using the characteristic daughter ions for the compound of interest. Using this technique, as little as 50 pg of a constituent desorbed from a resin trap can be identified and quantitated with a sample turn around time of only 2-3 minutes. Some applications thus far have included the detection of part-per-trillion levels of organo-phosphonates in air and the quantification of nicotine in environmental tobacco smoke (ETS).

Experimental

The thermal desorption apparatus used for these experiments was designed and constructed at Oak Ridge National Laboratory. It is designed to accept resin traps 3 inches long and 0.25 inches diameter with a 1-1.5 inch bed of resin. Thermal desorptions are performed by heating the resin traps with 450 watts of power for 10 seconds while purging with helium at a flow rate of 20-25 ml per minute. Effluent from the desorber is admitted into the ITMS through an open-split interface with a split ratio of approximately 100:1 as shown in Figure 1. A 16 unit automated version of the thermal desorption apparatus has recently been completed. In addition to the ability to perform direct thermal desorptions into the ITMS, this system also features hardware necessary for cryofocussing or capillary column dynamic focussing of desorbed constituents.

For the experiments described here, the ITMS was used in the selective mass storage mode and isobutane was used as the CI reagent. Ionization times were typically 10 msec and CI reaction times ranged from 50-100 msec. MS/MS spectra were generated for the target compounds and comparative spectra were acquired in each case using authentic standards.

Results and Discussion

Typical thermal desorption profiles are shown in Figures 2a and b. The top profile corresponds to the total ion current for the dissociation of m/z 163 from a sample of ETS. The bottom trace shows the actual profile for nicotine generated by plotting the extracted ion current for m/z 84, which is a characteristic daughter ion of protonated nicotine (m/z 163). In this case, no sample focussing was used, yet the peak shape was excellent and the width at half height was only 15 seconds. A response curve ranging from 300 pg - 50 ng of desorbed nicotine is shown in Figure 3. It was generated by plotting the sum of the integrated ion currents for characteristic daughter ions at m/z 84, 106, 120, and 132. No internal standards were used for the quantitative determinations yet the correlation coefficient for the calibration curve was 0.9996 and reproducibility for replicate samples was approximately $\pm 15\%$. Because of the low detection limits that can be achieved for nicotine, air samples can be collected on resin cartridges by sampling approximately 1 liter of air and then analyzed in less than 5 minutes. A comparative study of this method with a standard gas chromatographic method for determining nicotine in ETS has shown that the ITMS method has better detection limits and is considerably faster.

*Research sponsored jointly by the Office of the Program Executive Office - Program Manager for Chemical Demilitarization under Interagency Agreement 1769-1757-A2 and the National Cancer Institute under Interagency Agreement 0485-0485-A1 with Martin Marietta Energy Systems, Inc., under contract DE-AC05-84OR21400 with the U.S. Department of Energy.

"The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. DE-AC05-84OR21400. Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U.S. Government purposes."

Results for organo-phosphonate compounds are very similar to those for nicotine. Detection limits as low as 50 pg of either di-isopropylmethyl phosphonate (DIMP) or dimethyl-methyl phosphonate (DMMP) have been demonstrated and linear calibration curves have been generated from 50 pg-5 ng of desorbed material. Sample turn around of less than 2 minutes has also been accomplished for these compounds.

IDENTIFICATION OF O-ETHYL O'-(2-DIISOPROPYLAMINOETHYL) METHYLPHOSPHONITE
DEGRADATION PRODUCTS BY CHEMICAL IONIZATION MASS SPECTROMETRY
Dennis K. Rohrbaugh, U.S. Army Chemical RD&E Center, AFG, MD 21010-5423

The objective of this study was to develop a method for the detection and identification of products from the degradation of O-ethyl O'-(2-diisopropylaminoethyl) methylphosphonite (EDMP), which is one of the compounds used in the production of the nerve agent O-ethyl S-(2-diisopropylaminoethyl) methylphosphonothioate (VX). This information is of interest from both an environmental and safety standpoint. Identification of phosphonites and other organophosphorus compounds containing the 2-diisopropylaminoethyl group is difficult on the basis of EI fragmentation alone because extensive fragmentation results in little or no molecular ion information. In this study we apply methane CI capillary column GC/MS to identify ten EDMP degradation products produced during storage.

Spectra were obtained on a Finnigan 5100 GC/MS equipped with a fused silica 15m x 0.25mm ID SE-54 capillary column. Injection temp was 220°C, GC/MS interface temp was 220°C and the oven was programmed from 60°C to 220°C at 10°C/min. The CI reagent gas was methane with an internal source pressure of 0.6 Torr. The mass range was scanned at a rate of one scan per second (0.95 sec up scale with a 0.05 sec hold at the bottom) from 60-450 amu.

Figure 1 illustrates the total ion chromatogram for the stored sample of EDMP. The identification of each of the ten compounds detected is listed in Table 1. These products result from moisture-catalyzed disproportionation (1 and 9), hydrolysis (2, 4 and 6), oxidation (3 and 7) and Michaelis-Arbuzov rearrangement (8 and 10) reactions.

Table 1. Compounds Identified in a Stored Sample of EDMP

R.T. (min)	Mol. Wt.	Peak Number	Name	Structure
1.1	136	1	O,O'-Diethyl Methylphosphonite	$\text{Me-P}(\text{OEt})_2$

16.7	334	10	O-(2-Diisopropylaminoethyl) 2-Diisopropylaminoethyl- methylphosphinate	$\text{Me-P}(=\text{O})\text{CH}_2\text{CH}_2\text{N}(\text{iPr})_2$ $\text{OCH}_2\text{CH}_2\text{N}(\text{iPr})_2$

Figure 1

Methane chemical ionization provides the valuable molecular and fragment ion information necessary to identify these compounds. Table 2 summarizes the characteristic CI fragmentation ions observed. The phosphonites containing the 2-diisopropyl-aminoethyl (R) group are unusual in that formation of (M-1)⁺ ions were observed rather than (M+H)⁺ ions. EDMP and compounds 6,7,9 and 10 have as their base peak the ion at m/z 128. The absence of this ion for peak 8 suggests that the Michaelis-Arbusov rearrangement forms MeP(O)(OEt)(R) rather than MeP(O)(OR)(Et). The P-R bond cleaves much less readily than the O-R bond.

Table 2. CI Fragmentation Observed for EDMP Decomposition Products

ANALYSIS OF CHEMICAL WARFARE AGENTS IN A COMPLEX MATRIX BY GC-MS AND GC-MS/MS

P.A. D'Agostino, L.R. Provost and J.F. Anacleto, Defence Research Establishment Suffield, Ralston, Alberta, CANADA, T0J 2N0 and P.W. Brooks, Institute of Sedimentary and Petroleum Geology, Calgary, Alberta, CANADA, T2L 2A7.

Chemical weapons, although prohibited by the 1925 Geneva Protocol, have been used recently in several armed conflicts, including the Iran/Iraq war (1). Verification of chemical agent use has often been difficult, due principally to inadequate sampling and identification procedures. Gas mask canisters from protected troops at the scene of a chemical attack may be used as a sampling device. Recent international interlaboratory exercises indicated chemical warfare agent detection difficulties associated with the complexity of the battlefield volatiles. This background matrix contained numerous hydrocarbons characteristic of diesel exhaust emissions (Table I). A capillary column GC-FID, GC-MS and GC-MS/MS study was initiated with the principal objective being the development of methods for the trace detection of sarin (GB), soman (GB) and mustard (H) in the presence of numerous interfering diesel exhaust components.

Air from a diesel exhaust environment was sampled through a Canadian C2 charcoal canister for four hours at the typical working respiratory rate of 20 L/min. The canister charcoal (108 g) was Soxhlet extracted for six hours with 250 mL of dichloromethane and concentrated to 10 mL under a gentle stream of nitrogen. Extraction efficiency was estimated to be in the 10-15% range for GB and GD and 70% for H based on the extraction of 100 ug of agent spiked charcoal (10 g). Capillary column GC analyses were performed on Varian 3700 or HP 5890 gas chromatographs equipped with an on-column injector and a 15 m x 0.32 mm ID J&W DB-5 column under the following temperature program: 40 or 50°C (2 min) 10°C/min 280°C (5 min). GC-MS analyses (full scanning 400-35 u; 1 sec/decade) were performed on a VG 70/70E under the following conditions: a) EI (70 eV, 100 uA, 200°C, 6 kV) and b) ammonia CI (50 eV, 500 uA, 120°C, 9×10^{-5} Torr, 6 kV). GC-MS/MS analyses (source: 8 kV, 70 eV, 100 uA, 250°C) were performed on a VG 70S under the following reaction ion monitoring (RIM) conditions: a) H analysis (m/z 158 to 109 and m/z 158 to 96, CAD cell (58 eV, 5×10^{-7} Torr air)) and b) GB and GD analysis (m/z 99 to 79, CAD cell (50 eV, 5×10^{-7} Torr air)).

Diesel exhaust extracts were spiked at the 50 ng/mL, 5 ng/mL and 500 pg/mL level with GB, GD and H and analysed by GC-FID, GC-MS (EI and ammonia CI) and by GC-MS/MS under reaction ion monitoring (RIM) conditions. At the 20 ng level matrix interferences masked both GD and H during GC-FID. Figure 1 illustrates GC-MS (EI) chromatograms obtained for the charcoal extract and this extract spiked with 20 ng and 2 ng of GB, GD and H. All spiked chemical warfare agents, detected at the 20 ng level, were effectively masked by the matrix at the 2 ng level. The chemical noise associated with this matrix negated the use of selected ion monitoring. The specificity of GC-MS (ammonia CI), a technique routinely used for chemical warfare agent analysis (2-4), improved this full scanning detection limit for GB and GD to about 5 ng (ammonia CI not amenable to H analysis). GC-MS/MS under RIM conditions was the most specific and sensitive method for the confirmation of these chemical warfare agents in the presence of interferences levels two to three orders of magnitude greater than the spiked agents. Figures 2 and 3 illustrate the chromatograms obtained for H, and GB and GD respectively spiked into the extract at the 500 pg level. Sample detection limits (S/N=5:1) of 70 pg, 60 pg and 30 pg were estimated for GB, GD and H based on this data.

Use Of Benzene Charge Exchange At Atmospheric Pressure
For Low Level Detection Of Pollutants In Air*

S.N.Ketkar, J.G.Dulak, S. Dheandhanoo and W.L. Fite
Extrel Corporation, Pittsburgh, PA 15238

Analysis of trace quantities of compounds is becoming increasingly important in air pollution studies where it is often necessary to detect impurities in the concentration range of parts per billion or less. Atmospheric pressure ionization has been shown to be an extremely sensitive real time method to achieve sensitivities in the range of few tens of parts per trillion. In atmospheric pressure ionization use is made of the proton transfer reaction between the hydronium ion (H_3O^+) and the analyte of interest (M) to produce the protonated molecular ion MH^+ . This reaction depends critically on the proton affinity of the analyte of interest. Analytes with low proton affinities, like the organo-sulfur compounds, can not be detected by the atmospheric pressure ionization technique. The analytes with low proton affinity can be detected using atmospheric pressure ionization technique if one uses a charge exchange reaction with a reagent ion rather than the conventional proton transfer reaction with the hydronium ion.

We report here the use of benzene charge exchange, at atmospheric pressures, for the low level detection of 2-chloroethyl ethyl sulfide. All experiments were performed using an EXTREL triple quadrupole mass spectrometer system with an atmospheric pressure ionization source. A vapor generator based on a heated nebulizer was used to generate low levels of 2-chloroethyl ethyl sulfide in air. Concentrations as low as a part per trillion were accurately generated using such a vapor generator.

Tests were performed to measure the response of the system to varying concentration of 2 chloroethyl ethyl sulfide in air, in the range of 40 ppt to 600 ppt. Fig. 1 shows the response of the system to varying concentrations of 2-chloroethyl ethyl sulfide in air. Fig. 2 shows the linearity plot for the system response. Regression analysis using 95% confidence bounds was performed on the data. The

analysis indicates a statistical detection limit of 13 ppt using a corona discharge source, operating at atmospheric pressure, coupled to an EXTREL triple quadrupole mass spectrometer.

FORMATION OF ADDUCT IONS IN THE METHANE ENHANCED NEGATIVE ION
MASS SPECTROMETRY OF ARYL-N-METHYLCARBAMATES

M.J.I. Mattina* and L.Q. Huang
The Connecticut Agricultural Experiment Station
Department of Analytical Chemistry
123 Huntington Street
New Haven, Connecticut 06504

Because carbamate pesticides are in widespread use, there is substantial interest in the development of analytical procedures for their qualitative and quantitative identification. The thermal instability of this class of compounds may be minimized by careful attention to the analytical procedure employed. The thermal instability may be eliminated by preparing the trifluoroacetyl (TFA) derivative. In our study capillary gas chromatography coupled with methane enhanced negative ion chemical ionization mass spectrometry (NICIMS) was investigated as an analytical technique for the identification of seven aryl-N-methylcarbamate pesticides (ROCONHCH_3 , where R=aryl).

Each carbamate was introduced separately through a capillary GC column into the high pressure CI source of a Hewlett Packard 5988A quadrupole mass spectrometer. The instrument was tuned in negative ion mode using perfluorotributylamine (PFTBA). Methane was used as the buffer gas and the source temperature was held at 100°C. The negative ion mass spectrum of Sevin (Carbaryl) illustrated in Figure 1a is typical of the NCI mass spectrum recorded for the aryl-N-methylcarbamates in the present study. In addition to the $[\text{M}-1]^-$ and RO^- ions, ions a, b, and c at m/z values greater than that of the parent ion, are noted. Possible ion/molecule reaction pathways responsible for formation of these adduct ions are:

Residual chloride ions are noted in our mass spectrometer source under the experimental conditions employed and result in the formation of ion a as described in Equation a. Ion/molecule reactions resulting in the formation of adduct ions similar to that proposed in Equation c have been observed previously under positive chemical ionization (PCI) conditions for heterocyclic compounds¹ and under NCI conditions for oxime carbamates.² Adduct ions of the type b (as well as of type d, see below) are observed for the first time under high pressure NCI conditions. The proposed ionization/neutralization/ionization pathway implied in Equation b for the formation of ion b is supported by the methane enhanced NCI mass spectrum of Methiocarb (Mesurol) illustrated in Figure 1b. In addition to adduct ions of the types a, b, and c, a fourth adduct ion at m/z 289 is noted in the spectrum of Methiocarb whose formation via Equation d is proposed:

As an alternative to the neutralization implied in equations b and d for the formation of ROH, fragmentation of ion c to form ion b or of ion b to form ion d, cannot be unequivocally eliminated.

It must be demonstrated that the adduct ions observed in the NCI mass spectra of these compounds are attributed solely to reactions occurring in the high pressure mass spectrometer source. EI spectra were obtained under the same GC conditions as for chemical ionization at the same retention times as for NCI mode and agreed in all respects with the published EI spectra for the compounds. The positive ion, methane enhanced chemical ionization mass spectra for these compounds also agreed with published data and again were recorded at the same RT as before.

Finally, in order to corroborate that aryl-N-methylcarbamates can readily undergo reactions in the high pressure chemical ionization source, Sevin was introduced into the source at 100°C through the GC simultaneously with the introduction of pentachlorophenol through the DIP. In the resulting negative ion spectrum shown in Figure 2 ions appear at m/z values 179, 395, and 431. These ions are not present in the NCI of either Sevin

or pentachlorophenol and so must be attributed to ion/molecule reactions between the two compounds occurring in the mass spectrometer source.

It is of interest to note that under the same experimental conditions (source temperature, source pressure, GC conditions, and sample concentration), no adduct ions are observed in the NCI of the seven trifluoroacetyl derivatives of these carbamates. The methane enhanced NCI of the Sevin-TFA derivative is reproduced in Figure 3. Apparently, the substitution of the N-H hydrogen of the carbamate with COCF_3 moiety in the derivative eliminates the ion/molecule reactions responsible for adduct ion formation.

The conclusion may be drawn that for certain classes of compounds, such as N-methylcarbamates, conditions prevailing in the high pressure chemical ionization source are favorable for ion/molecule reactions in which ion fragments derived from the substrate react with the neutral substrate. Additional ion/molecule reactions may follow the neutralization of some ionic fragments from the substrate.

CONFIRMATION OF ETHYLENETHIOUREA (ETU) RESIDUES IN FOODS BY CAPILLARY GC/TANDEM MASS SPECTROMETRY

John A. G. Roach, Denis Andrzejewski and Richard T. Krause,
Division of Chemical Contaminants, FDA, Washington, DC 20204

Ethylenethiourea (ETU) is a degradation product of ethylenebisdi-thiocarbamate fungicides. Over 130 million pounds of these fungicides are applied annually to agricultural crops throughout the world. Concern that ETU may be an oncogen prompted the FDA to monitor the food supply for ETU.

The recent introduction of a new high pressure liquid chromatographic assay employing an electrochemical detector improves FDA surveillance for ETU by circumventing many of the problems associated with previous methods. The new assay determines ETU in an aqueous system without derivatization. The electrochemical detector is sensitive and selective.(1)

In spite of the selectivity of the new assay, it was still necessary to confirm alleged ETU residues by an independent technique to eliminate any chance of false positives. Several mass spectrometry techniques were evaluated from the perspective that ETU residue confirmation could be performed with either quadrupole or magnetic instruments.

The HPLC method provides an aqueous extract containing underivatized ETU suitable for chromatographic introduction to the mass spectrometer. Nitz, et al reported the use of Carbowax 20M to gas chromatograph underivatized ETU.(2) We report that capillary gas chromatography (GC) on a cyanopropyl phenyl column (DB-1701) results in a very narrow and symmetrical GC peak that clearly augments the sensitivity of the analysis.

The EI and CI spectra of ETU are characterized by abundant species indicative of molecular weight. Additional fragmentation is of low relative abundance. Methane CI of ETU is significantly more sensitive than EI in the quadrupole instruments (Finnigan 3300, 4000, TSQ-46) that we evaluated. EI is the more sensitive mode of detection with our ZAB-2F magnetic instrument. Data are presented for the quadrupole instruments in the methane CI mode and the EI mode for the magnetic instrument.

The methane CI spectrum contains little more than molecular weight information. GC/MS/MS improves the specificity of the CI analysis by providing ETU daughter ion data at the retention time of ETU. Daughter ion isotope data suggests the elemental composition of the daughter ions and aids in the interpretation of the daughter ion spectrum:

Multiple ion monitoring of the daughter ions of ETU readily confirms 10 ppb ETU in food extracts:

GC/MS/MS Conditions:

10M x 0.32mm i.d.
1u film DB-1701 J&W
inj 200C, xfer 220C
col 60-240C @ 20C/min
He carrier 140 cm/sec
methane 0.25 torr
collision cell 1.8 mtorr
collision energy -20V

MID 103 daughters:

44, 59, 60, 70, 86

Fragment ions in the EI spectrum of ETU are of low abundance relative to the molecular ion. High resolution provides the elemental compositions of the principal ions:

m/z	mass composition	error (mmu)
72	C2H2NS	0.08
73	C2H3NS	0.10
74	C2H4NS	0.09
60	CH2NS	0.07
45	CHS	0.20
43	C2H5N	0.10
43	CH3N2	0.10

Full scan low resolution EI data can provide adequate confirmation of ETU by demonstrating the absence of coeluting coextractives in a detected signal. Scan cycle time limits the sensitivity of a full scan GC/MS assay. Multiple ion monitoring is a more sensitive scan mode, but our 1979 vintage ZAB 2F is not capable of magnet stepping multiple ion monitoring under data system control. The sensitivity of the instrument for ETU in the full scan mode is 10 ng or 100 ppb.

The EI CID MIKES spectrum of the molecular ion of ETU contains broad fragment ions of low relative abundance. The majority of the detected ETU signal is carried by the parent ion. The low yield of ETU fragment ions in the EI CID-MIKES mode limits the sensitivity of this assay. The sensitivity of the instrument using multiple ion monitoring under data system control in the CID-MIKES mode is 10 ng or 100 ppb.

SUMMARY AND CONCLUSIONS

Aqueous extracts of cabbage, collards, green beans, potatoes and spinach were examined for ETU by GC/MS and GC/MS/MS. No coeluting interferences were observed at the retention time of ETU. The GC column was not affected by aqueous injections.

Capillary GC/MS/MS can provide confirmation of ETU in aqueous extracts at a concentration of 10 ppb. The instrumental conditions chosen by the analyst must consider both the capabilities of the individual instrument and the analytical behavior of ETU.

MASS SPECTROMETRY OF TRIAZINES
UNDER METHANE ENHANCED NEGATIVE CHEMICAL IONIZATION CONDITIONS

L. Q. Huang and M. J. I. Mattina
Department of Analytical Chemistry
The Connecticut Agricultural Experiment Station
New Haven, CT 06504

Studies on the fate of triazine herbicides in the environment have prompted the need for and the development of a sensitive and specific assay for these compounds. Because of its high sensitivity for this class of compounds and its inherent specificity, negative chemical ionization (NCI) should be useful in the screening and confirmation of triazines.

It is well documented that mass spectra obtained under electron capture, negative chemical ionization conditions are significantly dependent on a number of instrumental parameters and experimental conditions. Previous detailed NCI studies undertaken on an HP 5985B mass spectrometer (MS) have resulted in a tuning procedure and delineation of experimental parameters for this instrument. Differences in instrumental control as well as instrumental configuration between HP 5985B and HP 5988A MS made it necessary to develop a systematic tuning protocol for the HP 5988A MS operated in NCI mode under HP ChemStation control. We have demonstrated the validity of this protocol by using it to produce NCI mass spectra for decafluorotriphenylphosphine (DFTPP) with acceptable relative ion abundances for the m/z 167, 275, 365, and 442 ions. Furthermore, the instrument sensitivity was maximized by examining the variation of total negative ion current as a function of reagent gas pressure in the high pressure source of the HP 5988A MS. We are thus able to report reproducible NCI mass spectra for the *s*-triazines obtained under well defined operating conditions.

The methane enhanced NCI mass spectra of 22 triazines were acquired at ion source temperatures of 100°C and 250°C. For twenty of the compounds the M^- or $[M-1]^-$ is observed. Fragmentation patterns for $-Cl$, $-OCH_3$ and $-SCH_3$ substituted triazines are contrasted. For the $-Cl$ substituted compounds fragment ions are more intense at 250°C than at 100°C. There are, however, more fragment ions at greater intensity at 100°C than at 250°C for $-SCH_3$ substituted triazines. For the $-OCH_3$ substituted compounds most of the ion current is in the $[M-1]^-$ ion. In addition to the fragment ions observed, a number of unusual adduct ions are noted, including $[M+11]^-$, $[M+12]^-$, $[M+13]^-$, $[M+14]^-$, $[M+25]^-$, and $[M+28]^-$. An example is given in Figure 1.

The results of this study show that methane enhanced negative chemical ionization is an alternative mass spectrometric technique for qualitative analysis of *s*-triazines. The fragmentation patterns of the NCI mass spectra of these compounds were found to be a function of the substituent at the 2 position of the aromatic ring. Adduct ions were observed at abundances which could result in the misidentification of the M^- . Further investigation of the adduct ions is expected to provide their structural identities and pathways of formation in the high pressure chemical ionization source.

Figure 1. Methane enhanced NCI mass spectra of ametryne at source temperatures of 100°C and 250°C.

ESTIMATION OF MUTAGENIC/CARCINOGENIC POTENTIAL OF ENVIRONMENTAL
CONTAMINANTS BY ION-MOLECULE REACTIONS AND TANDEM MASS SPECTROMETRY

J. A. Freeman, R. A. Yost, J. V. Johnson, M. E. Hall,
Chemistry Dept., Univ. of Florida, Gainesville, FL 32611;
D. W. Keuhl, U.S. EPA Duluth, MN 55804.

Potentially mutagenic and carcinogenic chemical contaminants are recognized to be reactive electrophiles capable of modifying biological macromolecules. These represent only a small portion of the total number of contaminants in the typical environmental sample. Accurate evaluation of these chemicals to provide data for human and ecosystem risk assessment depends upon analytical procedures to isolate, identify, and quantify each chemical and to provide a measure of electrophilic reactivity. There is a substantial need for a rapid, cost-effective technique to screen complex environmental samples for contaminants. Our approach is to study ion-molecule reactions in the ion source or collision cell of a tandem quadrupole mass spectrometer using model nucleophiles to represent biological macromolecules.

The reaction of adenine with benzoylchloride has been studied in the ion source of a TSQ 45. Adenine is introduced into the ion source continuously by a solids probe and benzoylchloride by a 3m DB-1 capillary column. All species in the ion source are ionized by methane CI (0.4 Torr). Figure 1 depicts the positive and negative mass spectra obtained from the reaction of adenine and benzoylchloride. The m/z 240 is the $(P+H)^+$ of the reaction product and m/z 239 is the P^+ of the adduct. In addition to the DNA adduct ions, methane adduct ions of both reactants form in the positive mode while chloride adduct ions of the nucleophile can be observed in the negative mode. The daughter spectra of the $(P+H)^+$ and P^+ adduct ions produced in the ion source provide a means for identification of the DAN adduct. Argon CAD of 240⁺ and 239⁺ are complementary to each other; 240⁺ fragments to the benzoyl ion whereas 239⁺ fragments to the adenine ion. Further confirmation is achieved by comparison of the daughter spectra obtained from the adduct ion and the synthesized standard.

Reaction of pyridine with various electrophiles has been studied in the collision cell of a TSQ 70. Pyridine is introduced continuously into the ion source by a fine-metering valve and the electrophiles are introduced into the collision cell by a 6m DB-5 capillary column. The M^+ ion of pyridine, produced by methane CI, is mass-selected by Q1 and reacts with the neutral electrophiles in the collision cell at collision energies of 1 eV. Product ions are then mass analyzed in Q3. The mass spectrum of the allyl chloride/pyridine reaction in the collision cell is compared to one obtained from the ion source in Figure 2. The collision cell mass spectrum is simpler and less ambiguous since only one ion is present in the collision cell to react with the electrophiles eluting from the GC. In contrast, the m/z 120 ion can correspond to the $(N+C_3H_5)^+$ methane CI adduct ion of pyridine and/or the reaction product of pyridine M^+ and allyl chloride.

Figure 3 illustrates mass chromatograms obtained by alternately mass-selecting 79⁺ of pyridine and 17⁺ of methane to react with the electrophiles eluting from the GC into the collision cell. Thus, mass chromatograms are obtained which depict only the components which react with pyridine and simultaneously, the CI mass spectra of all the components in the GC sample. Chromatograms A, B, and C are a result of mass-selecting 79⁺ to react with the electrophile. Chromatogram A displays the RIC and is relatively uninformative. Chromatogram B displays the trace of 79⁺ and demonstrates the difficulty of monitoring the loss of reactant ion since loss of 79⁺ also occurs by charge exchange with the electrophile. Chromatogram C is the RIC minus 79⁺; it illustrates the capability to monitor eluents which react in any way with the reactant ion. Chromatogram D displays the RIC resulting from mass-selection of 17⁺ and subsequent reaction with the eluting electrophiles. This chromatogram illustrates the ability to detect all compounds in the GC sample whether the compounds react with 79⁺ or not.

Allyl compounds are known carcinogens which react with DNA to form adducts, whereas the analogous propyl compounds are non-carcinogenic and therefore should not react with DNA. The results of alternating between 79⁺ of pyridine and 17⁺ of methane, shown in Figure 4, were compared for equivalent amounts of the two classes of compounds. The allyl halide chromatograms C and D demonstrate the gas-phase reactivity of the carcinogenic allyl compounds with 79⁺. The propyl halide chromatograms C and D illustrate that no significant reaction with 79⁺ is observed for these non-carcinogenic compounds.

Comparison of collision cell gas-phase reactivity and mutagenicity for various carcinogenic and non-carcinogenic electrophiles displays the same order of mutagenicity, but not the same magnitude.

The ability to produce and detect products of nucleophilic/electrophilic reactions has been

demonstrated in the ion source and collision cell of a tandem mass spectrometer. Mass spectra of reactions in the ion source tend to be complicated; furthermore, it is difficult to determine which form of each species is reacting ($[M+H]^+$ or M^+). Mass spectra of reactions in the collision cell are less complicated, as only one mass-selected reactant ion is allowed to interact with the neutral electrophiles. MS/MS confirmation of the product ion by daughter mass spectra is one advantage of reactions in the ion source, since CAD of collision cell reactions cannot be performed without the use of an instrumental capable of MS/MS/MS.

APPLICATION OF PURGE AND TRAP GC/MS FOR THE ANALYSIS OF
OCTAMETHYLCYCLOTETRASILOXANE IN WATER AT SUB-PART PER BILLION LEVELS

Edward C. Tews, Valerie J. Bujanowski, and John A. Moore
Dow Corning Corporation, Midland, Michigan 48686

Purge and Trap (P&T) or dynamic headspace analysis using capillary column gas chromatography is becoming more popular for the analysis of volatile organics in aqueous samples. The use of cryofocussing with capillary columns has greatly improved the resolution and analysis time over packed columns. The use of capillary columns has also allowed direct coupling between a gas chromatograph and a mass spectrometer. Using a mass spectrometer in a selected ion monitoring mode yields specific detection with high sensitivity.

The objective of this work was to develop a method for analyzing octamethylcyclotetrasiloxane (OMCTS) in aqueous samples at sub-part per billion levels

OCTAMETHYLCYCLOTETRASILOXANE

(OMCTS)

with minimal sample size. There are several problems associated with OMCTS. First, the solubility of OMCTS has been reported from 10,000 to 0.05 ppm. This vast range of values has been proposed to be due to the ease of OMCTS to form stable colloids in water, yielding high values for solubility. Second, a high Henry's Law Constant of approximately 1000 times greater than benzene has been determined for OMCTS. This high value implies that OMCTS tremendously favors the volatilization from the aqueous phase to the gas phase. Combining the above characteristics, establishing a method to detect and quantitate OMCTS will require low detection limits and careful sample handling.

Purge and trap GC/MS was chosen to address these problems for several reasons. The purge and trap methodology has several advantages over extraction techniques. First, there is a large concentration factor, typically 500-1000 fold without involving very large sample sizes. The sample preparation is minimal which reduces the loss of volatile constituents, introduces fewer artifacts, and improves the reliability of the analysis. There are, however, associated disadvantages with purge and trap. Background chemicals in the laboratory environment are easily observed in the analysis when looking at these levels and can cause interfering problems. Many of these disadvantages can be overcome using selected ion monitoring mass spectrometry.

Advantages of selected ion monitoring (SIM) mass spectrometry are reduced interferences from other compounds (selectivity) and increased sensitivity, approximately 100 times better than full scan mode. However, the cost of the mass spectrometer as a detector can be quite high compared to other GC detectors. The reliability and selectivity of the data may overcome this disadvantage.

After loading the sample, this system of a Tekmar 4000 dynamic headspace concentrator, interfaced to a Finnigan 4600 GC/MS with a cryofocussing module was automated to collect and analyzed the data. After receiving a ready signal from the P&T unit, the mass spectrometer acquired and processed the data. During the acquisition, a procedure was utilized to change the range over which the mass data was acquired. Three ranges, first, covering a broad mass range, then SIM of two internal standard ions, and finally, SIM of two OMCTS ions were utilized. The detected peaks were checked against library entries and the OMCTS was quantitated.

This method was evaluated with six samples of OMCTS over the range of 0.75-120ppb and yielded a correlation coefficient of 0.999 comparing response versus concentration. The corresponding response factors over this range were determined to be within 5% relative standard deviation (RSD). Repeatability from five replicate samples was determined to be 5% RSD. Further evaluation determined the purge efficiency of OMCTS from water at 96% using a 5ml sample size, purged with approximately 480ml of helium. With this method defined, a solubility apparatus was assembled as shown below. This apparatus

APPARATUS FOR SOLUBILITY DETERMINATION

has a small layer of OMCTS over water which is gently being stirred to avoid vortex formation and possible colloidal dispersions. This experiment was allowed to equilibrate for at least 24 hours before sampling, generating a saturated solution of OMCTS in water. Several samples were analyzed at varying "equilibration" times and were used to determine a solubility of OMCTS at room temperature (22°C) of 77ppb.

In conclusion, an automated purge and trap GC/MS method was developed for the analysis of OMCTS in aqueous samples at sub-part per billion levels using only approximately 10 milliliters of sample. The method was determined to have good repeatability and linear response from 0.75-120ppb OMCTS. This method was also used to determine the solubility of OMCTS at 77ppb.

Determination of the Photodegradation Products of Disperse Orange 29 by GC/MS and HPLC/MS

C.A. Haney, H.S. Freeman, and S.A. McIntosh, N.C. State Univ. Raleigh,
North Carolina.

R.D. Voyksner Research Triangle Inst. Research Triangle Pk.. NC

Azo dyes readily undergo light promoted reactions which ultimately result in fading of the color. Additionally, some dye degradation products are suspected carcinogens. Understanding the degradation process will lead to the development of more fade-resistant dyes, more environmentally safe dyes and will help in evaluating the environmental fate of existing dyes. In order to do this it is important to identify the reaction pathways involved. The use of both GC/MS and HPLC/MS will allow characterization of a wide variety of photodegradation products. In particular this study focuses on one disazo dye, Disperse Orange 29:

The fading was performed by irradiating the dye with xenon light for 1000 hrs. Both dyed fabric samples and an ethylacetate solution of the dye were faded. The solution sample was analyzed without further workup. The fabric samples were powdered and extracted with ethylacetate.

The GC/MS experiments were performed on a Hewlett-Packard 5985B quadrupole mass spectrometer. The GC separations were performed on a 15M DB5 fused silica capillary column programmed from 50°C to 300°C at 10°C/min. For EI, the scan range was 40-450 daltons, source temperature was 200°C and electron energy was 70 eV. For CI, methane reagent gas was used, the scan range was 90-500 daltons.

The HPLC/MS experiments were performed on a Finnigan MAT 4500 quadrupole mass spectrometer equipped with a Vestec thermospray interface. The separations utilized a LC-1 (25 cm x 4.6 mm) column with a 30 minute linear gradient of 25% methanol to 95% methanol containing 0.1M ammonium acetate at 1 mL/min. flowrate. UV detection was performed at 254 nm for general screening and at 410 nm, characteristic for the orange color. Thermospray spectra, generated by ion evaporation, were obtained. The vaporizer temperature was 185-190°C, source temperature was 250°C. The scan range was 140-600 daltons with both negative and positive ion detection.

The solution fading experiments proved uninformative due to the many products resulting from reaction of the dye and the solvent. For this reason, the major effort was directed towards identification of the photodegradation products from fabric fading. GC/MS analysis identified three products (Figure 1). The EI spectra showed fragmentations patterns which were used in identification. Molecular weights were confirmed by methane CI and also by direct probe high resolution MS. Thermospray HPLC/MS permitted detection of two additional photodegradation products (Figure 1). The products detected by thermospray HPLC/MS retained an orange color, evidenced by their UV-VIS adsorption at 410 nm. This indicates that the conjugation and azo linkages remain essentially intact. Confirmation of these identifications is in progress. The thermospray HPLC/MS spectra provided few fragment ions for interpretation. Also, the presence of

compounds with molecular weights greater than the parent dye suggests reaction of the photodegradation products with the solvent used for extraction.

In conclusion, the major photo-induced decomposition pathway is fragmentation adjacent to the azo bonds. Minor pathways include reduction and cleavage of the azo bonds and radical induced conversion of the nitro to an hydroxyl group.

DEVELOPMENT AND TESTING OF ICP/MS
METHOD 6020 FOR ENVIRONMENTAL ANALYSIS

D.E. Dobb, G.A. Laing, J.R. Donnelly, M.L. Hurd*, and L.C. Butler**, Lockheed Engineering & Sciences Company, 1050 E. Flamingo, Las Vegas, NV 89119, * U.S. Environmental Protection Agency, AOB, 401 M Street SW, Washington, D.C. 20060, ** U.S. Environmental Protection Agency - EMSL, P.O. Box 93478, Las Vegas, NV 89193-3478.

Inductively Coupled Plasma/Mass Spectrometry (ICP/MS) is a new technique for the analysis of complex sample matrices, such as those encountered through the US EPA Superfund Contract Laboratory Program (CLP). The proposed Method 6020 has been written specifically for use in the production environment of the CLP to allow digestion followed by analysis of complex environmental sample matrices by ICP/MS. Evaluation of comparability and acceptability of Method 6020 Inductively Coupled Plasma Optical Emission Spectrometry (ICP/OES) and Graphite Furnace Atomic Absorption Spectrophotometry (GFAAS), was the ultimate goal of a recently conducted multi-laboratory validation study.

A total of twelve Special Analytical Service (SAS) laboratories having ICP/MS capabilities participated. For comparison, a total of twelve Routine Analytical Service (RAS) laboratories, representing nearly half of these in the CLP, were utilized. The SAS laboratories followed ICP/MS 6020, whereas the RAS laboratories followed Statement of Work (SOW) 787 currently in use by CLP for ICP/OES and GFAAS analyses.

A total of sixteen different raw sample types having an historical data base were analyzed in the study. Those materials included tap water, analyte spiked waters, electroplating sludge, hazardous waste soil, river sediment, estuarine sediment, fly ash, and analyte spiked soils. Concentrations of analytes in the materials ranged from very low ppb levels to moderate ppm levels. Blind duplicates of each sample type were submitted to all SAS and RAS laboratories for digestion and analysis.

To test sample preparation precision, two of the waters and seven of the solids were digested in bulk by our laboratory following sample preparation procedures specified in Method 6020. Homogenous splits of the bulk digests were submitted in blind duplicate to each SAS and RAS laboratory. With digestion variability removed through the use of splits, comparison could be made to each laboratory's own digestion, enabling separation of sample preparation precision from instrumental analysis precision.

An alternate digestion method was also included in the study to evaluate its efficiency when compared to the currently proposed 6020 digestion. The alternate method that was used was the GFAAS preparation method from SOW 787. The GFAAS sample preparation avoids chlorides which cause interfering ions in ICP/MS. The same two waters and seven solids that were used to test the Method 6020 sample preparation precision were digested by the alternate method in bulk, and splits were submitted in blind duplicate to each laboratory.

The total number of raw and digested samples that were submitted to each laboratory was 68. This value, multiplied by 24 laboratories, gave 1632 total samples that were evaluated. Since the number of analytes totaled 22, over 35,000 analyses were received in the study. Additionally, over 50,000 Quality Assurance/Quality Control analyses were required to support the sample analyses. Participants in the study

completed and reported approximately 96% of all expected analyses. Outlier rejection by the Grubbs Test appears to be about 4% of the 35,000+ reported analysis. It is estimated that about half of the outliers may be correctable and could be reentered into the data base after modification.

DISCUSSION

Elements which are typically present at high concentrations, such as aluminum, generally showed good comparison between methods. Similar values between the soil, the bulk 6020 soil digest splits, and the bulk GFAAS soil digest splits indicate sample preparation methods are equivalent to present CLP methods. The deviations on the bulk digests were smaller than on the individual laboratory digests, indicating a significant portion of method precision is due to sample preparation. The largest factor, however, remains attributable to analytical measurement precision. Elements occurring at high concentrations presented more problems than other analytes from an operational standpoint with ICP/MS. The high levels that can and do appear in environmental samples must be diluted to get levels within the linear dynamic range.

Medium-to-low-level analytes such as cadmium also showed good comparability between the data bases. The superior sensitivity of the ICP/MS technique was clear for all analytes in this concentration range.

Low level GFAAS analytes such as arsenic generally showed good comparability. Most errors found in a historical data base using ICP/OES seemed to be the result of the poorer sensitivity with the ICP/OES technique, when analyzing for arsenic. Data for silver also demonstrated the better detection limits achieved by ICP/MS.

In conclusion, for the elements and matrices discussed, the proposed Method 6020 obtained values comparable to those obtained by ICP/OES analysis in the CLP. In some instances, the ICP/MS method is clearly superior to those presently employed in the CLP, particularly when very low levels are being analyzed or when an analyte is difficult to determine by the CLP method (e.g., selenium and arsenic).

FACTORS CONTRIBUTING TO THE EFFICIENCY AND LINEARITY OF COLD-ON-COLUMN INJECTORS
FOR USE IN THE GC/MS EPA METHOD 625

Q. G. Grindstaff, R. E. Slagle, and J. T. Sheen

Plant Laboratory
Oak Ridge Y-12 Plant*
Martin Marietta Energy Systems, Inc.
Oak Ridge, Tennessee 37831-8189

Chemical compounds analyzed according to EPA Method 625 vary greatly in their chemical and physical properties. The compounds range from the nonpolar polycyclic aromatic hydrocarbons to the polar benzidines and phenols. To quantitatively analyze these compounds to very low concentration levels, the GC/MS system must be designed to handle these varied properties. As shown in a previous presentation,¹ large gains in response, linearity, and reproducibility were made in going from hot Grob split-splitless to cold-on-column injection and the deactivation of connectors and ionization chamber walls.

Further work on the GC/MS system has improved both overall and long-term performance. A comparison has been made between two types of on-column injectors. The first type is not gas-tight during injection, while the second type is. The non-gas-tight injector forms the pressure seal during injection between the injection needle and the metal body of the injector. The gas-tight injector employs a triple layer, prepunched septum and a domed, side-delivery syringe needle. Table 1 shows the importance of a gas-tight injection. These data show that if the compound is volatile at the injection conditions of the cold-on-column injector, approximately 20% of the compound is lost. Consequently, the gas-tight injector prevents discrimination on the basis of volatility.

After combining the gas-tight on-column injector with the other modification, good responses and linearity were obtained for the compounds of Method 625. However, these responses and linearity for the more polar compounds, especially the phenols, were not well maintained over a period of time. At this point, a new prototype injection system was developed that effectively removed the time dependence of the system. Before the new injection system was installed, a decrease of approximately 30% in the response factors of the phenols was common in the first several days of operation. Table 2 shows the results of a 14-day study with the new injection system. Except for 2-methyl-4,6-dinitrophenol, there is essentially no change in the response factors for the phenols over this period. The reason for this change is now understood and is being corrected for in the design of the injector. The design and performance of the new injector shows great promise of long-term stability for even the most highly reactive compounds of EPA Method 625.

THE QUANTITATIVE EFFECTS OF ION ABUNDANCE TUNING CRITERIA
ON MODERN QUADRUPOLE MASS SPECTROMETER SYSTEMS,
RESULTS FROM AN INTERLABORATORY STUDY

A. D. Sauter, Andrew D. Sauter Consulting, Henderson, NV 89014;
D. Bottrell, U.S. EPA, EMSL/LV, Las Vegas, NV 89114; and J. Fisk, U.S. EPA
OERR, Washington, D.C. 20460.

As a part of an interlaboratory study to understand the effect of ion abundance tune on quantitative GC/MS analysis, approximately 20,000 GC/MS response factors (RF's) and related statistics have been compiled for 82 analytes of environmental interest. Data was acquired over five tune regimes for seven different GC/MS systems using a common EI GC/MS protocol, common analytical standards and a floppy disc based data submission protocol. This paper reports selected aspects of this study.

With the elimination of the worst performers for each tune, interlaboratory, five level RF RSD's were found to average approximately 10, 12, 15, 11 and 13 percent for tunes A, B, C, D and E, respectively. The worst laboratory performance was found when "low" mass ion current was suppressed. From a quantitative analysis perspective, this observation suggests that new ion abundance criteria should carefully consider lower limits of low mass values, as significant non-linear response can be observed, quite naturally, when ion current is suppressed. (RF RSD's for certain systems approached an average of 25.0 percent for the 82 analytes studied when m/z 51 of DFTPP was in the 5-20% range.)

The effect of ion abundance tune was directly observed in GC/MS RF values. For example, response factors varied across all tunes for all seven laboratories as expected, depending on the degree of enhancement or suppression of ion current for the mass range of interest. Within laboratory "tune caused" RF variation was reduced by an average factor of 4 when corrected for relative ion transmission. Unfortunately, however, between laboratory RF values differed significantly. (For example, for hexachlorobenzene, the 6 laboratory mean RF range was 0.187-0.297. One laboratory had an RF value which was approximately twice previously published values, and it was eliminated from this comparison.) This observation prompted attempts to derive intersystem correction factors needed to establish a practical EI RF reference set. Intersystem correction factors were derived which yielded, for hexachlorobenzene, estimated/observed RF values whose average intersystem agreement was within a narrow range compared to unaligned values, i.e., approximately 3%. These results suggest that a practical reference set of EI GC/MS RF values is attainable despite the significant design differences among the modern quadrupole GC/MS systems studied.

These and other observations, along with data presented at this meeting in our paper addressing qualitative aspects of this study (1, 2), suggest that a national reference set of EI GC/MS RF values (where $N = 82$ compounds) and related statistics can replace ion abundance criteria for DFTPP (where $N = 1$ compound). As we originally proposed at the 1983 ASMS meeting (3), such an approach would provide a more thorough characterization of the quantitative and qualitative capabilities of modern quadrupole GC/MS systems utilized in environmental applications of GC/MS.

ANALYSIS OF HAZARDOUS SUBSTANCES IN FISH TISSUE BY GC/MS

Lily Yang, David Ben-Hur, M. Fullerton, T. T. Osterman and J. M. O'Neal
Keystone Environmental Resources, Inc., Houston, TX 77063

Many hazardous substances can be bio-accumulated through food chains in water and can remain in high concentration at the end of the biological system. Analysis of target compounds and pesticides from the hazardous substances list (HSL) in fish tissue monitors our water system as well as the environmental toxicological impact on our ecosystem.

This paper presents a GC/MS method developed in our laboratory for analysis of hazardous substances in fish tissue. The preparation method uses a hexane-methylene chloride (50/50 V/V) solution with a tissue mixer to extract fish tissue sample. (1)

The clean-up and concentration process involves the removal of lipids by gel permeation and Kuderna-Danish (K-D) concentration. By means of this simple sample preparation, the GC/MS method is applicable to the analysis of hazardous substances in fish tissue. Sixty five semi-volatile HSL compounds and twenty pesticides in fish tissue can be analyzed in a single GC/MS run. Figure 1 shows the total ion chromatogram of sixty five semi-volatile HSL compounds and six surrogate standards spiked into blank fish tissue sample. Figure 2 shows the GC/ECD chromatogram of fourteen pesticides spiked into the blank fish tissue.

Recoveries and method detection limits are shown in Table 1 and Table 2. The recoveries were in the range of 41-100% for eleven matrix spike semi-volatile compounds, 63-106% for six semi-volatile surrogate standards and 57-92% for fourteen pesticide standards, respectively. The relative standard deviations of method recoveries for these compounds are in the range of 2.6% to 9.6%. Recoveries of sixty five semi-volatile HSL compounds are within the range of 40-106% except for Benzoic Acid, 2,4-Dinitrophenol, Bis (2-Ethylhexyl) phthalate and Di-n-Octyl phthalate.

The method detection limits of eleven matrix spike compounds are in the range of 0.54 to 3.0 ppm with 95% confidence (2) by GC/MS and 0.0060 to 0.0096 ppm for thirteen pesticides and 0.12 ppm for Archlor 1254 by GC/ECD.

CHARGE EXCHANGE CI/ELECTRON ATTACHMENT NCI AS AN ALTERNATE
IONIZATION MODE FOR CHARACTERIZATION OF ENVIRONMENTAL SAMPLES:
APPLICATION TO MARINE MAMMALS

Douglas W. Kuehl and Brian C. Butterworth
U.S. EPA, Duluth, MN 55804

Elizabeth Lundmark and Philip Marquis
University of Wisconsin-Superior, Superior, WI 54880

The use of Argon charge exchange positive ion chemical ionization pulsed with electron attachment negative ion chemical ionization was investigated as an alternative ionization mode to the well established electron impact ionization mode for routine characterization of environmental samples. Although CE-CI and NCI have been shown to be of significant potential value for routine environmental sample analysis, EI remains almost exclusively the ionization mode of choice. Two primary reasons exist for this fact, 1st large EI spectral libraries are available for assistance in spectral interpretation, and 2nd the U.S. EPA Contract Laboratory Program requires EI for all GC/MS work. The argument for use of Argon PPINICI rather than EI is not simply having two ionization modes rather than one, but that the addition of negative ion information offers uniquely sensitive and selective data for highly toxic molecules¹. The success of Argon PPINICI then to replace EI depends upon the acceptance of searching EI libraries with CE spectra², and meeting quantification criteria established in QA/QC documents. We have investigated these points.

CE and EI spectra for over 100 pesticides and industrial compounds commonly found as environmental contaminants were searched against the EPA/NBS EI mass spectral library and ranking of FIT and RFIT results for the correct response were compared. It was found that the success rate for correctly identifying the analyte was equal (>95%) for both ionization modes. Also, a sensitivity comparison for 35 analytes indicated comparable levels of detection, and regression coefficients of quantification standards were comparable. Further, relative standard deviations for peak areas indicated that "sensitive" compounds were more stable during CE than EI.

Argon CE-CI/NCI was used along with both low and high resolution GC/MS in a study of contamination of Atlantic Bottle Nosed Dolphins by pesticides and industrial chemicals. This study was undertaken because of world wide concern over the deaths of numerous species of marine mammals³. Our initial analysis showed high levels of PCBs and chlorinated pesticides frequently found in freshwater biota. PCB levels, for instance, were found as high as 275 ug/g lipid in liver of one of the animals. This value is nearly 20X that measured in the liver of a human victim of PCB poisoning in Yu Cheng, Taiwan⁴.

- 2 -

Perhaps the most interesting observation was the complex distribution of bromine containing contaminants. Although marine species contain naturally brominated organics⁵, we have identified a series of polybrominated diphenyl ethers which we believe have anthropogenic origin. We observed that the distribution of tribromo- to heptabromo- compounds in the dolphins was similar to the distribution observed in a commercial flame retardant formulation. Polybrominated diphenyl ethers have also been identified in fish from Europe⁶. These studies continue.

**"DIRECT TRACE ANALYSIS OF VOLATILE ORGANICS IN AIR AND WATER
BY MEMBRANE/MASS SPECTROMETRY"**

M.A. LaPack^{1,2}, J.C. Tou¹, and C.G. Enke²

¹The Analytical Sciences Laboratory, Dow Chemical, Midland, MI 48667

²Department of Chemistry, Michigan State University, East Lansing, MI 48824

Trace analysis of organics in water or air by mass spectrometry generally requires laborious and time-consuming extraction and concentration procedures. Sample work-up may be eliminated with a membrane device. Non-polar volatile organics may be continuously analyzed from air or water with ppb detection limits and a dynamic range of 10^3 (Figure 1). In this study, the membrane is a 1" long, .020" i.d., .037" o.d. silicone hollow fiber (Dow Corning Silastic Medical Tubing).

The sensitivity of membrane techniques is determined by the enrichment factor (the analyte/matrix permeability ratio) and parameters including membrane area/thickness ratio, sample linear velocity, and temperature. Permeability is the product of diffusivity and solubility. Steady state permeation is achieved within a few minutes, as governed by diffusivity. Compared with non-polar organics, air and water are quite insoluble in the silicone polymer. The membrane serves as a very good organic extraction medium as well as a barrier between the sample and the high vacuum MS.

We investigated two membrane sampling geometries reported in the literature; flow-over(1) and flow-thru(2). A sample flowing through the inside of the hollow fiber with molecules of interest permeating to the outside (flow-thru) demonstrated more than 10X the sensitivity of the alternate geometry of flowing the sample over the outside while analyzing the extract on the inside (flow-over). Figure 2 shows response vs. concentration plots for these two geometries. Flow-thru is preferred since the area/thickness ratio is maximized (the hollow fiber does not collapse) and high linear velocities are easily obtained.

Heating the membrane inlet produces desirable as well as undesirable effects: Diffusivities increase, therefore response times decrease with increasing temperature (Figure 3). However, heated membranes exhibit lower solubilities for organic compounds. In the case of air samples, this means that the membrane extracts organics from the matrix less efficiently. This decrease in solubility is not offset by the increase in diffusivity. A decrease in organic permeations result. Organics in heated aqueous samples exhibit greater permeations. However, the increase in water permeation is even greater. Decreased enrichment results (Figure 4). Proposed explanations include; a) partitioning of organics into the membrane increases at higher temperatures, and b) mixing improves at higher temperatures. In any case, enrichment is independent of membrane surface area, thus improved sensitivities are more efficiently obtained at low temperatures by using a longer hollow fiber. Table 1 shows response time and detection limit data for several compounds.

**DETERMINATION OF SELECTED PRINCIPAL ORGANIC HAZARDOUS
CONSTITUENTS FROM INCINERATORS USING
CAPILLARY COLUMN GC/MS/DS.**

Rafael Infante, Catholic University of Puerto Rico. Ponce, PR 00732

and

Anibal Torres, SK&F Lab. Co. Guayama, PR 00654.

INTRODUCTION

The Resource Conservation and Recovery Act (RCRA) requires that facilities which treat hazardous waste by incineration ensure that the incinerator are operated in a manner which do not endanger human health or the environment. The incinerators must be operated so that principal organic hazardous constituents (POHC's) are destroyed and/or removed with a minimum efficiency of 99.99%. To determine the destruction and removal efficiency (DRE) an analysis to quantify POHC's in the waste feed material and stack gas effluent must be performed.

Characterization of stack emissions from hazardous waste incinerators constitutes a challenge for the analytical chemist. The use of packed columns for the characterization of POHC's in incinerator stacks have been reported. However if the sample consist of complex products from incomplete combustion it may cause high background in the analytical system and thus interfere in the identification and quantification of the compounds of interest. The modification presented here makes use of capillary columns to improve resolution. In addition, capillary columns yield better quality mass spectra, and decrease the analysis time. Information on the use of high resolution capillary column and selective ion monitoring low resolution mass spectrometry to quantitate POHC's in incineration stack in order to meet the EPA trial burn test criteria will be presented.

EXPERIMENTAL

The sampling of POHC's in the stack gas was performed using the VOST. Approximately twenty liters of gas were sampled. After sampling, VOST cartridges were sealed and stored in clean 25 x 150 mm screw-cap test tube and kept in a refrigerator until the analysis. All field samples were taken from the stack of a liquid waste incinerator above the mist eliminator at an elevation of approximately 42 feet. Cartridges were then spiked with internal and surrogate standards and thermally desorbed for 11 minutes with a flow of He at 40 ml/min at 180° C. The gas is carried into an organic free water column and the organics trapped on the analytical trap of the purge and trap concentrator. The analytical trap is then heated rapidly to 180° with the carrier gas flow reversed so that the effluent flow is directed to a cryogenic system in the inlet of the GC/MS (HP5890-MSD). The pre-column is automatically heated and the organics are directed to a GC where they are separated and detected with a mass spectrometer in the single ion monitoring mode. The GC conditions were as follows: carrier gas- He, 1 ml/min; column temperature program, hold 5 minutes at 35° C then to 110° at 4° C/minute and hold; run time 25 minutes; MS parameters: electron ionization at 70 eV, source temperature set at 280° C, capillary column connected to the ion source through an open split interface. At least three ions for each of the the target POHC's are monitored, the observation time is 50 msec. Qualitative identification of target POHC's is obtained by comparing retention time data and the intensities of the most prominent ions monitored. Concentration of the POHC's are determined from the integrated ion current for the particular POHC's and following the internal standard technique. Normal routine for analyzing a set of cartridges from each of the method evaluation runs was to analyze a blank Tenax and blank Tenax/charcoal cartridge spiked with internal and surrogate standards, a calibration standard, a VOST leak check sample, and the VOST samples.

EPA audit cylinders were obtained from Research Triangle Park, NC. Audit standards were sampled using the VOST at the same flow rate utilized in the field and analyzed following the same procedure outline above. The amounts (ng) of POHC's delivered to the Tenax cartridges were calculated from the volume of gas sampled.

RESULTS AND DISCUSSION

The POHC's (carbon tetrachloride, toluene and chlorobenzene) were selected taking into account the EPA ranking system. The relative standard deviation of the response factor for selected POHC's was less than 10 % for a particular calibration in the 50-1000 ng range, and less than 11% taking into account all calibrations made. Relative standard deviation for the response factor of surrogate standards was less than 15 %. No significant differences in response factor of surrogates and POHC's obtained at different dates was observed.

Replicate analysis of a standard check sample, at the 5 and 20 ng/L gas phase concentration, was used to assure that the analyte in question has been detected and quantified acceptably and reliable. Results for carbon tetrachloride appear to be similar with total recoveries ranging from 85 to 111% of the expected value. Although a breakthrough volume of 20 liters has been reported for carbon tetrachloride adsorbed in Tenax, percent recoveries were higher than 85% in all cases. No major deficiency in the method or the use of Tenax for quantitatively sampling carbon tetrachloride was observed. Results for toluene showed a much narrower range. The extremes varied from 88% to close to 100% of the expected value. Results for chlorobenzene are also narrow ranging from 84% to 90% of the expected value. No significant differences were observed in the average recovery and standard deviation obtained at the two concentration levels.

The method detection limit (MDL) calculated, based on sampling 20 liters, are quite reasonable although, the recoveries are consistently over 100 %. MDL ranged from .11 to .55 ng/L. No significant differences were observed in the recoveries of target POHC's obtained at this concentration range with the ones obtained at a concentration of 5 and 20 ng/L. Based on these detection limits a hazardous waste incinerator achieving a destruction removal efficiency of 99.999%, the POHC's can be present in the waste feed at a concentration as low as 500 ppm and still be detectable in the stack by the GC/MS analysis.

In the analysis of EPA audit cylinder a negative bias was observed for all cases, even for toluene. The highest negative bias was observed for chlorobenzene, although the concentration determined was well within the uncertainty level of the cylinder ($\pm 17\%$). The negative bias obtained for carbon tetrachloride, -4%, was very low considering that approximately 50% of the breakthrough volume (20L) was sampled. Our results indicate that Tenax is suitable for sampling quantitatively these compounds.

Two trial burn test involving three days of sampling were done. A minimum of three samples per day were collected. The first sample on each day was used to evaluate the occurrence of breakthrough. All other samples were analyzed in pairs. Results for carbon tetrachloride were consistent among each of the sampling days and between the two tests. The relative standard deviation was less than 25% in the 1 ng/L range for single pair analysis. Results for chlorobenzene show a higher relative standard deviation, however, the concentration at which is observed is much lower. The results are consistent among each of the sampling days and between the two tests. A difference in the concentration of toluene was observed between the two tests. However, excellent agreement exist among the concentration of toluene obtained during sampling days in each of the tests. Differences in the results can be due to operational conditions of the incinerator or differences in the synthetic waste composition. In general, the results were quite good and did not indicate major deficiencies in the sampling and analysis methods. Accuracy of three replicate cartridges analyzed were better than the $\pm 50\%$ suggested by EPA.

A formal quality control program was conducted in order to establish the acceptable precision and accuracy for the analysis of POHC's following this method. Upper and lower control limits for method performance was determined using the average area response and standard deviation for the internal standard, d_8 -benzene. The reproducibility of the internal standard area counts (m/z 84) was very good with an average variation of less than 30%. No significant difference in d_8 -benzene area counts with the type of trap; e.g. Tenax and charcoal/Tenax traps used for stack sampling (wet) and Tenax traps spiked with the calibration standards (dry) was observed. Among the surrogate standards utilized, the recoveries for fluorobenzene exhibited the best precision while BFB exhibited the worse, d_{10} -ethylbenzene fell somewhat in the middle. This behavior can be due to the difference in retention time between each of the surrogate and d_8 -benzene used as internal standard.

DETERMINATION OF ORGANICS IN PUBLICLY OWNED TREATMENT WORKS (POTWS) BY ON-COLUMN GC/MS: A COMPARISON OF THREE FACILITIES. Linda B. Clark¹, Robert T. Rosen², Thomas G. Hartman², Thomas Atherholt³, Charles Hertz⁴, and Joseph D. Rosen¹. Food Science Department¹ and Center for Advanced Food Technology², Cook College, Rutgers University, New Brunswick, NJ 08903; Coriell Institute³, Camden, NJ; Division of Science and Research, NJ DEP, Trenton, NJ.

The function of Publicly Owned Treatment Works (POTWs) is to treat household waste and municipal sewage. The Resource Conservation and Recovery Act and the Domestic Sewage Exclusion provides that when hazardous waste is mixed with domestic sewage, the subsequent waste is not legally considered hazardous. This exclusion makes it very cost-effective for many industries to discharge their waste to POTWs.¹

Much analytical data has been accumulated concerning priority pollutants from POTWs. However, little data has been published on other materials present in the treated water. On-column GC/MS using electron ionization was the technique utilized, since it is simple and applicable to environmental analysis, and allows for the determination of many polar and thermally labile organics. In addition, EI allows for library searchable data. We have identified approximately 300 components from the three POTW sites. Classes of organics found include: phenols, halogenated compounds, heterocyclics, polyaromatic hydrocarbons, nitrogen and sulfur containing (non-heterocyclic), ketones and aldehydes. A few examples of compounds identified are bromotetradecane, furobenzopyrantrione, trichlorophenol, tetramethyldecynediol, methylanthralene, and methoxybenzene acetonitrile.

The large number of non-priority pollutants found in the effluent raises many questions about the types and amounts of organic compounds being discharged from these facilities into the drinking water supply. It was observed that the two POTWs which had a 30% industrial contribution had much higher concentrations of organic compounds, including nitrogen containing and halogenated species, in their effluent.

In comparison to a previous study¹ on semi-volatile priority pollutants (+10) in POTWs, using US EPA method 625, it was observed that the on-column injection technique is far superior for the detection of organics in complex mixtures.

A companion Salmonella typhimurium assay on total effluents revealed that the facility which had the largest number of heterocyclics, nitrogen containing (non-heterocyclic), polynuclear aromatics compounds, and halogenated species exhibited the highest mutagenic activity. This facility also had the highest industrial contribution, demonstrating a need for improved methods to eliminate organics from POTW effluent.

USE OF THE ISOTOPE COMPOSITION OF LEAD AS A NATURAL TRACER IN
THE ENVIRONMENT

MARJA KEINONEN
UNIVERSITY OF HELSINKI, DEPARTMENT OF RADIOCHEMISTRY
UNIONINKATU 35, SF-00170 HELSINKI, FINLAND

Elemental lead is composed of four stable isotopes, with mass numbers 204, 206, 207, and 208. Isotopes Pb-206, Pb-207, and Pb-208 are formed continuously by the radioactive decay of U-235, U-238, and Th-232, respectively, while Pb-204 has no radioactive precursors. The relative abundance of the four isotopes in an ore depends on the geological time at which lead was segregated from the source rock and concentrated in a mineral deposit. The Pb-206/Pb-207 ratio in the world's most intensively mined deposits varies from 1.04 to 1.39, and in spite of the mixing and averaging processes in manufacturing, significant differences in the isotope ratios of lead in lead products are maintained.

This study explored the feasibility of using the differences in the isotope composition of lead as an indicator of the contribution of various emission sources to the lead in the environment and man in Finland, and especially in the Helsinki area.

The ratios of the stable isotopes were determined in the sources of lead in Helsinki (gasoline, incinerator and lead smelter emissions, coal), in the Helsinki air, and in the indicators of long-term deposition of lead: lichen, highway soil, and lake sediments. Isotope ratios were also determined in autopsy samples of liver, lung, and bone from individuals from Helsinki. The isotope ratios were measured mainly in samples from the Helsinki city area, with a few samples from Lapland studied for comparison.

Pb-206/Pb-207 ratios in the samples were determined with a thermal ionization mass spectrometer after chemical separation of lead by anion exchange and electrodeposition. The total lead concentrations were determined with an atomic absorption spectrophotometer using graphite furnace method.

Wide variations were found in the isotope ratios of lead in gasoline, the ratios of Pb-206 to Pb-207 in samples collected between 1968 and 1987 ranged from 1.063 to 1.1727. The mean of the isotope ratios of 33 samples was 1.124 ± 0.026 , which indicates that the lead in gasoline additives used in Finland mainly originates from geologically older deposits (Precambrian, such as in Australia, with low isotope ratios).

Significantly higher ratios (Pb-206/Pb-207 1.149-1.226) than in gasoline were obtained for other pollution sources in Helsinki -- the main waste incinerator, the two lead smelters, and coal. It can be concluded that, in general, lead used in manufacture of lead products other than lead alkyls for gasoline originates from geologically young deposits with high Pb-206/Pb-207 ratios.

Isotope ratios and lead concentrations in Helsinki air at the end of the 1960s and beginning of the 1970s were comparatively high, indicating the major influence of the incinerators, lead smelters, and coal burning at that time. Better control devices in the secondary lead smelters and shutting down of the incinerators have decreased the atmospheric lead concentrations in the Helsinki area in recent years. The influence can also be seen in the isotope ratios of lead in air samples, which have diminished from 1.156 in 1972 to about 1.110 in the 1980s. The mean of the ratios in the air samples collected between 1966 and 1984 was 1.123 ± 0.013 .

Snow represents a short-term indicator of the deposition. The Pb-206/Pb-207 ratio in snow from the center of Helsinki in 1984 was 1.123 ± 0.002 , which is the same as the mean ratios in gasoline and air samples over that period. Clearly gasoline was the source of lead in snow. The lead in soil taken from beside a highway likewise originated almost entirely from vehicle exhausts, since the mean Pb-206/Pb-207 ratio of the soil samples was equal to that in gasoline (soil 1.136 ± 0.003).

Lichen effectively absorbs lead from atmosphere and soil, and being a slow growing plant it is an excellent indicator of long-term deposition. The mean of the ratio in all the lichen samples was 1.148 ± 0.006 . This value is significantly higher than the mean ratio in gasoline or in Helsinki air. A significant difference was found between the isotope ratios of lead in lichen from Southern Finland (1.152 ± 0.006) and from Lapland (1.144 ± 0.003). This is evidently due to the industrial lead emissions in Southern Finland. The decrease in the ratios of both lichen groups from 1966 to 1985 reflects the diminished influence of the industrial sources of lead in recent years.

The mean Pb-206/Pb-207 ratio in human liver, lung, and bone were 1.142 ± 0.015 , 1.151 ± 0.011 , and 1.156 ± 0.013 , respectively. No difference was found between the tissues from Southern Finland and Lapland.

The wide range of isotope ratios of lead in Finnish gasoline complicates the evaluation of lead sources from isotope ratios. According to calculations made with a highly simplified model, about 70-80% of the lead in Finnish human tissues of individuals dying in the late 1970s originated from gasoline. In earlier years when industrial sources made a greater contribution to the atmospheric lead, an estimated 60-80% of the lead in Helsinki air was from gasoline. In the 1970s and 1980s almost 100% of the lead in air was estimated to originate from gasoline.

In the lake sediments, a correlation was found between the isotope ratios, lead contents, and depth. The lowest isotope ratios were measured at the surface, where lead concentrations were highest. Lead in the lowest parts of the cores clearly originated from non-anthropogenic sources. Deep in the sediment, Pb-206/Pb-207 ratios were about 1.2-1.3, which is equal to the ratio in bedrock. The amount of anthropogenic lead increases toward the surface and the ratios approach those of lead in air. It was estimated that in the studied lakes, about 40-60% of the total lead in the surface sediments was of atmospheric origin.

COMPARISON OF LC/MS AND CZE/MS FOR THE ANALYSIS OF ENZYMATIC DIGESTS AND RELATED BIOLOGICAL SAMPLES, Jack Henion and Eric Huang, Drug Testing and Toxicology Program, Cornell University, 925 Warren Dr., Ithaca, NY 14850.

There is growing interest in the analysis and characterization of complex biological samples. Typically the composition of intractable samples such as fermentation broths and enzymatic digests requires analytical methodology beyond the capability of "modern" capillary GC/MS and electron ionization mass spectrometry. The limits of such analytical techniques are challenged because the physical characteristics of the components in such mixtures are considerably different than those of drugs, metabolites and many environmentally important compounds. The peptides and intact proteins present in a tryptic digest, for example, are typically organic ions dissolved in aqueous solution. These ions often have molecular weights close to or beyond the mass range of our mass spectrometers, are thermally unstable, and characteristically involatile. It would appear that new approaches to characterizing these compounds are needed.

To further complicate the issue the chemical complexity of enzymatic digests and other biological mixtures requires highly efficient separation techniques in order to isolate the individual components for further characterization. Typically HPLC is the method of choice for resolving the components from each other, but sometimes even this technique lacks the necessary capability to isolate individual components. Even if HPLC does separate the components of interest preparative collection of each peak is a tedious and time consuming process.

Recent developments in capillary zone electrophoresis (CZE) suggest that separation efficiencies approaching several hundred thousand plates are possible. This capillary format of classical electrophoresis promises to compliment HPLC and has aroused considerable interest in the fields of biotechnology and biochemistry.

Unfortunately routine HPLC and CZE typically uses conventional non-specific UV or fluorescence detection. The availability of successful and routine on-line mass spectrometric detection would be of considerable value. Unfortunately, most common approaches to LC/MS do not lend themselves to handling compounds like high molecular weight peptides and proteins. Recently, however, developments in electrospray ionization in the laboratories of Fenn, Smith and Henion have shown that this alternative approach offers some unique benefits. Our adaptation is referred to as ion spray LC/MS and this system provides routine, high sensitivity on-line LC/MS and CZE/MS on an atmospheric pressure ionization mass spectrometer (APIMS).

Ion spray LC/MS provides a simple, ambient temperature interface between a liquid inlet system and an APIMS. If the effluent analytes are ions in solution and in a flowing stream of between 10-50 $\mu\text{L}/\text{min}$ the total effluent may be passed through the ion spray LC/MS interface, subjected to electrospray ionization, and the gas phase ions produced by coulombic explosion or field assisted ion evaporation are then sampled into the mass spectrometer. The benefits of this process include very mild ionization, high sensitivity, and multiple charging. The latter aspect is very useful for determining the molecular weights of peptides and proteins which lie far outside the mass range of the mass spectrometer. This results because

the denominator of "m/z" can become very large thus allowing even a quadrupole mass spectrometer to pass high molecular weight compounds.

EXPERIMENTAL

The APIMS system used in this work was a Sciex TAGA 6000E tandem triple quadrupole mass spectrometer (Sciex, Inc., Thornhill, Ontario, Canada). The ion spray LC/MS interface was constructed in-house and has been described in the literature. It is a concentric pneumatic nebulizer carrying micro HPLC effluent through a stainless steel capillary held at 3kV. The electrospray droplets are further nebulized and evaporated at ambient temperature by coaxial nitrogen gas with a measured linear velocity of over 200 m/sec. The APIMS system was operated in either the MS or MS/MS mode with a collision energy of 50 eV in the latter. The CZE system was also constructed in-house and the exit of the capillary was connected directly to the same ion spray LC/MS interface with no other changes. The anode of the CZE capillary was held at 30kV while the ion spray interface acted as the cathode. Typically, therefore, the voltage across the CZE column was 27kV. The details of this system have appeared recently in the literature.

RESULTS AND DISCUSSION

A variety of enzymatic digests have been analyzed by the LC/MS and CZE/MS systems described above. These include tryptic digests of hemoglobin, myoglobin, bovine serum albumin, and human growth hormone. On-line total ion current profiles in addition to selected ion current profiles have been obtained under gradient LC/MS conditions consisting of 1mm x 100mm C8 packed columns using gradients going from 0-100% over 30-45 min. The quality of the TIC is comparable to that obtained from UV detection, and the molecular weight of each component may be obtained even if it lies outside the mass range of the mass spectrometer. Thus multiply-charged ions of high molecular weight peptides may fall easily within the 1400 dalton mass range of our instrument.

The same digests described above for LC/MS may be subjected to on-line CZE/MS with concomitant increase in separation efficiency, but usually significantly reduced selectivity. Thus a TIC electropherogram may have most of the peptides eluting within a rather short time region of the separation, but the rest of the electropherogram may be devoid of peaks. This can be a troublesome matter which can require considerable development time to optimise the separation. In addition, the very small injection volume (5-15nL) for CZE requires at least low ppm concentrations of samples injected to have enough material to detect with the mass spectrometer. Also, a careful balance must be met between buffer concentration and type that will affect a CZE separation and those conditions desirable for ion spray mass spectrometry. Usually a compromise can be met, but it may require extra development time.

In summary, both on-line LC/MS and CZE/MS separation and identification is possible using the ion spray interface to APIMS. Mild ionization and multiple-charging provide two valuable benefits to identifying biologically important compounds. Given a choice between these two separation/inlet systems LC/MS using packed microbore or possibly packed capillaries seems to offer the best compromise between practical sample handling and adequate separation efficiencies. It is possible that improvements in CZE technologies may expand the practical utility of this potentially exciting analytical technique.

COMBINING CF-FAB WITH SEPARATIONS TECHNIQUES

Richard M. Caprioli

The Analytical Chemistry Center and
Department of Biochemistry and Molecular Biology
The University of Texas Medical School at Houston
Houston, Texas 77225

Continuous-flow fast atom bombardment (CF-FAB) mass spectrometry has been shown to be an extremely useful technique for the analysis of aqueous samples. Since a great deal of work is done with samples derived from biological sources where complex mixtures of compounds are to be analyzed, combining separations techniques with CF-FAB offers important advantages. Perhaps foremost is the capability of performing a complete analysis of molecular species directly on an aqueous sample routinely at the 2-10 pmol level without the need for sample preparation and derivatization methods.

The basic principal of operation of CF-FAB involves the balance of the flow of liquid to, and evaporation from, the sample stage in the source of a FAB mass spectrometer. For normal commercial instruments, this maximal rate of flow is approximately 20 $\mu\text{L}/\text{min}$, depending on pumping capacity. A narrow bore (e.g., 75 micron) fused silica capillary is used to deliver the liquid to the sample stage in order to isolate the high voltage present in the source of magnetic mass spectrometers. Easy use of the device is accomplished by utilizing the direct insertion lock of the instrument. Formation of gaseous ions is accomplished by bombarding the surface of the liquid sample with energetic xenon atoms.

Several significant advantages have been noted when CF-FAB is used for sample introduction as compared to the normal or standard (std) FAB method. First, the mass spectra obtained with CF-FAB are characterized by a significantly lower background than that produced by std-FAB (1), the result of the higher aqueous content of the solutions being analyzed (only 5% glycerol is used). The major effect of this is to significantly increase the sensitivity, often 100-fold or more. Second, the dynamic nature of the surface of the sample using CF-FAB leads to a decrease in the ion suppression effect often seen with samples analyzed by std-FAB. This suppression effect is produced as a result of the tendency of a more hydrophobic compound to occupy the surface of the liquid relative to a more hydrophilic compound.

The combination of mass spectrometry and high performance liquid chromatography offers a powerful method to routinely identify peptides in proteolytic digests. We have focused on the use of microbore LC with 1 x 50 mm C-18 columns operated at flow rates of about 25 $\mu\text{L}/\text{min}$, under both isocratic and gradient elution conditions, because these conditions are well suited to the CF-FAB technique (2). The general technique utilizes a pre-injector splitter to provide rapid gradient formation (200 $\mu\text{L}/\text{min}$) while allowing only 25 $\mu\text{L}/\text{min}$ to pass into the column. A second splitter is used to direct 5 $\mu\text{L}/\text{min}$ to the mass spectrometer and 20 $\mu\text{L}/\text{min}$ to the UV detector or fraction collector. Most peptide mixtures are separated with an acetonitrile gradient from 0 - 50%. Glycerol is kept at 5% in all solutions. The mass spectrometer is generally scanned from m/z 2800 - 400 in approximately 10 seconds per scan. The mass spectra show excellent signal-to noise characteristics at the 2-10 pmol level.

We have also coupled CF-FAB with capillary zone electrophoresis. This separations technique is particularly well-suited because it has very low flow rates (about 0.1 $\mu\text{L}/\text{min}$) and has the potential for achieving separations with millions of theoretical plates. An interface is required between the exit end of the CZE capillary and the entrance to the CF-FAB capillary because of the different rates of flow. The CF-FAB probe requires about 5 $\mu\text{L}/\text{min}$ to maintain stable operation whereas electro-osmotic flow only provides about 0.1 $\mu\text{L}/\text{min}$. Any greater flow in the CZE capillary would destroy the high resolution separations achieved. The interface we have used is essentially a coaxial design and is similar to that reported by Minard (3) and Tomer (4), and is

described in more detail elsewhere in this volume. Essentially, it allows the mass spectrometer to draw the 5 $\mu\text{L}/\text{min}$ volume necessary for the CF-FAB probe without disturbing the much lower flow volume of the CZE. The separation buffer is aqueous in nature, containing 40 mM ammonium citrate or acetate at pH 5. Samples are loaded pneumatically and are of the order of 0.2-20 pmol for peptide mixtures.

We have combined microdialysis with CF-FAB (5). Microdialysis is a technique which separates low molecular weight compounds from complex mixtures containing high molecular weight polymers, such as enzymes, in microliter volumes. In one study, the microdialysis probe built by Carnegie Medicin (Uppsala, Sweden), was placed in a solution containing 400 pmol of bombesin in 20 μL of buffer and carboxypeptidase added. The inner volume of the probe was continually flushed at 4 $\mu\text{L}/\text{min}$ with water containing 5% glycerol. This solution then flowed into the MS through the CF-FAB interface. The consecutive loss of five C-terminal amino acid residues could be followed through identification of the series of truncated molecular species produced.

CONCLUSIONS

CF-FABMS can be coupled with separations methods to provide a very effective analytical tool for the analysis of mixtures of compounds. The molecular specificity of mass spectrometry can be used quite effectively in these on-line analytical applications where aqueous samples are directly used. The work cited above demonstrates the viability of the techniques employed and points to the advantages which will be obtained as this methodology and technology is improved and developed.

CARBOHYDRATE STRUCTURAL DETAIL BY SELECTIVE OXIDATION, DERIVATIZATION AND MASS SPECTROMETRY

V. N. Reinhold, S. Y. Chan, R. S. Johnson. Division of Biological
Sciences Harvard University School of Public Health, Boston, MA 02115

The problems of oligosaccharide separation appear to be greatly assisted by SFC. Subsequent molecular weight profiles of these components, using SFC-MS, provide further structural insight and introduce the techniques used very successfully in GC-MS, but expanded to compounds of high molecular weight, (e.g., isotope dilution, single ion monitoring). Most important of these techniques has been the opportunity to utilize signal enhancing derivatives coupled with negative-ion chemical ionization (1). This combined approach of SFC-NCIMS is demonstrated in Figure 1.

Other details of carbohydrate structure, however, are only partially resolved by mass spectrometry. Molecular weight and oligomer linear sequence can be determined by desorption MS, and branching by CID (2). Linkage composition and the determination of structural isomers require techniques that include derivatization, polymer degradation, and a chromatographic approach to resolve the complex mixtures obtained. The details of linkage position and component isomers are not available in FAB-MS spectra.

Alternatively, Angel, et.al., (3) has studied oxidized, reduced and methylated oligosaccharide samples by FAB to relate sequence to linkage position. This generalized approach appears most attractive as a technique to introduce greater molecular specificity into these isomeric samples. We have initiated studies into this oxidation-derivatization approach on polysaccharides and analyzed the products by DCI-, FAB-, and SFC-MS. Amino sugars, N-linked glycans, mono-, di-, and oligosaccharides have been tagged with pyridinyamine (PA) and/or pentafluorobenzyl aminobenzoate (PFBAB) reducing-end derivatives and the samples periodate oxidized. These materials were analyzed directly to evaluate the stability of the reducing-end tag under oxidation conditions and to maximize yield. Three derivatives were studied which were prepared by: (i) reduction and permethylation, (ii) hydroxylamination and acetylation, and, (iii) methoxylamination and acetylation, Scheme 1.

OXIDATION & DERIVATIVE FORMATION

Scheme 1

Problems were experienced with recovering small amounts of sample under conditions of reduction and permethylation, although these procedures appeared satisfactory with larger amounts of starting material. Nitrile derivatization was most interesting as a sample for subsequent CID studies, but quantitative nitrile formation has so far proven to be difficult under the conditions studied. Interestingly, the first step of hydroxylamination seemed to be more quantitative

than the subsequent step to induce nitrile formation. Of the three approaches, the methoxylamine derivative proved to be most suitable. Control studies with low molecular weight samples indicated quantitative derivatization and application of this chemistry to N-linked glycans, previously labeled with PA is progressing satisfactorily. Presented in Figure 2 is the FAB-MS of the $\text{Man}_6\text{GN-PA}$ methoxylamine peracetyl derivative. Although only partially apparent in this FAB-MS, fragmentation appears directed to glycosidic linkages providing sequence along with considerable insight into linkage, (monomer mass intervals), furan/pyran structure and branching detail. Coupling of selective chemistry, derivatization, SFC-MS with CA, and array detection could hold considerable promise for resolving the analytical complexity in this most difficult field.

B. Brassard, J. Machin, D. Maxwell and J.V. Headley - Chemex Labs Alberta Inc. 2021 - 41 Avenue N.E. Calgary, Alberta T2E 6P2 Canada.

In a complex tar sands processing operation there are a number of potential sources of emissions which are perceived to effect air quality both in the plant area and downwind. As part of an odour impact assessment program to study this problem, investigations have been performed in which sensory studies have been combined with detailed chemical analyses of the composition of fugitive emissions and ambient air. Characterization of the latter pertaining to GC/MS analyses are discussed in this paper.

The broad scope of this project required the use of several sampling techniques and analytical methodologies.¹ Groups of compounds specifically targeted for analysis included alkenes, thiophenes, thiois (mercaptans), thioethers (sulphides), dithioethers (disulphides), alkyl benzenes, polycyclic aromatic hydrocarbons (PAH's) and aliphatic hydrocarbons. Other compounds studied included hydrogen sulphide and carbonyl sulphide. Samples types investigated included (a) processed gas sources, (b) liquid hydrocarbon sources, (c) and ambient air around a discharge tailings pond. Samples were collected using grab sampling, cryogenic trapping, charcoal tubes and tedlar bags.

CRYOGENIC SAMPLING

Cryogenic trapping was employed to separate wet hydrocarbon gases into three phases. Water and naphtha present in gas streams were condensed in glass impingers. The dry gas volume corresponding to the volume of liquid collected was measured using a dry test meter. At one cubic foot increments during sampling the aspirator pump was actuated to proportionally fill the tedlar bag.

Instrumental analyses were conducted using extracts from solvent desorption and automated headspace sampling. Qualitative GC/MS analyses were conducted using a Hewlett Packard 59970C MSD. Reference standards were employed to confirm GC/MS identifications as required. Quantification of the component of interest was performed using off line GC/FID and GC/FPD, utilizing external standards. The accuracy of the quantitative data is estimated to be $\pm 25\%$ based on preliminary evaluation of collection and desorption efficiencies of test mixtures.

The emissions from sources investigated are summarized in Tables 1-5.

The results indicate that (1) cryogenic sampling is an effective means of separating high dewpoint gas streams into three distinct phases to facilitate analysis, (2) automated headspace sampling is well suited to the study of airborne vapours, (3) on site analysis of reduced sulphur compounds is required to minimize artifacts and (4) reduced sulphur compounds and alkenes are the major odoriferous compounds detected and were most prevalent around the tailings discharge pond.

The Gas Chromatographic Separation and
Mass Spectrometry of Neutral and Phenolic Polymeric
Chlorinated Aromatic Compounds Found in Technical Pentachlorophenol

D. A. Griffin and M. L. Deinzer
Oregon State University
Department of Agricultural Chemistry & Environmental Health Sciences Center
Corvallis, Oregon 97331-6504

Technical pentachlorophenol contains a considerable amount and variety of highly chlorinated impurities. In addition to the neutral and phenolic dimeric compounds normally reported (dibenzodioxins, dibenzofurans, diphenyl ethers), a series of phenoxy polymers of those compounds also exists (Figure 1). We have 1) developed a separation scheme to remove impurities and concentrate the compounds of interest for mass spectral examination and trace level determination; 2) empirically sought a combination of injection technique and capillary column to provide optimum separation of these compounds and stay within the safe temperature limits of the column; and 3) confirmed the identity of these compounds and subsequently investigated their electron capture (E.C.) chemical ionization behavior.

The separation procedure is outlined in Figure 2. Technical Pentachlorophenol (80 gms) was dissolved in 2 liters of 0.6 N NaOH and extracted exhaustively with dichloromethane to give the neutral fraction. The pH was adjusted to 7 with H₂SO₄, and the solution was extracted again with dichloromethane to provide the phenolic fraction. Residual phenolic or neutral impurities in each fraction were removed by use of deactivated alumina; the phenolic fraction was methylated, and then each fraction further separated on supergrade basic alumina.

The Mass Spectrometry was performed using a Finnigan 4023 (with a 4500 Source) equipped with a Varian 3400 glc and a short interface heatable to 400°C. Separations were carried out on a J and W 30 Meter DB-1 capillary with 0.25 MM ID and 0.1 µm phase thickness. The column was programmed from 50°C to 330°C using a 3 step program with a 2°/min rate during elution of the major polymeric compounds. In the electron impact mode the source was operated at 190°C; In the methane E.C. mode the source was operated at 190°C and 120°C with an indicated pressure of 0.65 torr; in the hydrogen E.C. mode the source pressure was 0.55 torr and temperature 120°C.

Typical chromatograms for the polymeric region of each fraction are shown in Figure 3. The E.C. sensitivity for the polymers is high relative to the dimers with the greatest sensitivity being shown for the polyethers. The predominate electron capture fragmentation pathways can be seen in the spectra shown in Figure 4. Two or three examples were chosen for each basic structure to show the range of fragmentation observed for that species.

The polymers generally show cleavage of the ether linkages with the production of phenoxide anions (dimeric and monomeric). Loss of chlorine is also common; at 190°C loss of a single chlorine predominates while at 120°C sequential loss of additional chlorines becomes dominant. Dissociative capture is generally the rule; the molecular ion is rarely observed. Phenoxy dibenzodioxins show cleavage on both sides of the ether linkage to form phenoxide and "dioxin" anions.

The E.C. spectra provide information about the number of rings; the number of chlorines on each ring and the basic structure. The appearance of the fragmentation patterns in an observed spectra for a given core structure are extremely dependent on the position of the chlorines and phenoxy substitution. We are currently studying the relationship between the observed pattern and the structure of the molecule.

CHARACTERIZATION OF POLYAROMATIC HYDROCARBONS BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Chhabil Dass

University of Tennessee-Memphis, Memphis, TN 38163

This study reports on characterization of polyaromatic hydrocarbons (PAH) by fast atom bombardment (FAB)-mass spectrometry (MS). PAHs are highly mutagenic and demand sensitive methods for their characterization in environmental samples. GC and GC-MS have been used with success. The requirement of a reasonable vapor pressure limits the use of these techniques to low mass PAHs only. FAB-MS has proven to be a valuable technique for non-volatile compounds. In positive ion FAB-MS, the molecular ion is generally formed by addition of a proton to yield $(M+H)^+$ ion. PAHs have poor proton affinity, and therefore, do not yield measurable $(M+H)^+$ ion current when polar matrices are used.

Recently, we reported a FAB-MS method for characterization of a set of anthracycline antibiotics (Dass, et al.). By use of sulfolane as a FAB matrix, it was demonstrated that these antibiotics yielded abundant radical cation M^+ . The rationale for the formation of radical cations was the presence of conjugated π -electrons system. Because PAHs are also characterized having conjugated π -electrons, it is expected that they may be amenable to FAB-MS when sulfolane is used as the liquid matrix.

The experiments were performed by using a VG 7070E-HF instrument. FAB was accomplished with ca. 7 keV Xe atoms. The MS/MS spectra of the PAHs were acquired in the B/E linked-field scan technique. Collisionally-activated dissociation (CAD) of the mass selected M^+ was carried out in the first FFR with helium as the collision gas.

A typical example of the FAB mass spectra using sulfolane as the matrix is presented in Figure 1 for pyrene (m/z 202). An abundant M^+ ion is seen at m/z 202. The use of glycerol as the FAB matrix did not yield any meaningful information (Figure 2). Only a negligible ion current was obtained at m/z 203 (see inset of Figure 2). Other PAHs examined also yielded M^+ radical cations in reasonable abundance.

The use of FAB-MS was also explored for differentiation of isomeric PAHs. The ratio $(M+H)^+/M^+$ was found to be characteristic of individual PAH. As is evident from the data in Table 1, the isomeric anthracene and phenanthrene (m/z 178), pyrene and fluoranthene (m/z 202), and the four isomers of m/z 228 are all distinguishable on the basis of the $(M+H)^+/M^+$ ratio.

Although the fragment ions are not identified readily from the matrix background, the MS/MS technique can be used to provide a diagnostic mass spectrum. A B/E linked-field scan technique coupled with CAD was used to obtain the MS/MS spectrum. Figure 3 exhibits a typical B/E -CAD spectrum of fluoranthene. The B/E -CAD data can also be used to differentiate the isomeric compounds as is exemplified for anthracene-phenanthrene and pyrene-fluoranthene isomeric pairs.

RAPID ANALYSIS OF VOLATILES ORGANICS IN WATER AND SOIL USING DIRECT PURGE INTO AN ITMS

Marcus B. Wise, Michelle V. Buchanan, and Michael R. Guerin
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6120

Analysis of volatile organics in water typically includes a trapping step which concentrates the materials prior to analysis by GC/MS. This step adds at least 15 minutes to the GC/MS analysis, which can require up to an hour. We have demonstrated that volatile organics can be purged directly from water into an ion trap mass spectrometer without an intermediate trapping (concentration) step, allowing the entire analysis to be completed in a few minutes. In addition to speed, other characteristics of direct purge ITMS approach are selectivity, sensitivity, and accuracy.

All experiments were conducted using a Finnigan ITMS with the standard open/split capillary GC interface and specially equipped with two 330 L/s air cooled turbomolecular pumps and an electropolished vacuum chamber. The open/split GC interface was used to introduce the samples directly to the ITMS. In the case of purged solutions and soil slurries, a 40 mL glass VOA vial was used as a purge vessel. As shown in Figure 1, a screw cap and teflon coated silicon cap liner were placed on either side of a stainless steel disk and were used to seal the purge vessel. Two 1/16" stainless steel tubes were welded through this disk, with the longer tube (extending to near the bottom of the purge vessel) serving as an inlet for the helium purge gas. The shorter tube (flush with the disk) serves as the exit for the purged materials and passes through a tee, with one line joined to the open split interface of the ITMS and the second line connected to a needle valve. This valve can be adjusted to change the flow into the ITMS transfer line. Helium is used as the purge gas at flows between 20 and 100 mL/min. Water from the purged sample was used as the chemical ionization reagent and a 50 msec reaction time was employed. The ITMS was used in the selective mass storage mode to obtain optimum sensitivity.

The purge profile of benzene (Fig 2) illustrates that the volatile material is efficiently purged in just a few minutes. The instrument was calibrated for quantitative measurements by plotting the sum of the integrated ion currents from the purge profiles for each concentration level. Using this approach, detection limits of 1 ppb or less have been achieved for benzene, toluene, tri- and tetrachloroethylene, methylene chloride, vinyl chloride, chloroform, chloroethane, and bromomethane in 15 mL of water. Calibration curves were linear over two orders of magnitude with a precision of about 15% without the use of an internal standard. Using the MS/MS capabilities of the ITMS, benzene has been detected in water at 500 parts per trillion (see Fig 3). Even lower detection limits are possible if the open-split ratio is increased.

Volatiles in soils can be analyzed similarly. In this case, 5 g of soil is weighed into a 40 mL VOA vial and 15 mL of distilled water is added. The capped vial was slowly stirred with a magnetic stir bar for two minutes prior to analysis. Detection limits achieved with volatiles in soils are estimated to be in the low ppb range at this time.

The direct purge method shows considerable promise as a means of rapidly screening environmental samples for the presence of volatile organics or to quantitatively measure targeted compounds much faster (and more inexpensively) than conventional purge and trap GC/MS methods. Potential applications include use in hazardous waste site characterization, spills, and real-time monitoring, such as wells, soil, bioreactors, and process streams. We have recently used this approach for detection of targeted materials in physiological samples as well.

COMPARISON OF TWO MAGNETIC INSTRUMENTS IN OBTAINING NEGATIVE CHEMICAL IONIZATION MASS SPECTRA. Robert T. Rosen¹, Thomas G. Hartman¹, Joseph Lech¹ and Joseph D. Rosen², Center for Advanced Food Technology¹ and Food Science Department², New Jersey Agricultural Experiment Station, Cook College, Rutgers University, New Brunswick, New Jersey 08903.

Negative ion chemical ionization (NICI) is the method of choice for the quantitation of environmentally sensitive species and for the determination of metabolites and parent compounds of many pharmaceuticals in biological fluids. NICI is especially useful for compounds with good electron capturing properties, or for polar metabolites which can be derivatized with halogenated reagents.

While all manufacturers of mass spectrometers offer negative ion capability on their research instruments, it has been only recently that publications have been presented studying the effects of temperature, pressure and source parameters on the reproducibility of NICI spectra for quadrupole mass spectrometers. Oehme *et al.* compared a Finnigan 4000 MS with a HP5985B MS. They found that the Finnigan MS showed major ions characteristic of Cl^- and HCl_2^- , and while the Hewlett Packard MS did not show appreciable amounts of these ions, both systems had the same high mass spectrum. Stemmler and Hites studied instrument parameters on a HP5985B, and designed experimental criteria for duplicating spectra on their HP mass spectrometer on a day to day basis. These papers implied that it would be extremely difficult to develop a universal NICI method which would apply to different makes and models of quadrupole mass spectrometers.

Our study involved the use of two different magnetic mass spectrometers for the NICI study of macrocyclic trichothecene fungal toxins. These compounds are ideal for NICI as they contain an electron capturing butadienyl lactone moiety. One major factor suspected in obtaining reproducibility was reagent gas pressure. Spectra taken from an instrument with low CI source pressure compared to high CI source pressure were compared. The instruments had optimum source pressures of 0.3 and 0.8 Torr. It was observed that the NICI spectra on the two instruments did not differ significantly at low concentration (picogram to low nanogram range), but did differ at high concentration in the ion sources. Other source parameters, with the exception of repeller voltage and source temperature, were not important factors in reproducing spectra. In magnetic instruments the repeller, in CI, should always be set to zero volts, and when set to zero, the spectra between the two instruments were similar. Also, problems involving a time-based calibration as compared to a Hall probe or field calibration were discussed.

The conclusion of this study was that the differences in spectra were related to the total concentration of methane in the ion source and had little relation to parameters such as source voltages. The methane "electron sink" or reagent gas is actually fairly poor relative to the electron capturing properties of the sample molecules themselves. It is postulated that at higher sample concentration, the analyte itself becomes the molecule directly involved as an electron capturing agent and the NICI mass spectra start to differ because of the direct fragmentation of the analyte after capture of a high energy electron.

Identification of a derivative of kepone in sediment
by gas chromatography-mass spectrometry

J. Greaves and R. Edstrom
Virginia Institute of Marine Science
College of William and Mary
Gloucester Point, VA 23062

Kepone (chordecone, CAS #143-50-0, $C_{10}Cl_{10}O$, mol. wt. 486) is an organochlorine insecticide derived from the dimerisation and oxidation of hexachlorocyclopentadiene. It is closely related to mirex $C_{10}Cl_{12}$. In the USA it was used primarily as an anti-fireant agent, but its uses were more extensive worldwide. From 1966-1975 more than 3 million pounds of kepone were manufactured in Hopewell, Virginia, with more than half being synthesized in 1974-1975. Production was halted in 1975 with the identification of health hazards. Due to improper disposal and spillage, James River sediments from Hopewell to the mouth of the river, a distance of approximately 100 miles, became contaminated with kepone (1). As a result of the spillage, the James River was closed to commercial fishing in 1975. Although this ban has been progressively relaxed on various occasions since then, it was not lifted fully until 1988. Toxicity of kepone includes both chronic and acute effects. It is a possible carcinogen and is known to cause spinal deformities in fish.

Kepone, in common with many organochlorines, is highly persistent. To date there has been no evidence of degradation products of kepone in sediments (2) and relatively little information on biological metabolism. During a project to monitor occurrences of organochlorines in fish and sediments from Virginia, a number of unanticipated compounds were observed in samples from the James River. These samples were prepared by soxhlet extraction followed by gel permeation chromatography and analysed by fused silica capillary gas chromatography with electron capture and Hall electrolytic conductivity detection. Additional separation by high performance liquid chromatography on a semi-preparative cyano-amino column was used to fractionate the sample and reduce sample complexity prior to the GC-MS analysis. Ubiquitous pollutants such as PCB were excluded by collection of polar fractions. The resulting polar fractions in which the compounds of interest were observed were analysed by GC-MS.

The GC-MS (Extrel, Model ELQ 400-2) was used in NCI with methane as the moderator gas. A number of unknown chlorinated compounds were observed in the sediment extract. These included a compound with a molecular weight of 488, two mass units greater than kepone. The fragmentation pattern of the unknown showed losses of 2 HCL, 2 Cl and CO. The molecular ion is ~10% intensity while the base peak cluster is at m/z 346 and corresponds to the loss of 2HCL and 2Cl. This pattern, along with the GC retention time, corresponded to those of kepone alcohol ($C_{10}Cl_{10}H_2O$). In kepone alcohol, the double bonded oxygen atom has been reduced which accounts for the increase of 2 in the molecular weight. Although this compound and its glucuronide have been described as metabolites in man, it has not been identified in sediments before. The source or mechanism of formation in the sediments are unknown. Quantities of kepone alcohol vary considerably, ranging from 0-50% of the kepone concentration (up to ~100 ug/kg). The kepone alcohol is concentrated primarily in the areas closest to the original sources of the kepone. The identification of the other unknown chlorinated compounds and the distribution of the kepone alcohol in the lower James River are currently being investigated.

Polychlorinated Dibenzo-p-dioxins (PCDD) and Dibenzofuran (PCDF) Levels in Humans: Vietnam Veterans; Occupational (Production) and Environmentally Exposed (Residential and Recreational) Individuals

D.G. Patterson, Jr., * L.R. Alexander, W.E. Turner, L.L. Needham,
J.L. Pirkle, and E.J. Sampson

Center for Environmental Health and Injury Control, Centers for Disease
Control, Atlanta, Georgia 30333

INTRODUCTION

Worldwide public concern of the toxicity of PCDDs and PCDFs has catalyzed extensive research in many toxicologically related areas. One of these compounds 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD), has been called the most toxic compound synthesized by humans. 2,3,7,8-TCDD is only one of 22 TCDDs and only one of 75 (mono-octa) PCDDs--there are 135 PCDFs. Several chemical processes produce PCDDs and PCDFs as trace contaminants. Trace levels of these compounds are also produced during incineration of waste materials, combustion of leaded gasoline, and the bleaching of wood pulp. These compounds are remarkably stable and the most toxic ones, those that are substituted with chlorine at the 2,3,7,8-positions, bioaccumulate in the human foodchain. Twelve to fourteen of these 2,3,7,8-substituted PCDDs and PCDFs can generally be found at the parts-per-trillion (ppt) levels in the lipid stores of humans, particularly those living in an industrialized society. We have developed and are currently applying adipose tissue and serum methods for measuring PCDDs and PCDFs which utilize high-resolution gas chromatography/high-resolution mass spectrometry with an isotope-dilution technique for quantification. Large-scale epidemiologic studies (U.S. Air Force Ranch Hand; NIOSH Occupational Workers; Missouri residents; and Seveso, Italy residents) that have detailed medical information, as well as laboratory body burden measurements of PCDDs and PCDFs, offer the best opportunity to find any possible correlation between health effects and exposure.

RESULTS FROM VARIOUS STUDIES

VIETNAM VETERANS

From 1962 to 1970, the herbicide Agent Orange was used as a defoliant in Vietnam. The herbicide was contaminated from less than 1 to greater than 20 parts-per-million with 2,3,7,8-TCDD, which was formed as an unintentional byproduct during the manufacture of one of the compounds used in formulating Agent Orange. The veterans in studies that actually measured 2,3,7,8-TCDD body burden levels can be divided into two groups: 1) those who handled Agent Orange as part of their military duties (Operation Ranch Hand); and 2) those who served in a combat role but did not directly handle Agent Orange (ground troops).

Ground Troops. A large-scale study of U.S. Army Vietnam veterans was conducted by CDC to determine if military records could be used to identify veterans exposed to Agent Orange. No association was found between current serum TCDD levels and any indirect measure of exposure. The serum TCDD distribution in the Vietnam veterans was nearly identical to that in non-Vietnam veterans (see Table 1 and Figure 1).

Agent Orange Handlers. In 1987, the U.S. Air Force (USAF) in collaboration with CDC began a study to measure 2,3,7,8-TCDD levels in 150 members of USAF Ranch Hand Unit which sprayed Agent Orange in Vietnam and 50 matched controls. The results from this study show a large difference between the mean level in the Ranch Hand veterans and the controls (see Table 2). The distribution of levels in the two groups also differed markedly as seen in Figure 2. As the data in Figure 2 shows, however, ~38% of the Ranch Hand veterans had levels less than 20 ppt which is within the range normally found in unexposed populations. Because of this, rather large misclassification, the USAF has decided to measure TCDD levels in all 1,267 Ranch Hand members.

Table 1. TCDD Levels--Ground Troops

Place of Service	Mean + SD (ppt)
Non-Vietnam (n=97)	4.1 ± 2.3
Vietnam (n=646)	4.2 ± 2.6

Table 2. TCDD Levels--AO Handlers

TCDD (ppt)	Ranch Hand (n=147)	Controls (n=49)
Mean	49.4	5.2
Median	26.5	4.7
Range	3.2-313	2.0-21.3

Figure 2. TCDD Distribution in Ranch Hand Vietnam Veterans and Controls

Half-Life of 2,3,7,8-TCDD in Humans. The half-life of 2,3,7,8-TCDD in serum was measured in 36 USAF Operation Ranch Hand Vietnam veterans. From serum samples taken in 1982 and 1987, the median half-life was found to be 7.1 years (95% confidence interval about the median of 5.8 to 9.6 years).

MISSOURI CASE/CONTROL STUDY

The CDC in collaboration with the state of Missouri conducted a study to compare TCDD levels in persons who had potentially been exposed to 2,3,7,8-TCDD contaminated waste oils, with Missouri residents with no known exposure. Participants from each of the four exposed groups had TCDD levels greater than the highest level measured in the control group (see Table 3). The workers involved in production of substances contaminated with TCDD had levels higher than those that worked in other departments of the same company (See Figure 3).

Table 3. Adipose Tissue TCDD Levels

in 51 Exposed Missouri Participants (ppt)

Exposure Status	n	Range	Mean	SD	Median
TCP Production	9	42-750	245	287	122
Horse Arena	16	5-577	145	202	24.1
Residential	16	5.2-59.1	26.8	18.9	19.5
Waste Hauling	10	3.7-25.8	12.4	8.3	9.0
Controls	128	ND-20.2	7.0	4.0	6.1

SEVESO, ITALY

The CDC in collaboration with Italian scientists measured TCDD in 14 serum samples that have been collected in 1976 immediately following the plant explosion in Seveso, Italy. The results of the study are shown in Figure 4 and are the highest levels ever reported in humans. The three highest levels are from children who developed the most severe types chloracne. As can be seen in Figure 4, however, no apparent threshold level for chloracne is obvious.

Figure 3. TCDD Levels in Company Employees vs. Days Employed in Production

Analysis of Polychlorinated dibenzo-p-dioxins and Polychlorinated
dibenzofurans by Hybrid-Mass Spectrometry

M. Judith Charles, Department of Environmental Sciences and
Engineering, University of North Carolina, Chapel Hill, N.C.

Bryan N. Green, VG Analytical Instruments, Inc., Manchester, U.K.

Yves Tondeur and J. Ronald Hass, Triangle Laboratories, Inc.,
Research Triangle Park, N.C.

Problems arise in the analysis of tetrachlorodibenzo-p-dioxins (TCDDs) when samples are co-contaminated at high levels with interfering compounds. Sample-clean up procedures and mass spectrometric techniques are commonly used to enhance selectivity. Sample clean-up procedures using a combination of chromatographic materials are generally capable of removing interferences but cases exist, however in which these procedures are not effective. For example, if a sample is co-contaminated with TCDD at ppt levels and PCBS at ppb levels, PCBs can remain in the sample extract. Resolving powers of 300,000 for the hexachlorobiphenyl isomers and 48,000 for the heptachlorobiphenyl isomers are needed to resolve the TCDD confirming ions at m/z 257 and m/z 259 from interferant ions, and a resolving power of 12,500 is needed to resolve the heptachlorobiphenyl isomers from the TCDD analyte ion at m/z 322 (Tondeur *et al.* 1987). Sample clean-up procedures are also not effective in removing chlorinated xanthenes. Tetrachlorinated xanthenes remaining in fish and sediment extracts co-elute with TCDDs and interfere with the molecular ion of TCDD at m/z 320 (Kuehl *et al.* 1987). A resolving power of 18,000 is needed to resolve these ions from each other. Mass spectrometric techniques used to enhance selectivity are electron-capture negative ion chemical ionization (ECNCI), high-resolution mass spectrometry (HRMS) and mass spectrometry/mass spectrometry (MS/MS). Of these techniques, MS/MS shows the greatest promise for selective analysis of 2,3,7,8-TCDD. This isomer is not responsive in ECNCI and high-resolving powers are needed to resolve interferant ions. The power of MS/MS lies in transmitting a parent ion into the collision cell and forming characteristic daughter ions by collision-induced-dissociations. Instrumental parameters affecting the formation of daughter ions, and thus sensitivity of tandem MS/MS methods are collision gas, collision energy and collision-gas pressure. The objective of this study was to evaluate the effect of collision energy and collision-gas-pressure on the formation of PCDD and PCDF daughter ions.

The instrument used in these experiments was a VG 70-250SEQ hybrid mass spectrometer. The instrument has a EBQ₂ configuration. The first mass analyser (MS1) is a Nier-Johnson type forward geometry double-focusing configuration (EB), and is followed by a collision region formed by a RF-only quadrupole field (Q₁) and a quadrupole mass filter (Q₂).

TCDD ions monitored in HRGC/MS experiments were m/z 319.8965 (M^+) and m/z 321.8936 ($M+2^+$); ¹³C-labelled TCDD ions monitored were m/z 331.9368 (M^+), m/z 333.9339 ($M+2^+$). A PFK lock mass ion m/z 318.9792 was monitored at a resolving power of 10,000 and m/z 316.9824 was monitored at a resolving power of 18,000. Dwell times were 40ms or 60ms.

In HRGC/MS/MS experiments parent ions of PCDDs and PCDFs and ¹³C-labelled TCDD (332,334) were transmitted into the collision region using MS1 in the selected-ion-monitoring mode at a resolution about 700. Multiple-reaction-monitoring of daughter ions formed due to the loss of COCl during collision-induced-dissociations was completed by synchronously stepping the voltages on MS2. These ions were chosen because the loss of COCl is selective to PCDDs and PCDFs. Collision energies were varied between 10-50 eV and 60-100 eV in 10 eV steps with sampling times of 15ms, or maintained at 20 eV with sampling times of 40 or 60 ms.

Initial studies were conducted to determine the general trends in daughter ion formation as a function of changes in collision energy and

argon-gas pressure. Collision energies were varied between 10-100 eV across the GC peak at pressures of 1×10^{-5} mB, $.5 \times 10^{-6}$ mB and with no gas in the collision cell. Similar trends were observed for all compounds investigated - 2,3,7,8-tetrachlorinated dibenzo furan (TCDF), 1,2,3,6,7,8-hexachlorinated dibenzo-p-dioxin (HxCDD), octachlorinated dibenzofuran (OCDF) and octachlorinated dibenzodioxin (OCDD). Greater responses were observed at higher gas pressures and at collision energies of 20-40 eV. In the interest of determining whether the optimum collision energy varied between PCDD and PCDF isomers, we compared the response between 1,2,3,7,8,9-HxCDD and 1,2,3,6,7,8-HxCDD. Greatest responses for both isomers were observed at the highest pressure tested - 1×10^{-5} mB and collision energies optimized at 20-40 eV.

Having determined the range of optimal collision energies to be 20-40 eV, our next experiments were conducted to further evaluate the effect of argon pressure on the formation of the M-COCl daughter ion of TCDD and TCDF. A collision energy of 20 eV was used and pressures were varied between 1×10^{-5} mB, 3×10^{-5} mB and 1×10^{-4} mB. Formation of the M-COCl daughter ion optimized at the highest pressure of 1×10^{-4} mB. Increases in response by a factor of about 2 and 3.5 were observed between 1×10^{-4} mB and 3×10^{-5} mB and 1×10^{-5} mB, respectively. The detection sensitivity using a collision energy of 20 eV and a collision-gas pressure of 1×10^{-4} mB was then determined. A S/N of 43:1 was measured on 8.6 pg and S/N=34:1 was measured on 11.6 pg 2,3,7,8 - TCDF. In our final experiments, the selectivity of the method was demonstrated through the analysis of municipal ash and pulp effluent extracts. In these cases, interferences were eliminated by HRGC/MS/MS and not by HRGC/MS at resolving powers of 10,000 and 18,000.

For the conditions used in this study, the sensitivity of HRGC/MS/MS for the analysis of PCDDs and PCDFs is enhanced at increased collision gas pressures and at lower collision energies. A collision energy optima was between 20-40 eV and enhanced sensitivities at argon pressures of 1×10^{-4} were observed. These optimal conditions do not appear to vary between isomers or congeners. The detection sensitivity for 2,3,7,8 - TCDD and 2,3,7,8 - TCDF under these conditions was about 50x less than HRGC/MS. In the cases we examined HRGC/MS/MS improves selectivity. These cases represent those in which the overriding concern is selectivity not sensitivity. In such instances HRGC/MS/MS is a powerful and useful technique.

A $C_{15}H_6Cl_{12}$ MOLECULE IN TECHNICAL CHLORDANE AND IN HUMAN ADIPOSE TISSUE

Mark A. Dearth and Ronald A. Hites*, School of Public and Environmental Affairs and Department of Chemistry, Bloomington, Indiana 47405.

Introduction. Technical chlordane, a mixture of more than 50 compounds (1, 2), is a common pesticide. Due to its toxicity, its carcinogenic potential, and its persistence in the environment, chlordane was banned from general use in 1981, and it was voluntarily removed from the market by Velsicol in 1988. Because of technical chlordane's commercial and environmental importance, there have been many efforts aimed at identifying (and quantitating) its components. Compounds with 10 carbons and up to ten chlorines have been previously reported or identified (3-6). We report here the presence of a compound with 15 carbons and 12 chlorines in technical chlordane and in human fat.

Experimental. Human breast tissues were obtained from the pathologist at Bloomington Hospital, Bloomington, IN. The fatty tissue was homogenized into a fine paste, and 10-20 g of the homogenate were mixed with pre-extracted, anhydrous Na_2SO_4 . This porous mixture was soxhlet extracted for 24 hours with an 1:1 (v/v) mixture of acetone and hexane. After soxhlet extraction, the percent fat of the extract was determined by weighing 100 μ L of the extract, allowing it to evaporate for 24 hours, and reweighing the residual. Two to three ml of the extract were used for GPC separation. The solvent mixture used to elute the column was 3:2 (v/v) cyclohexane and methylene chloride. These methods have been described elsewhere (7). The solvent was removed by rotary evaporation, and a final cleanup was performed on 1% water deactivated silica. The final volume was reduced using a dry N_2 stream. Gas chromatographic analyses were performed on an HP 5890 instrument equipped with a 30 m x 0.25 mm ID, J & W DB-5, fused silica, capillary column and an electron capture detector. Electron capture, negative ionization, gas chromatographic mass spectrometry was performed on an HP 5985B mass spectrometer using the following conditions: The ion source temperature was set at 100°C; the ion source methane pressure was monitored using an MKS Baratron capacitance manometer and adjusted to 0.43 torr. The chromatographic conditions were the same as given above. The GC/MS interface was maintained at 285°C. For trace analyses, selected ion monitoring of the most abundant ions in the mass spectra of the component of interest was used. Full scan mass spectra were obtained by scanning from 34 to 650 daltons in 1.5 seconds.

Results and Discussion. During a study of human dosimetry, human tissues were being analyzed for chlordane components with selected ion monitoring GC/MS in the electron capture, negative ion mode. One ion we were using was m/z 235 due to $C_5Cl_5^-$, a common fragment ion in the mass spectra of chlordane-like compounds (8). Responses were observed for the common Cl_7 - Cl_9 chlordane-like components; in addition, responses were observed for components with much higher GC retention time. We also noted the same responses during the analysis of technical chlordane. We were curious about the possible identity of these high retention time compounds. Thus, we obtained complete mass spectra of these compounds by injecting 190 ng of technical chlordane and scanning the mass spectrometer only during the retention time window of interest. The electron capture, negative ion mass spectrum of the most abundant component is shown in Figure 1.

Figure 1. Mass spectrum of the $C_{15}H_6Cl_{12}$, chlordane-like molecule.

This spectrum clearly indicates that this compound has a molecular weight of 606 and 12 chlorines. The molecular ion isotope cluster agrees with that predicted from 12 chlorines. This compound could have at most 15 carbon atoms; this suggests the elemental composition of $C_{15}H_6Cl_{12}$. From this elemental composition we calculate that this molecule has 7 rings and/or double bonds. (An alternative composition of $C_{14}H_8Cl_{12}$ would be fully saturated; this seemed unlikely and was not considered

further.) This compound shows fragment ions corresponding to the sequential loss of 34 daltons. This corresponds to the loss of a chlorine atom and the addition of a hydrogen; this is a typical fragmentation process for highly chlorinated compounds under negative ion conditions (8). The prominent ion cluster at m/z 235, $C_5Cl_5^-$ due to the retro Diels-Alder fragmentation of the molecular ion (8), is also apparent in the spectra.

At this point in the interpretation, we thought it wise to consider the industrial synthesis of chlordane and chlordane. Technical chlordane is produced by the chlorination of chlordene, a $C_{10}H_6Cl_6$ compound formed by the Diels-Alder condensation of hexachlorocyclopentadiene (hex) and cyclopentadiene (see Figure 2, top). The further chlorination of chlordene produces technical chlordane (see Figure 2, lower right). We believe that the compound we observed is synthesized during the formation of chlordene. If an additional molecule of hex were to add to the double bond of chlordene at C_1 - C_2 , it would give a C_{12} compound.

Figure 2. The synthesis steps for chlordene, gamma-chlordane, and the $C_{15}H_6Cl_{12}$ molecule.

Of course, the structure given in Figure 2 was only a hypothesis. To confirm this structure, we synthesized this compound. Hex and chlordene were mixed in equimolar amounts in a small sealed vial and then heated to $180^{\circ}C$ for 30 min. The mixture turned from a pale yellow to a deeper orange-brown. The mixture solidified upon cooling. The product was isolated from the precursors by repeated washings with hexane, in which the product is only slightly soluble. The product was recrystallized from trichloroethylene. The synthetic compound had the same mass spectrum and GC retention index (2958) as that found in the technical chlordane mixture. The structure of the synthetic compound was confirmed by x-ray crystallography. In fact, the conformation given in Figure 2 was the result of this x-ray study.

As mentioned above, these C_{15} compounds were also present in human adipose tissue. To quantify these compounds, the major ions in the mass spectra of these compounds were monitored during GC/MS analysis of a composite human adipose tissue sample. The same ions were monitored during the analysis of a technical chlordane standard. The average concentration in technical chlordane was 300 ppm, and in human fat it was 0.7 ng/g of fat. It seems as though this compound is not easily metabolized and is well retained in fatty tissues. The initial metabolic step may hinge on the availability of adjacent unchlorinated carbons for epoxidation.

Evaluation of a Hollow Fiber Membrane for the
Determination of Volatile Organics in Water

Mark R. Bauer and Larry E. Slivon
Battelle, Columbus, OH 43201

Jim Ho and William E. Budde
U.S. Environmental Protection Agency, Cincinnati, OH 45268

Semipermeable membranes are an effective and simple mechanism for isolating liquid matrices from the high vacuum requirements of the mass spectrometer. Many early applications, which used planar membranes, exhibited detrimental response times and memory effects. Recent work involving hollow fiber membranes has demonstrated improved sensitivity and response time. Small diameter hollow fibers provide thin membranes and excellent dimensional stability. We have evaluated a hollow fiber interface which uses a flow of helium to purge the membrane interior and transport analytes into the mass spectrometer.

The sampling system under development consists of a length of Silastic™ tubing (0.17 mm thick) connected between two lengths of untreated fused silica capillary. One end of the fused silica capillary is inserted through the GC/MS interface and into the ion source. The other end is attached to the injection port of a GC which is used to maintain a flow of helium through the membrane system. The membrane portion of the system is immersed in the liquid matrix for analysis. The apparatus used for these experiments is shown in Figure 1.

Experiments were conducted to evaluate sensitivity and response time as a function of He flow rate, fiber configuration, and fiber length. It was determined that, while analytes were detectable if no helium was used to purge the interior of the fibers, the intensity of the ion signal was much stronger if helium was used. The response time (time for the ion current to reach 90% of maximum) is independent of the helium flow rate, within the accuracy of the timing equipment used. The response time is likely only proportional to membrane thickness. Sensitivity is, however, inversely proportional to helium flow rate. As shown in Figure 2, the intensity of the observed signal decreases with increasing helium flow. Maximum intensity is obtained when the flow is reduced to near zero, as long as there is some positive flow. It is suggested that the decrease is attributable to both physical dilution of the analyte delivered to the ion source, and helium suppression during the ionization process. Similar experiments determined that sensitivity is proportional to fiber length (with an upper practical limit of between 20 and 30 cm) and that sensitivity does not improve with parallel fibers. A comparison of one 30 cm fiber vs. six parallel 5 cm fibers indicated that the only difference is a slower response time attributable to the increased dead volume introduced by the added plumbing needed.

Using this system, we have determined several volatile organic compounds, including chloroform, trichloroethylene, and benzene, in water at the part-per-billion level. Figure 3 shows the total ion current response collected from the sequential injection of the analytes into reagent water. The individual extracted ion profiles for the base peaks of the four analytes are also shown. After the final injection had plateaued, the membrane was quickly removed from the spiked water and quickly transferred to a separate beaker of clean reagent water. The peak at the beginning of the benzene response curve suggests that the benzene did not disperse evenly and that a some of the concentrated solution may have reached the membrane before the solution equilibrated. The m/z 97 ion profile shows two plateaus, the first is due to a fragment ion of trichloroethylene, while the second is due to the trichloroethane. These compounds are distinguishable however by examining their background subtracted spectra (not shown), and suggest a reason why this interface would be useful when attached to a tandem mass spectrometer.

Figure 4 shows the total ion and a selected ion profile from the analysis of laboratory tap water. Repetitive scan data acquisition was initiated while the silicon membrane was immersed in reagent water. After several minutes the membrane was quickly transferred to a beaker of tap water. There is a noticeable rise in the signal intensity that occurs when the membrane is placed in the tap water. An averaged background subtracted scan is also shown. The ions at m/z 83 and 85 have an abundance ratio suggesting the presence of chloroform.

The hollow fiber membrane sampling system under development has significant potential for continuous monitoring of aqueous systems for trace levels of certain organic compounds. Potential applications include continuous monitoring of industrial process and waste streams, drinking water treatment streams, natural surface water streams, and subsurface groundwater.

With the increasing concern of suspected health effects from chemicals, several states now require monitoring of ground water supplies for certain polynuclear aromatic compounds (PNAs). PNAs represent a class of compounds which include benzo(a)pyrene, benzo(g,h,i)perylene, benzo(b)fluoranthene, indeno(1,2,3-cd)pyrene and others which are suspected carcinogens. PNA contamination of ground water supplies may occur with the release from creosote coated materials (eg., telephone poles and railroad ties) and other sources. In areas where creosote has been spilled or dumped, carcinogenic PNAs may seep through soil or fractures and contaminate ground water supplies. Recommended Allowable Limits (RALs) for PNAs are generally expressed as total nanograms of PNAs present, with individual compound detection limits of 1 or 2 parts per trillion. These low concentrations are typically difficult to routinely achieve.

The detection of PNAs have been achieved (as reported by Cole, Price and Hall; 1985) using full-scan mass spectrometry with a ppinici source. To obtain the necessary sensitivity, instrument conditions must be fully optimized and an extremely experienced operator must perform this analysis. The high level of interfering compounds precludes automated quantitation and requires analyst intervention for spectral interpretation and quantitation. The nature of selected ion monitoring (SIM) reduces interferences and provides greater sensitivity. Consequently, instrument conditions need not be so rigorously optimized and maintained to perform this analysis.

This presentation will report results from the analysis of field samples that were analyzed by both methods. Samples were chosen over a wide concentration range. The results provided by the two analytical methods were surprisingly similar.

Given these results, the SIM method for part per trillion analysis of PNAs in drinking water provides an excellent alternative to full-scan monitoring. The SIM method provides similar quality data but does not push the detection limits, as does the full scan methodology. SIM also reduces the number of interfering compounds. Consequently, if Selected Ion Monitoring of PNAs provides similar quality data as compared to full-scan methodology, than SIM analysis is a superior method.

Very Low Energy Chemistry of Gas Phase Ions

Mark A. Smith, Michael Hawley and Lakshman Randeniya
Department of Chemistry, University of Arizona, Tucson, AZ 85721

Ion-molecule reactions have been widely studied in bulk media over the past 30 years, however, few studies have been made at temperatures below 80 K. Ion-molecule chemistry is now accepted as being an important part of molecular synthesis in interstellar gas clouds. It is important to develop methods for the direct study of ion reactions in the 5 to 50 K temperature regime within which many of these clouds exist. In addition, temperature dependent rate studies have done much to elucidate mechanisms of complex chemical reactions. Extension of rate studies for gas phase ion chemistry to temperatures below 5 K promises to improve upon our understanding of ion-molecule reactive collisions.

We have recently developed a free jet flow reactor method which allows the measurement of absolute ion-molecule rate coefficients in the temperature regime below 30 K.¹⁻⁴ A general schematic of the reaction zone of this instrument is shown in Figure 1. A mixture containing a small fraction (< 1%) of a suitable ion precursor, 1 to 5% of a neutral reactant gas and a buffer gas is expanded through a pulsed molecular beam valve into a vacuum chamber. The resulting isentropic expansion cools the molecules and leads to a supersonic jet with relative intrajet translational energies characterized by temperatures below 30 K. These temperatures may be controlled by variation of the beam nozzle diameter, stagnation pressure of the gas behind the nozzle, or the nature of the carrier gas species. Selective laser multiphoton ionization of the precursor molecules downstream of the nozzle (at position LF in Figure 1) produces a packet of selected cations and free electrons without perturbing the local energy distributions. The subsequent collisions of these ions with neighboring reactant neutrals in the jet can lead to chemical reactions at the low thermal energies of the expansion. This chemistry is monitored, as a function of flow distance, by periodic extraction and mass analysis of the travelling ion packet using time-of-flight mass spectrometry. The resulting temporal history of the ion density and mass distribution can be converted to absolute reaction rate coefficients for the observed reactions. To accomplish this, it is necessary to account for the thermal anisotropies inherent to free jet expansions.⁵

Figures 2 and 3 show recent results for the reaction rate coefficients obtained in this manner for, respectively, the reactions:

Both of these reactions follow strict T^{-n} rate coefficient laws with $n=1.92$ and 1.86 , respectively. These rate laws are found to be very well supported by statistical phase space theory (the calculations in the zero pressure limit are shown as the solid lines). The results strongly support the statistical nature of four atom cationic collision complexes formed at total collision energies down to 4 K.

We have also recently investigated the bimolecular reactions:

Reaction 3 proceeds with a collision efficiency less than 1% at 300 K and is not observed to proceed at 80 K. When C_3H_2^+ in its ground vibrational state is prepared in an H_2 expansion with a characteristic translational temperature of 4 K, we observe reaction to proceed at 6% of the collision rate. Reaction 4 is not observed to proceed under similar conditions in D_2 jets. When one quanta of the C-C stretch is placed in C_3D_2^+ , reaction 4 is found to proceed at near 10% of the collision rate. Coupled with the earlier bulk studies of Reaction 3, a mechanism is proposed involving production of a long lived ethylene radical cation collision complex. A barrier in the reaction exit channel, of approximate height $2.5 \text{ kcal mole}^{-1}$, inhibits direct reaction below 300 K. At very low temperatures, products from H containing complexes are formed by a slow tunnelling channel through this barrier in competition with complex dissociation back to reactants. Bulk rate coefficients cannot yet be provided, owing to the strong disequilibrium present between rotation and translation in H_2 jets. Current studies using HD and para- H_2 should to resolve this. It is very clear, however, that extremely long lived complexes play an important role in the low temperature chemistry of C_3H_2^+ . These complexes allow new mechanisms to emerge and efficient reaction channels to activate, mechanisms which may not be effectively open to higher energy reactants.

Time-Resolved Photodissociation and Energy Relaxation Processes in Styrene Ions

Robert C. Dunbar
Case Western Reserve University
Cleveland, OH, 44106

Using time-resolved photodissociation in the ICR ion trap, the fragmentation rate of styrene ions excited by an excimer-laser pulse at 308 nm was measured. Ions which were thoroughly thermalized by numerous collisions with parent neutral showed a dissociation rate constant of $1.1 \times 10^8 \text{ s}^{-1}$. This was in accord with the RRKM prediction assuming a somewhat tight transition state and an activation energy (0 K) of 2.32 eV. At low pressure and short time after ion formation the dissociation rate was greatly increased, due to unrelaxed excess energy from electron impact ionization. By following the dissociation rate as a function of pressure from 3×10^{-9} to 3×10^{-8} Torr, and as a function of delay after electron impact from 0 to 3 s, both collisional and IR-radiative relaxation of this excess energy could be followed. The transition from collision-dominated relaxation to IR-radiation-dominated relaxation occurs around 1×10^{-8} Torr of parent neutral.

Excimer laser 308 nm (4.02 eV)
Time-resolved ICR detection

Relaxation results

Initial energy E_0 (11.5 eV electron impact)	0.50 eV
Collisional Relaxation	5×10^{-10}
Radiative Relaxation	$0.65 s^{-1}$

Conclusions

- Time-resolved PDS of styrene ion measures internal energies to $\pm .03$ eV in the 0.5 to 0.1 eV range
- Dissociation in the 10^5 to $10^6 s^{-1}$ region follows RRKM with a tight transition state, $E_0 = 2.32$ eV, $\Delta S^0(1000K) = -6.4$ eu
- Relaxation requires 2 collisions or 1.3 s.

**Gas-Phase Chemistry of CH_3SOH , CH_2^+SHOH , $\text{CH}_3\text{SO}^\bullet$ and $\text{CH}_2\text{SOH}^\bullet$
by Neutralization-Reionization Mass Spectrometry**

F. Turecek, D.E. Drinkwater and F.W. McLafferty
Department of Chemistry, Cornell University, Ithaca, 14853 NY

Methanesulfenic acid, CH_3SOH , has been suggested to occur as a reactive intermediate in photolytic oxidative degradation of methyl sulfide and dimethyldisulfide that belong to major natural and man-made atmospheric pollutants. We have generated CH_3SOH by flash-vacuum pyrolysis of methyl tert-butyl sulfoxide, or by neutralization of CH_3SOH^+ prepared from methyl n-propyl sulfoxide.

Ions CH_3SOH^+ decompose unimolecularly to give $\text{CH}_2=\text{S}^+\text{OH} + \text{H}^\bullet$, $\text{CH}_2=\text{SH}^+ + \text{OH}^\bullet$, and $\text{CH}_2=\text{S}^+ + \text{H}_2\text{O}$. The ion products were identified through their CAD spectra in MS/MS and MS/MS/MS experiments. The losses of $\text{OH}^\bullet$ and H_2O are preceded by isomerization of CH_3SOH^+ to a distonic isomer, $\text{CH}_2^+\text{SH-OH}$, which was generated independently from di-n-butyl sulfoxide and characterized by its CAD spectrum.

Neutralization of fast CH_3SOH^+ and CH_2^+SHOH with mercury vapor yielded the corresponding molecules, CH_3SOH and $\text{CH}_2^+\text{SH-OH}$, which upon reionization with O_2 gave distinct $^m\text{NR}^+$ mass spectra (Figure 1). Decompositions of neutral CH_3SOH and $\text{CH}_2^+\text{SH-OH}$ were further enhanced by collisions with helium in $^m\text{N/CAD/R}^+$ experiments (Figure 2). Following CAD, CH_3SOH undergoes C-S bond cleavage to give $\text{CH}_3^\bullet + \text{SOH}^\bullet$ ($\Delta H_f^\circ = 357 \text{ kJ/mol}$). CAD of $\text{CH}_2^+\text{SH-OH}$ yields mainly two types of products: $\text{CH}_2\text{SH}^\bullet$ and $\text{OH}^\bullet$ are formed by simple cleavage of the S-O bond ($\Delta H_f^\circ \approx 86 \text{ kJ/mol}$). $\text{CH}_2\text{S}^\bullet$ and H_2O arise by hydrogen 1,2-migration in $\text{CH}_2^+\text{SH-OH}$ to transiently form unstable $\text{CH}_2\text{S}^+-\text{OH}_2$ which decomposes spontaneously by a highly exothermic reaction. Semiempirical MNDO calculations indicate that $\text{CH}_2^+\text{SH-OH}$ is less stable than CH_3SOH , while the isomers are separated by a significant energy barrier.

CAD and $^{+}NR^{+}$ mass spectra were also used to distinguish isomeric ions $CH_3S^{+}=O$ and $CH_2=S^{+}OH$, and radicals $CH_3SO^{\cdot}$ and $\cdot CH_2SOH$. According to spectral evidence and MNDO calculations, the order of stability is $CH_2=S^{+}OH > CH_3S^{+}=O$, while $CH_3SO^{\cdot} > \cdot CH_2SOH$.

Observation of Dissociative and Radiative States of N_2H by
Neutralization Ion Beam Techniques

S. F. Selgren, P. W. McLoughlin, and G. I. Gellene
Department of Chemistry, University of Notre Dame, IN 46556

An important industrial process for reducing nitric oxide emission from smoke stacks involves the addition of ammonia to the flue gas.¹ One of the critical reactions in this so-called thermal $DeNO_x$ process is believed to be that of the amidogen radical with nitric oxide:²

Previous kinetic experiments have determined that H_2O and OH are products of reaction 1³, but despite careful searching, product hydrogen atoms have not been identified.⁴ This negative evidence suggests indirectly that the previously unknown N_2H radical may be produced and live long enough to undergo bimolecular chemistry. In the present study, the first direct experimental information on this radical is obtained.

The $N_2H(D)$ radical was studied experimentally by measurement of the kinetic energy release in its unimolecular dissociation following formation by electron transfer from metal atoms to high velocity, mass-resolved ion beams and theoretically by *ab initio* techniques. Calculations of the minimum energy pathway for the ground state of the radical at the MP4/6-311G**//MP3/6-311G** level of theory indicate that the radical is unstable with respect to N_2 and H by 0.6 eV but separated from the dissociation products by a 0.4 eV barrier. One dimensional tunneling lifetimes are determined to be 7.0×10^{-12} s for N_2H and 3.6×10^{-10} s for N_2D . Neutralization of the ion with Zn targets produces predominantly radicals in the $^2A'$ ground state with dissociative lifetimes $\tau < 0.5 \mu s$, in agreement with the calculations. However due to the large ion/neutral geometry change (linear to 116° bent) it can be questioned whether the local minimum of the neutral surface was accessed in these experiments.

Mg targets were found to produce the radical in a mixture of the $^2A'$ ground and $^2A''(\pi)$ excited states with a branching ratio dependent on the internal energy of the precursor ion. A higher excited state of the radical, suggested to be an $n=3$ Rydberg level, is produced with K targets and is inferred to undergo radiative transitions.

Very recently, a new theoretical investigation of the N_2H radical has determined a significantly greater dissociation barrier (0.53 eV) using the CASSCF/CCI methodology.⁵ This new potential energy surface coupled with our tunneling analysis leads to predicted lifetimes of 3×10^{-8} s and 9×10^{-5} s for N_2H and N_2D respectively. We intend to test these predictions by producing the N_2H^+ ion from dissociative ionization of diimine thereby hoping to selectively excite the bending mode of the ion.

THE LASER MICROPROBE FTMS

M. Pelletier, G. Krier, J. F. Muller*,
Laboratoire de Spectrometrie de Masse et de Chimie Laser,
Universite de Metz, le du Saulcy, B.P.794, 57012 Metz Cedex 1 France.

Nicolet Analytical Instruments, 6416 Schroeder Road, Madison, WI 53711.

Surface characterization is important in material science and solid-state chemistry. The laser microprobe provides an alternative to the ion microprobe for the qualitative analysis of metals, polymers, organic or inorganic contaminants, and for localized elemental distributions in various matrices. Isobaric mass spectral interferences and matrix effects are often observed with these techniques. To overcome these limitations, we have combined the high mass resolving power of Fourier Transform Mass Spectrometry (FTMS) with the selectivity of laser desorption, ionization, or ablation processes, as well as the resonant two-photon process.

Instrumentation: The laser microprobe FTMS [1] is comprised of a dual FTMS source/analyzer FTMS-2000 mass spectrometer (Nicolet Instruments Corporation), a specially designed sample introduction system and state-of-the-art laser and viewing optics. The instrument consists of two parts (Figure 1):

i) The source side at medium pressure (10^{-8} Torr) contains an external manipulator 5 that is attached to the transfer rod, a sample introduction chamber pumped by a turbomolecular pump, a sample stage that is attached to an x-y-z internal Peltier effect manipulator 3 [1], and a blocking mechanism 4 that is attached to the sample manipulator to eliminate vibration the manipulator.

ii) The analyzer side at low pressure (10^{-9} Torr) comprises of laser focusing optics 6 that can be adjusted in the z-direction as a function of the laser wavelength, inverted "Cassegrain" mirror optics for the visualization and illumination of the sample, an endoscope 2 with illumination (improved contrast) for use in positioning the manipulator, and an external optics bench that contains a telescope, beam expanders and movable mirrors.

Fig 1: Laser microprobe FTMS a) minimum size of laser impact; b) detection of ^{24}Mg (5×10^{14} atoms/cm³) in GaAs matrix.

The ionizing laser (wavelength 190 nm to 360 nm) is focused normal to the sample surface. The placement of the sample at the focal point of the laser occurs from the data station by adjusting the current to the Peltier cells placed between two performed memory alloy blades [2]. The current induces a differential heating of the two blades and consequently a movement of the sample stage. A magnified view (X250) of the sample is available by using a telescope equipped with a zoom lens or by a CCD camera connected to the high-resolution video monitor near the data station.

The laser spot size is controlled by adjusting the distance between the two lenses in the laser beam expander. This design also permits resonant or nonresonant postionization of the expanded microplasma (or desorbed neutrals).

Experiments: Ionization was performed by using an excimer laser charged with KrF (249 nm) or ArF (193 nm). To enhance the detection of minor abundance ions, the major ions were ejected prior to the excite/detect event.

Results: The minimum laser spot size at low energy is 4 microns (Figure 1a). High resolution permits the easy separation of isobaric ions. For example, by operation the instrument at a resolving power of 160,000, $^{44}\text{Ca}^+$ was easily be separated from $^{88}\text{Sr}^{2+}$ at m/z 44; and $^{58}\text{Ni}^+$ and $^{60}\text{Ni}^+$ were distinguished from $^{116}\text{Sn}^{2+}$ and $^{120}\text{Sn}^{2+}$. For trace elements, the direct mode detection with a large number of data points (128 K) is preferable.

The sensitivity of LDMS is dependent on the ionization potential and work function of the element and matrix effects. For example, ^{24}Mg implanted by ion bombardment in Ga/As or In/P semiconductors (0.02 ppm or $5 \times 10^{14} \text{ atoms/cm}^3$) was only detected in the Ga/As matrix (Figure 1b). The detection threshold of Mg is 1-to-10 ppm per laser shot.

The ease of defocusing the laser and the precise control of the laser spot size (consequently the laser intensity) enables laser ablation and depth profile studies. For example, we have obtained a good separation between a Al/Cu layer and chromium layers on a silicon wafer.

Conclusion: The laser microprobe FTMS with Cassegrain optics has the following features: sample visualization (X250) for accurate positioning of the sample at the focal point of the laser; a homogeneous energy distribution for all experiments is guaranteed by the laser beam normal to the sample surface; and the automated micromanipulator that is controlled remotely from the data station. The detection sensitivity is comparable to other laser microprobe mass spectrometers such as LAMMA or LIMS.

PROPERTIES OF CARBON CLUSTER IONS, C_n^+ FORMED BY DISSOCIATIVE IONIZATION

C. Lifshitz, T. Peres and I. Agranat
Departments of Physical Chemistry and Organic Chemistry and
The Fritz Haber Research Center for Molecular Dynamics
The Hebrew University of Jerusalem
Jerusalem 91904, Israel

Carbon cluster ions C_n^+ have previously been formed by laser vaporization of graphite and their properties studied through MIKE¹ and CAD² spectra, ion molecule reactions³, *ab initio* calculations³ and photodissociation⁴. C_n^+ ions can also be formed by dissociative electron impact ionization of molecules. In fact, a large fraction of mass spectrometry has been devoted to carbon containing ions. It is interesting to enquire whether the structure, stability and fragmentation properties of carbon cluster ions formed by dissociative electron impact ionization of carbon containing molecules are the same as those made by laser vaporization of graphite. Overcrowded perchloro hydrocarbons are a good source of C_n^+ ions, which are generated by exhaustive chlorine elimination⁵. In the present study we have made C_n^+ ions with $n = 3, 5, 6, 7, 10, 11, 12, 14$ and 16 from six different precursor molecules. Some of the ions were made from more than one precursor molecule. These C_n^+ ions were studied by means of MS/MS experiments including unimolecular MIKES, CAD MIKES, kinetic energy releases and charge stripping experiments, employing a VG ZAB-2F double-focusing mass spectrometer of reversed geometry.

The average kinetic energy releases as well as the instability towards fragmentation were observed to increase with increasing cluster size (Figs. 1 & 2), and to be independent of the precursor molecule. A characteristic metastable peak shape is represented for $C_5^+ \rightarrow C_3^+ + C_2$ in Fig. 3. MIKE and CAD spectra demonstrated characteristic 'magic' neutral losses. For example, C_5^+ eliminates unimolecularly C_2 ; C_6^+ , C_7^+ , C_{10}^+ and C_{14}^+ eliminate C_3 each while C_{11}^+ and C_{12}^+ eliminate C_1 . The fragmentation pattern of C_{16}^+ involves C_1 , C_2 , C_3 and C_5 losses.

Charge stripping (CS) was observed for C_{10}^+ and C_{16}^+ (Fig. 4) yielding minimum values for the energy required to remove the second electron, $Q_{\min} = 15.5$ eV, for both ions.

All of the data are in remarkable agreement with available data on C_n^+ ions formed by laser vaporization of graphite, suggesting that the same ion structures are formed by both methods. Furthermore, MIKES, CAD and CS data indicate a change in the C_n^+ structure between $n = 9$ and $n = 10$ in agreement with earlier findings based on photodissociation spectra and ion/molecule reactions which suggest that C_n^+ ions with $n = 3-9$ are linear while those with $n \geq 10$ are cyclic.

The unimolecular reaction $C_{11}^+ - C_{10}^+ + C_1$ is suggested to be a carbon atom extrusion from a cyclic ion to form another cyclic ion - a reaction possessing a relatively low critical energy of activation and tight transition state. Under collisional activation C_3 elimination is preferred; while being a reaction possessing a higher energy requirement it transforms a cyclic structure (C_{11}^+) to a linear ion (C_8^+) via two consecutive C-C cleavages with loose transition states. The possibility of two coexisting structures of $n = 6, 7, 8$ has not been pursued by MS/MS techniques.

Aluminum cluster negative ions can be generated by laser ablation (without utilization of a bath gas or supersonic expansion) and studied with Fourier transform mass spectrometry (FTMS). The ease of aluminum cluster ion formation combined with the capabilities of FTMS for accurate mass measurements and ion trapping provide a powerful method for examining the structures and reactions of these ions. Specifically, charge exchange reactions, collision-induced dissociation, and ion-molecule reactions provide structural information for these clusters.

Laser ablation of a flat aluminum disk generated an abundance of negatively charged aluminum cluster ions ranging continuously from Al_3^- (m/z 81) to Al_{50}^- (m/z 1349), with Al_{13}^- observed as the most abundant cluster, Figure 1. Accurate mass measurements indicated that these clusters do not contain hydrogen or other ligands. Trapping these cluster ions for times up to 4 seconds with or without argon present indicated no change in the relative intensities of the cluster ion distribution, suggesting that any "hot" clusters have dissociated prior to ion detection. Figure 1 indicates that the odd-numbered clusters are more intense than the even-numbered clusters in the range of $n = 3$ to 15.

The aluminum cluster ions were reacted with either nitrogen dioxide (electron affinity, E.A. = 2.30 ± 0.10 eV) or para-benzoquinone (E.A. = 1.89 ± 0.10 eV) in order to investigate charge exchange. All clusters for Al_n^- where $n = 3-23$ indicated charge exchange with NO_2 . Al_3^- also indicated charge exchange with p-benzoquinone, implying E.A. (Al_3) < 1.89 eV. All of the other cluster ions were unreactive with benzoquinone, suggesting $1.89 \text{ eV} < \text{E.A.} (Al_n \text{ for } n = 4-23) < 2.30 \text{ eV}$, which are in good agreement with other experimental and theoretical values.

The collisional dissociation spectrum for most of these cluster ions is characterized by loss of one or more aluminum atoms. For example, Al_{13}^- fragmented to give products corresponding to Al_n^- where $n = 7$ to 12, shown in Figure 2. No fragments smaller than Al_7^- were observed. The fragmentation of these cluster ions is a competition between aluminum atom elimination (which is determined by the bond energy) and electron detachment (which is determined by the electron affinity of the neutral clusters). For clusters Al_n^- where $n = 4, 5, 8-13$, aluminum atom elimination was observed, implying that the bond energies for these ions are lower than the electron binding energies. For Al_3^- , Al_6^- , and Al_7^- , electron detachment was the primary fragmentation observed, indicating that the electron binding energies for these three ions are lower than their respective bond energies.

These aluminum cluster ions are unreactive with CH_4 and N_2O , but react quite specifically with O_2 . Clusters of Al_n^- for $n = 3-8$ react with O_2 to generate AlO^- and AlO_2^- , shown in equations 1 and 2 for Al_3^- . Large aluminum clusters ($n = 8-32$) also exhibit interesting oxygen reactions, shown in Figure

3. The even-numbered clusters react with O_2 to generate both AlO^- and AlO_2^- , whereas the odd-numbered clusters are unreactive. This size dependent reactivity may be a reflection of the stability of the neutral products which are generated (i.e. the neutral Al_n and Al_nO molecules).

THE FORMATION, DISSOCIATION, AND REACTION
OF INDIUM CLUSTER IONS, In_n^+ ($n = 2-9$)
F. L. King, M. M. Ross, and V. H. Wysocki
Chemistry Division, Naval Research Laboratory
Washington, D.C. 20375

INTRODUCTION

Investigations of indium, gallium, and aluminum cluster ions were conducted in order to identify behavior characteristic of cluster ions composed of Group IIIB elements. These species and their oxides are important in a variety of technological applications ranging from catalysis to optoelectronics where performance has been linked closely to particle size. From the wide variety of techniques available for the production and characterization of clusters we chose fast-atom bombardment for production and mass spectrometry for characterization.

EXPERIMENTAL

Fast-atom bombardment is a relatively simple technique permitting the rapid production of an abundant cluster ion population. Al_n^+ , Ga_n^+ , and In_n^+ were produced by bombardment of the respective pure metals with an 8-keV Xe beam produced by a saddle field discharge gun. Likewise, In_xO_y^+ clusters were generated by the direct bombardment of the pelletized oxide powder, In_2O_3 , target with the 8-keV Xe beam.

Investigations of cluster ion abundance were conducted utilizing a reverse geometry (BE) double focussing mass spectrometer. The unimolecular dissociation of selected cluster ions was studied by mass-analyzed ion kinetic energy spectrometry (MIKES) in the absence of a collision gas. Low energy collision-induced dissociation (CID) and collision-induced reaction studies of the cluster ions were conducted on a triple quadrupole geometry (QQQ) mass spectrometer. The QQQ instrument was tuned to reproduce the abundance observed with the BE instrument in order to minimize potential tuning effects.

RESULTS AND DISCUSSION

Herzog reported the production of Al_n^+ cluster ions ($n = 2-18$) from the bombardment of an Al target with a rare gas ion beam.¹ A decrease in cluster ion abundance was observed as cluster ion size increased, except for cluster ions having $n = 7, 9$, and 14 which exhibited anomalous abundances. The nascent distribution of cluster ions we observed to result from the sputtering of Al, Ga, and In targets is shown in Figure 1. The Al_n^+ abundance distribution is similar to that reported by Herzog, as are the Ga_n^+ and In_n^+ abundance distributions. The data indicate that such a distribution is characteristic of Group III B cluster ions produced by sputtering.

Begemann, Meiwes-Broer, and Lutz investigated the unimolecular dissociation of sputtered aluminum cluster ions, $n = 2 - 23$, and found that the $n = 9$ and $n = 14$ cluster ions decayed to a lesser extent than adjacent sized cluster ions.² In their study they observed no unimolecular dissociation for species having $n < 8$. In MIKES investigations of Al_n^+ , Ga_n^+ , and In_n^+ we observed the unimolecular dissociation behavior for $n = 2$ to 9 . The $\log \%$ unimolecular dissociation is plotted as a function of parent cluster ion size, n , in Figure 2. Similar behavior was exhibited by Al_n^+ , Ga_n^+ , and In_n^+ . Clusters containing 2, 7, 9, and 14 atoms showed enhanced stability

relative to adjacent cluster sizes. The principal dissociation process observed was the loss of a metal atom. In general, the charge remained on the polyatomic fragment leaving a neutral atom as the other fragment. For all cluster ions $n = 5$ to 7 and for Al_4^+ , unimolecular dissociation yielded an ionized atom and a neutral polyatomic fragment. However, in low energy CID studies the $n = 9$ cluster ion dissociates to yield the ionized atom. In low energy CID studies of Al reported in the literature, similar behavior has been reported.³ The difference in ionization potentials between the $n = 8$ fragment and the atom may be so small that the additional energy from CID is sufficient to favor the higher energy fragmentation channel. In general, these results indicate that for group III B clusters the ionization potentials peak above $n = 2$ and below $n = 7$ rather than gradually decreasing from the atomic ionization potential toward the bulk work function.

As has been reported for Al cluster ions⁴, collisions of In_n^+ , $n = 2-5$, with O_2 are dissociative at most collision energies studied. The principal species observed in the daughter spectrum are the same as those observed for unimolecular dissociation or CID as described above. At low collision energies products indicative of reaction, such as In_2O^+ and In_3O^+ , were observed. In_2^+ and In_3^+ yielded the product ion, In_nO^+ , in which the parent cluster remained intact adding a single O atom. In_3^+ was the only species for which a product containing more than one O atom was observed, In_3O_2^+ .

Dissociation of In_xO_y^+ clusters, produced by the sputtering of an indium oxide target, generally yields neutral fragments of InO , In_2O , and In_2O_2 . For such species the loss of O or O_2 is a minor process. In contrast, dissociation of In_xO_x^+ , $x = 2 - 5$, yields only neutral loss of O and/or O_2 .

DETECTION OF REACTION INTERMEDIATES IN THE
CONVERSION OF CYCLOHEXANE TO BENZENE ON Pt(111)

Donald P. Land, Claire L. Pettiette-Hall,
Robert T. McIver, Jr., and John C. Hemminger
Institute for Surface and Interface Science and Department of Chemistry
University of California, Irvine, California 92715

Dehydrogenation reactions catalyzed by transition metal surfaces have long been of great interest because of their importance in petroleum processing. In the conversion of cyclohexane to benzene on Pt, cyclohexene has been suggested as an intermediate, but it has never been directly detected. Presented here is the first direct observation of cyclohexene as an intermediate in this reaction. In addition, a second intermediate which is believed to be a bis(alkylidene) species is also detected. The reaction is studied as a function of temperature and time by laser-induced thermal desorption and Fourier transform mass spectrometry (LITD/FTMS). In the experiments described below, an excimer laser operated at low power (20 MW/cm², 248 nm, approx. 20 ns pulsewidth) is used to desorb molecules adsorbed on a Pt(111) single crystal. The Pt surface is not ablated and the adsorbates are removed as neutrals. The desorbed neutrals are ionized by a 70eV electron beam and detected by FTMS. The use of FTMS allows one to obtain a complete mass spectrum (m/z 10 to 600) for each single laser shot. Analysis of the mass spectra can provide molecular information about the composition of adsorbates on the surface.

A clean Pt(111) surface, supported in an ultra-high vacuum system, was cooled to 190K and exposed to gas-phase cyclohexane. Figure 1 contains four mass spectra obtained from laser-induced thermal desorption from the Pt(111) surface following a cyclohexane exposure which results in submonolayer coverage. Figure 1a is the LITD/FTMS spectrum obtained with a single laser shot after the cyclohexane has been on the surface for 3 minutes at 190K. This spectrum shows all the peaks expected for cyclohexane (mass 84 is the parent mass) and confirms that cyclohexane is stable on the surface at this temperature. In addition, there is no indication in Figure 1a of any unexpected peaks due to laser-induced cracking or pyrolysis of the cyclohexane adsorbate. A survey was then carried out by warming the sample in steps of about 3K. Several LITD/FTMS spectra were taken at each temperature (each at a different spot on the crystal) until there appeared to be no change between successive spectra taken several minutes apart. Three representative mass spectra are shown in Figures 1b-d. Figure 1b was obtained a few minutes after warming to 201K. There is no noticeable change in the cyclohexane intensity in Figure 1b relative to Figure 1a, as expected from TDS experiments by Rodriguez and Campbell which indicate no significant desorption between 190 and 201K.¹ In addition to the peaks due to cyclohexane, however, there are new peaks at m/z 50, 77, and 78 which indicate that benzene has formed on the surface. Also apparent in Figure 1b are new peaks at m/z 54, 67, and the expanded view shows a peak at m/z 82. These peaks are indicative that there is cyclohexene on the surface. To our knowledge, this constitutes the first direct observation of cyclohexene as a surface intermediate in this reaction. Additional experiments have shown larger cyclohexene concentrations, and that the relative concentrations of benzene and cyclohexene in the reaction mixture at this point are sensitive to the details of the reaction conditions. Previous direct desorption of benzene in this reaction was only recently achieved by Campbell, et al., using Bi-postdosing techniques.² Conventional thermal desorption conditions (heating rates 5-100 K/sec) result in dehydrogenation of the benzene product and also of cyclohexene at low coverages, as shown by Rodriguez and Campbell,³ so that neither product would be observed as desorption products in traditional thermal desorption spectroscopy of this reaction.

The spectrum in Figure 1c was taken after 20 minutes at 201K. The absence of a peak at m/z 84 indicates that cyclohexane is no longer present on the surface, and the absence of a peak at m/z 82 indicates that cyclohexene has also disappeared. There are several peaks that may be assigned to benzene (m/z 77 and 78), but the most prominent peaks in the spectrum at m/z 39, 41, 42, 54, and 67 are not due to benzene. This is clearly shown by

comparing Figure 1c and 1d. Figure 1d, which was obtained after warming the crystal to 314K for an additional 3 minutes, has all the peaks normally expected for benzene and is quite different from Figure 1c. The additional peaks in Figure 1c indicate that a distinctly different surface intermediate has formed. Although many C_6 hydrocarbons produce electron ionization fragment ions with masses similar to those in Figure 1c, the relative abundances are quite distinctive for each parent compound. Thus, if one compares Figure 1c with reference mass spectra for the C_6 hydrocarbons, only 1,5-hexadiene shows a close correspondence for both mass numbers and relative abundances. The distinctive features of the 1,5-hexadiene mass spectrum are a lack of parent ion and abundant fragment ions for cyclopropenyl ($C_3H_3^+$, m/z 39) and allyl ($C_3H_3^+$, m/z 41), as well as significant intensities at m/z 54 and 67.

Di-sigma bonded cyclohexene may undergo conversion analogous to olefin metathesis to form the bis(alkylidene), 1,6-hexa-dialkylidene, shown below. This species is similar to several u-bis(alkylidene) compounds identified in the organometallic literature. Laser desorption of this species would be expected to give a mass spectrum similar to that of 1,5-hexadiene and Figure 1c. Further support for the suggested mechanism is afforded by Macomber, et al., who have observed the reverse of this type of reaction.⁴

The high sensitivity of the LITD/FTMS technique has enabled us to identify the reaction product benzene, and two intermediates which, when laser desorbed, give cyclohexene and 1,5-hexadiene. Further LITD/FTMS experiments, including kinetics measurements, are being carried out to give a more complete understanding of the dehydrogenation processes involved.

IONIZATION TECHNIQUES BASED ON PROPERTIES OF SUPERCRITICAL FLUIDS:
I. MECHANISM OF IONIZATION.

by
Susan V. Olesik and William Larkins, Jr.
Department of Chemistry
The Ohio State University
Columbus, Ohio 43210

One of the largest barriers in the analysis of large molecules by mass spectrometry is the difficulty of volatilizing molecules without decomposition. This decomposition is often caused by thermal and/or electronic or vibrational addition of energy to the molecule.

We are developing new types of soft-ionization techniques. These techniques are based on the premise that the ionization properties can be controlled by varying the properties of the solvent, which is a supercritical fluid. The supercritical fluid expands into the vacuum by traversing through a supersonic jet expansion. Molecular clusters are present in the expansion due to cooling in the expansion but also due to their presence in the original solvent - the supercritical fluid. The size of the cluster that is present in the vacuum can be varied considerably by varying the properties of the supercritical fluid.

In this report, the ability to ionize the cluster systems which appear at the point of expansion was demonstrated. For the cases of carbon dioxide mixed with polar modifiers, such as methanol, both positive and negative cluster ions were produced. In the case of pure carbon dioxide only negatively charged clusters were produced. Ion beams with nanoampere currents were produced in all cases. Initial data on the possible mechanisms of cluster ionization were also shown.

AMERICAN SOCIETY FOR MASS SPECTROMETRY
BUSINESS MEETING

Fontainebleau Hilton
Miami Beach, Florida
May 24, 1989

President Ron Hites called the meeting to order at 11:20 a.m. Susan Weintraub presented the Secretary's report. She first announced the results of the 1989 ASMS elections. The new Board members will be: Robert Lattimer, Vice President for Arrangements; Veronica Bierbaum, Secretary; Richard Caprioli, Member-at-Large. Thanks were also expressed to the candidates who were not elected - David Millington, John Eyler and Charles Wilkins. Next, the list of winners of the 1989 Student Travel stipends was displayed. The recipients are: Amit Ghosh, University of Maine; James Ronald Gord, Purdue University; Richard P. Grese, University of Nebraska - Lincoln; Shenheng Guan, University of the Pacific; Lenaers Guido, Antwerpen University, Belgium; Richard J. Hughes, Trent University, Ontario, Canada; Martin Arthur Moseley, III, University of North Carolina - Chapel Hill; Johnny D. Reynolds, University of Tennessee - Knoxville; Kevin L. Schey, Purdue University; Lutz Schweikhard, University of Mainz, West Germany; Anthony G. Thompson, University of Illinois. The students were congratulated on their achievement.

Michelle Buchanan then gave the Treasurer's report. Charts depicting ASMS income and expenses were shown, and Buchanan explained that a net profit of approximately \$2,000 was realized last year. She added that the ASMS Board tries to maintain year-end assets at a level equal to one year's expenses.

The Vice President for Programs, Robert Murphy, spoke next. He first thanked the members of the Program Review Committee for their efforts in reviewing the abstracts. Those serving on the committee were: Michelle Buchanan, Richard Caprioli, Keith Clay, Charles DePuy, Gary Glish, Michael Gross, Ron Hites, Vernon Reinhold, Doug Ridge and Joe Zirrolli. Murphy continued by saying that initially, 50 abstracts were rejected; however, 26 were resubmitted and were included in the program. Murphy said that he feels that the quality of the abstracts has improved significantly since the review process was initiated.

Murphy next told about various aspects of the program. He explained that the structure of the program is based, to a large extent, on information gained from the interest groups and workshops. He added that he is currently soliciting suggestions about symposia and plenary speakers for next year. Murphy then displayed a chart which showed the number of oral and poster presentations from 1984 to 1989, noting that posters have increased dramatically over this period. He said that he feels that the society benefits greatly by the growth in the number of posters, as posters are such a good way to transmit information. Murphy then announced that there were 1623 registered attendees at the 1989 Conference. This number is slightly less than the total from the San Francisco meeting, but it follows the trend seen in the past.

Murphy concluded by thanking people who are assisting him with audiovisual and other arrangements at the conference - Kevin Hart of Michigan State, Casey Grimm of Oak Ridge, Michael Shirley of Colorado and George Yefchak of Michigan State. At this point, Mike Grayson commented favorably on the high quality of the poster boards being used at this conference, and he encouraged Murphy to obtain similar ones in the future. Murphy added that if this type of board is available, presenters would be able to use pieces of Velcro to mount their displays.

Gary Glish, the Vice President for Arrangements, gave his report next. He first explained about the beach party scheduled for that evening and said that members and their guests should wear their green name badges for admission to the party. He also said that various games would be held throughout the evening, and he listed the prizes which could be won.

Glish next showed slides of the hotels which will be used for the 1990 Conference in Tucson - the Ventana Canyon and the La Paloma. He then listed the dates and sites for future ASMS meetings. These are: 1991, Opryland Hotel in Nashville (May 19 - 24); 1992, the Hilton in Washington, D.C. (May 31 - June 5); 1993, the Riviera Hotel in Las Vegas (June 6 - 11). He noted that none of these dates includes the Memorial Day holiday.

Glish concluded by thanking the Board for their help. Sandy Markey then congratulated Glish on this year's arrangements, adding that the site was very pleasant. He was concerned, however, about the choice of Las Vegas for a future meeting. Glish said that the Board had carefully evaluated Las Vegas and felt that the outstanding

quality of the meeting space, the low room rates and the availability of meals at modest prices outweighed other aspects of the city. Glish continued by saying that there are not many facilities which can accommodate our meeting in a single hotel and that we are not yet large enough to use a convention center. Graham Cooks suggested that a straw vote be taken to measure the members feelings about Las Vegas. Ron Hites asked for those present at the meeting to applaud appropriately if they were "for" or "against" Las Vegas. The response was approximately equal, and Hites said that the Board will review the situation and make a final decision at their August meeting.

The Member-at-Large with responsibility for Education, Mike Story, was next to speak. He explained that he serves as chairman of the Education Committee. The members of this committee are Paul Goodley, Ann Goetz, Harry Hertz, Alan Marshall and Al Yerger. He reported that 5 short courses were offered this year and that there were 175 participants. Story reminded ASMS members to fill out and return the questionnaire about short courses which was distributed at registration.

Story next described a brochure about mass spectrometry which was developed by the Education Committee. This publication is a promotional booklet which will be given to undergraduate students in an attempt to interest them in mass spectrometry. Story said that special thanks were owed to Ann Goetz for her efforts on this project. Story then told about 2 "educational" symposia which were being presented this year - one on state-of-the-art research in mass spectrometry, organized by Harry Hertz, and the other, introductory lectures about various topics in mass spectrometry, organized by Al Yerger. Story said that there had been good attendance at these symposia and that he felt that they had been well received. In conclusion, Story expressed his thanks to Harry Hertz, Paul Goodley and Al Yerger, whose terms on the committee are ending.

Willard Harrison, the Member-at-Large responsible for the Proceedings, was next to report. He reminded the members to turn in their extended abstracts. Harrison said that in the past, the submission rate for extended abstracts has been about 95%, enhancing the quality of the Proceedings. He said, however, that he hopes to increase the number of abstracts from the plenary lecturers. Harrison then said that for 1988, the Proceedings cost the society \$11 per book and that approximately 2900 copies were printed. Harrison estimated that the cost to the society for the 1989 Proceedings will be \$12 and that 2900 copies will again be printed.

The Member-at-Large with responsibility for Measurements and Standards, Rodger Foltz, gave the next report. He described recent activities of the Measurements and Standards Committee, of which Foltz serves as chairman. In one area, they have worked with Phil Price to compile an updated list of definitions of terms in mass spectrometry. They have attempted to resolve conflicts of opinion in this regard and are in the process of revising their document. Work is also underway with a subcommittee directed by Jon Onstot to develop a standard computer format for transfer of mass spectral data. In addition, the committee is sponsoring a workshop, organized by Richard Martinez, concerned with CAD databases. Foltz then listed the members of the Measurements and Standards Committee: Bill Budde, Hank Fales, Ron Grigsby and Doug Cameron. Foltz explained that the terms of the latter three members are due to expire and that anyone interested in serving on this committee should contact Ron Hites.

ASMS President Ron Hites was next to speak. He began by expressing deep appreciation to Judith Watson for all of her work for the society. He said that the Board felt that she deserved added recognition and decided to change her title to be the "Executive Director of the American Society for Mass Spectrometry". Hites then asked Watson to come forward, and he presented her with a gift as a token of the Board's gratitude for her outstanding work. Hites next thanked the outgoing Board members, Gary Glish, Susan Weintraub and Willard Harrison, and presented each with a plaque from the society.

Hites next announced the winners of the 1989 ASMS Research Awards for young or beginning mass spectrometrists. Martin Janiak presented the VG Award, explaining that he was grateful to have the opportunity to provide support and say thanks to the mass spectrometry community. The recipient of the VG Award was Steven Kass of the University of Minnesota. The title of his project is "Unimolecular Rearrangements of Carbanions". Bob Finnigan then conferred the Finnigan Award to John Amster of the University of Georgia. His project is entitled "Gas Phase Reactions of Laser-Desorbed Neutral Molecules with Transition Metal Ions".

Hites then described several new activities for ASMS. First, he explained about the establishment of the ASMS Award for Distinguished Contribution to Mass Spectrometry. He said that ASMS expects to be able to present the first award at the Tucson meeting and that nominations are due by November 1, 1989. He added that the award is designed to recognize focused achievement or contribution to fundamental and applied areas of mass spectrometry. Hites said that a committee consisting of Jane Gale, Mike Grayson, Sandy Markey and Ron

Mitchum, chaired by Willard Harrison, had formulated the plans for the award. Hites also said that the ASMS President will appoint a special committee to select the recipient of the award. The composition of this committee will not be made known to the members.

Hites next presented information about a major innovation for ASMS - publication of an ASMS Journal. Hites displayed a representation of the cover of the new journal which will be called the Journal of the American Society for Mass Spectrometry and said that he expects that the first issue will be published in March of 1990. He said that the journal will be a great benefit to ASMS members and that publication of the journal will not prompt any dues increase in 1990. Hites further explained that the publisher of the journal will be Elsevier, and Hites was appreciative for the easy negotiations with that company. He added that the scope of the journal will include all areas of mass spectrometry; there will be a complete peer review process, and the editor will be Mike Gross. Four associate editors will be appointed along with a Board of Advisors. Hites then answered in advance two questions that he anticipates receiving. First, "Is another journal needed?" The answer is "yes". The ASMS Journal will be important for unifying the field by providing comprehensive coverage of a wide range of topics including applications and fundamentals. The journal will be available at a much lower cost than other mass spectrometry publications because of the large membership base (approximately 3000). In addition, the price for an institutional subscription is going to be \$230, much less than for other journals. The second question Hites expected to hear was, "Will costs go up significantly after the first year, necessitating a major dues increase?" Hites said that the answer to this is "no". He showed a graph depicting changes in ASMS dues over the past years. He explained that after correcting for inflation and indexing to 1989 dollars, there had, in fact, been little increase in the actual dues level. Hites did say that he anticipates that a \$10 increase in dues will probably be put into effect in 1991. He then said that from the results of the recent salary survey, the average member earns about \$48,000, making the cost of dues about 700 ppm!

Hites then invited questions from the audience. When asked about the number of issues, Hites responded that there will be 6 issues in 1990 and 12 in 1991 and that Mike Gross is already prepared to receive manuscripts. Hites also said that he expects it to be a great honor for an author to be included in the premier issue, and he urged the members to submit their work. Regarding the format, Hites answered that a 2-column, 8 1/2 x 11 inch format will be used with standard weight paper. Concerning the inclusion of short communications, Hites replied that he anticipates three types of presentations - brief reviews, research papers and short communications. One member wanted to know about advertising, and Hites said that a limited amount of advertising space will be available. Hites added that he has told the ASMS corporate members about the journal and advised them that they would be entitled to reduced rates for advertising in the journal. Hites continued by saying that it is important to keep the institutional costs down so that many libraries can subscribe to the journal. Since libraries are often dependent on their users for recommendations about acquisitions, Hites urged ASMS members to take the journal announcement that they will receive to their libraries and encourage institutional subscriptions. Hites said that there would not be any non-member rates since ASMS dues are so low. When asked about prices over the long term, Hites answered that costs and rate schedules have been built into the contract with Elsevier; arrangements have been made so that decisions about all major financial aspects of the journal are under control of the ASMS Board. Concerning the future of the Proceedings, Hites replied that at present, there would be no change in the way ASMS publishes the extended abstracts. Hites did say, however, that he anticipates that some changes may be instituted in five or ten years. A member wanted to know about financial exposure of the society because of the journal, and Hites answered that although there will be profit sharing, there is no risk sharing for the journal. The publisher assumes all of the risk and has the option to not renew at the end of the contract period. When asked about page charges, Hites said that there will not be any page charges and that authors will receive 50 free reprints of each paper they publish. A suggestion was then made that the Proceedings contain a regional directory of ASMS members. Hites said that such a directory could be organized by states and that this idea will be considered. In the final question from the floor, it was asked if the Spectaker would be incorporated into the journal. Hites responded that the journal will contain a society news page in addition to classified ads. The classified ads will be available at a nominal cost, by arrangements through the Elsevier redactory office. In conclusion, Hites thanked everyone for their attendance. The meeting was adjourned at 12:16 p.m.

Respectfully submitted,

Susan T. Weintraub

ASMS SURVEY OF 1989 SALARIES

At the behest of the members, the Board recently organized a salary survey of mass spectrometrists. A form was sent out with the most recent Spectaker; 757 responses were received. This is about 25% of all members. This is an excellent response and allows us to draw some valid conclusions about the compensation of mass spectrometrists. The data were entered by Judith Watson's office into a Lotus spreadsheet and analyzed by the Statistical Analysis System (SAS Institute, Cary, North Carolina) at Indiana University. Some of the categories on the original survey form were pooled with one another because of small numbers and because there were not significant differences between them.

The results are reported in the following table. Each entry is the 90th percentile (top), the median (50th percentile), and the 10th percentile. The data have been broken down by the four categories that are related to compensation: highest degree, gender, years of experience, and current employer. A blank cell in the table indicates that there were less than ten individuals in this category; for statistical validity, it seemed best not to report these data.

A couple of examples should make this table clear. The cell labeled "overall" tells us that the average member of the Society makes \$48,592; there are, however, 10% of the members who make in excess of \$75,000. The cell for university faculty with 15 to 19 years of experience tells us that these people make, on an average, \$60,000 but that there are 10% of these people who make less than \$34,000. Not surprisingly, those members with a Ph.D. make more money than members without this degree regardless of experience. Our typical male member makes \$9,000 more than our typical female member. The highest number on this table is \$170,000 for those in the 90th percentile with 15 to 19 years of industrial management experience; the lowest is \$12,761 for the 10th percentile of non-faculty, university employees. The compensation for university faculty is similar to those doing industrial research and development up until 20 years of experience, but after that university faculty are more well paid than their industrial counterparts. The lesson from these data should be clear to graduate students: Do not reject a faculty career because it is not as well paying. One merely has to be patient.

In the salary survey, two different questions were asked about salary: base salary and total compensation. With two exceptions, the total compensation was only 5 to 6% more than the base salary. The exceptions were university faculty, whose base salary was about 80% of their total compensation, and those working in the marketing and sales sector of industry, whose base salary was about 85% of their total compensation.

	Overall	Years of experience							Degree			Gender		Number (%)
		0-4	5-9	10-14	15-19	20-24	25-29	30+	Doctorate	Masters	Batchelor	Male	Female

ANALYTICAL UTILITY OF HIGH AND LOW ENERGY COLLISION REGIMES

A Workshop sponsored by the Biomedical Interest Group

Much recent work in tandem mass spectrometry has been performed in laboratories with principal interests in biomedical research. A variety of instrument types have been used, corresponding to substantially different conditions for the collisional activation (CA) of precursor ions. Accordingly, this Workshop was organized to provide a forum for discussion of the analytical implications of the distinctions between different CA regimes. The discussion was led by the following invited participants: Bob Boyd (National Research Council of Canada, Halifax), Simon Gaskell (Baylor College of Medicine, Houston), Don Hunt (University of Virginia, Charlottesville), Jim McCloskey (University of Utah, Salt Lake City) and Rick Yost (University of Florida, Gainesville). Approximately 70 people attended.

Simon Gaskell opened the proceedings with a discussion of the parameters which define CA conditions, not all of which are well understood. The collision energy (laboratory frame of reference, E_{lab}) and the masses of the precursor and target gas determine the maximum energy available (E_{center} , E_{cm}) for conversion to internal energy of the precursor ion, but other factors (such as time scale, multiplicity of collisions and efficiency of collection of scattered ions) are also important. Gaskell showed examples of analyses on a hybrid instrument where the high and low energy regimes are of complementary value. Some fragment types are observed only under high energy conditions.

Bob Boyd presented examples of peptide fragmentations (including 'charge site remote' fragmentations of amino acid side chains) which were observed under high E_{lab} (keV) conditions or (in modest yield) in a quadrupole collision cell with $E_{lab} > 200$ eV. On a reverse geometry hybrid instrument (BEQ), the products of high energy CAD (in the region between B and E) were best observed by simultaneous scanning of E and Q; a superimposed modulation of E facilitates efficient collection of all daughter ions.

Rick Yost described the comparison of daughter ion spectra from a triple quadrupole instrument using argon or nitrogen as collision gas under conditions of equal E_{cm} . The non-equivalence of the spectra reinforced the need to consider other experimental parameters. Yost suggested that the use of multiple collision conditions to increase in a stepwise fashion the internal energy of a selected precursor might be particularly effectively achieved in an ion trap MS. Drawing a contrast with common experience of CAD of positive ions, Yost reviewed data previously reported by Harrison (University of Toronto) which showed greater structural detail from low energy CA of small negative ions than was evident in the high energy CA spectra. The effect was attributed to the prevalence of electron detachment following electronic excitation under high E_{lab} conditions.

Jim McCloskey presented examples of tandem MS analyses of nucleosides at various values of E_{cm} and E_{lab} . The more energetic collisions clearly yielded increased structural information. The analytical utility of constant neutral loss scanning was particularly emphasized (executed in this case on a hybrid instrument).

Don Hunt discussed his analyses of peptides by CAD using a triple quadrupole instrument. The success achieved (albeit with very low resolution of both precursor and product ions) suggested that the limit of application was presently imposed by the mass range of the analyzer rather than by the ability to induce fragmentation. The decomposition mechanisms are certainly imperfectly understood and the apparent effectiveness of low E_{cm} CA of peptides to M_r 2000 requires further study.

In a brief contribution solicited at the time of the Workshop itself, Dick Smith (Batelle Northwest, Richland) described his recent findings on CAD of multiply charged ions (produced by electrospray) using a triple quadrupole instrument. He attributed the success of these experiments largely to the ability to generate "hot" precursor ions in the electrospray interface.

In summary, a number of issues were raised at this Workshop to emphasize the present limitations on our understanding of CA processes. Nevertheless, effective analytical applications are being made to a wide variety of biomedical research problems.

Report of the Biomedical Interest Group

This report is based on suggestions and comments made to me at the Miami Beach meeting, and, to a lesser extent, those made to me throughout the year.

Those expressing comments concerning the Miami Beach meeting were almost unanimously positive. The facilities were excellent, with sufficient space for posters to allow them to be examined at some leisure. The symposia and plenary lectures seemed to be well accepted and well attended. There were some difficulties with the slide equipment, but these were not of major consequence.

Only one clear suggestion was made for a symposium that would address the integration of mass spectrometry with other analytical techniques such as NMR, IR, etc. for deducing the structure of organic compounds of biological interest. This symposium would have a goal of elucidating the real-world approach to structural problems, for example, that a drug manufacturer might encounter in studies involving new drugs. A number of people greeted this idea for a symposium with enthusiasm.

Members are encouraged to send in additional suggestions for the 1990 meeting, particularly those involving biomedical interest, to the vice president for programs or to the biomedical interest group coordinator. Our group consists of a wide diversity of interests and applications, and our input is vital to the Board in preparing next year's meeting. If you feel there are areas not well represented and which you think are vital to the society, please write and give us your thoughts.

**A WORKSHOP
SPONSORED BY THE ACADEMIC LAB MANAGERS' INTEREST GROUP
BUDGET BLUES
OR
"WHERE DO I GET THE MONEY TO BUY A NEW MULTIPLIER?"**

Stemming from the results of our survey on the operation of mass spectrometry laboratories, and from several members' involvement in a study conducted by Robert Smith (West Virginia University) on operating cost variables for a mass spectrometry center, a workshop was held on the subject of budgets and the budgeting process. Approximately 50 people were in attendance throughout the 1.25 hour allotted time, with as high as 75 present at some time during the session. The discussion continued well beyond the designated stopping time.

To start the discussion, the question was asked: "How many have a 'formal' budgeting process?" Before any response could be measured, many members of the audience asked for clarification. In the ensuing discussion, it became clear that there were nearly as many different answers to the question of how one goes about this task as there were people in the audience. To provide some specific case studies, three individuals were introduced and asked to describe the structure of their organizations and the considerations they make in establishing a yearly operating budget.

William Howald (Dept. of Medicinal Chemistry, University of Washington) described the organization of his laboratory as a cost center. Having been established in 1979 as a research support lab for Medicinal Chemistry, they soon began providing services to other departments. Upon reaching a total of \$15,000 of extramural service work, the University required the laboratory to become a cost center. An operating budget was established whereby the real costs -- personnel salaries and fringe benefits, operating and maintenance costs, supplies, etc. -- were identified, predictions were made on the amount of work anticipated for a year, and users' fees were set in order to generate the necessary income to cover those costs (present fee \$50/hr, typical 1/2 hr for low res, 1 hr for acc mass, etc.). Further, the expectation was that the cost center account would achieve a zero balance at the end of the fiscal year, with $\pm 5\%$ tolerance. Deficits would be made up by deans and department heads involved, and profits would be given up to the general university fund, if not corrected by the end of the following fiscal year. The laboratory is forced to operate very much as a business, with all the penalties resulting from having lost money, but without the incentive of being able to retain profits to enhance the laboratory. Capital funds for new instrumentation or major upgrades must be generated from separate grants.

Robert Minard (Dept. of Chemistry, The Pennsylvania State University) contrasted his experience involving a remarkably open and organized budgeting process on his local public school board with the closed and disorganized nature of his departmental operating budget. Several years ago the old catch-as-catch-can budgeting process failed, and the Chemistry Department budget fell apart. Upon reorganizing, each of the shops and services supporting departmental activities collected information on past performances and established formal operating budgets for each facility. Since that time, Dr. Minard and others review the situation annually, and establish their best estimate of needs for the mass spectrometry laboratory, dealing mainly with operating expenses. An example, using this year's numbers, is given below. Part of the lab director's salary is covered by teaching duties. The present charge is \$16/hr actual cost to users from all departments. 40% is subsidized by the Department, making a per hour cost of *ca.* \$27/hr. The primary benefit derived by going through this formal process is that one knows ahead of time precisely what resources are available -- e.g. that there will be \$1,500 available for travel.

Dan Jones (Facility for Advanced Instrumentation (FAI), University of California - Davis) reported that the FAI includes significantly more than mass spectrometry services, and was originally started as an electron microscopy facility. It is a recharge center for campus-wide and departmental instruments. Administratively, the Center answers to a Vice Chancellor of the campus. The staff of the facility are all on "soft money" positions. The mass spectrometry staff consists of a lab director, a staff spectroscopist and a graduate student assistant. The director annually proposes a budget to the campus budget office. While the campus provides some subsidy, the facility is expected to generate the remainder of its budget through recharges paid by both on- and off-campus users (presently \$47/hr) or through extramural grants. A separate "insurance" fund provides for major instrument repair costs exceeding \$500 per event. Numbers for FY '89 are given below. The campus, with the FAI caught in the middle, is experiencing a stalemate: while the budget office endorses an increase in users' fees to decrease the deficit, the faculty are opposed to such a rate increase. While the existing facility continues to operate with a large deficit, numerous research groups are finding it easy to obtain funds to set up their own small gc-ms instruments, thus further diminishing the user base for a sophisticated central instrumentation facility. It is unclear how or when this vicious cycle can be broken.

After these presentations, the results of Robert Smith's study were summarized. The premise of Smith's study, using a Delphi analysis method, was to ask whether the structure of an operating budget proposed by Walling *et al.* in 1975 would still be valid for laboratories operating now, and whether new categories should be added. The cost variables list proposed by Walling *et al.* is given below. The values given are averages resulting from their survey

**Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL**

of operating costs for 192 laboratories in 1975, assuming one instrument per laboratory. They found an average \$402,000 start-up cost -- compared with \$392,000 reported by Florey *et al.* (1980) for their laboratory, and \$520,264 for the West Virginia University laboratory (Smith, 1987) -- and an average of \$184,300 per year in operating costs. NIH Biotechnology resources provided \$1.3 million in 1977 to establish eight mass spectrometry centers, with average funding of \$325,000 (1/2 provided by NIH, 1/2 provided by the institution) (Coulter, 1980). Smith found that the validity of most of these cost variables had not changed in the 12 years elapsing, but that several new categories and subcategories should be added to such a model budget. Smith's validated cost variables are given below. Smith quotes a number of observations from the Walling *et al.* report, which are still very appropriate for this discussion.

"Our research produced more questions than answers. There were few firm data on true costs of operating mass spectrometry centers available, and it seemed that there was reluctance on many of the centers to face up to the problem of keeping records showing the categories of such costs."

"The centers and labs investigated...substantially subsidize the cost of the instrumental analysis which they supply. We strongly recommend changes be developed in the funding patterns which will acknowledge these deficits and provide for the true costs of such services."

Interest Group Business Meeting: After the workshop, the following items were discussed. The group was polled for suggestions of Symposium and Plenary Lecture topics and speakers for submission to the ASMS board to plan for future meetings. The group was reminded that this route of communication with the ASMS board is very much alive and functioning. Group members should communicate their suggestions either through the group coordinator or directly to the ASMS board. Suggestions for future activities for this group were: (1) a salary survey of this group to compare with the ASMS general survey reported this year; (2) a discussion of the "job description" of an academic lab manager; (3) a workshop seeking to set up a dialogue with instrument companies to influence their development of new techniques and accessories; (4) a survey of capabilities of commercial analytical laboratories. Members having other ideas or strong feelings about any of these should communicate those feelings to the group coordinator.

DESORPTION PROCESSES INTEREST GROUP REPORT

Two workshops were sponsored by this Interest Group. "Ion Damage in Liquid SIMS" was moderated by Frank Field and "High Mass Ions in Quadrupole Mass Spectrometry" was moderated by Peter Todd. Prior to each workshop, questionnaires were distributed to obtain input for next years' meeting. Volunteers were solicited for the chair of the interest group for the next two years.

The workshop on "Ion Damage in Liquid SIMS" was attended by ten people. Brian Bentz initiated the discussion with slides showing various aspects of ion damage. He pointed out that from static SIMS data, the onset of damage becomes apparent in spectra at a dose of 10^{13} to 10^{14} particles per cm^2 . Such a dose corresponds to a time of about one second or less in a typical FAB or liquid SIMS experiment. Uncertainty in the onset arises from the variation with different organic materials. The domain of damage includes not only the usual assorted reactions, but includes charging and primary particle implantation.

Thomas Keough addressed the apparent radical chemistry of glycerol under bombardment from primary ions and from gamma rays. Evidence from GC/MS indicates that the radical reactions initiated in liquid SIMS involved carbon-centered radicals. This is in contrast to reactions initiated by gamma rays in that they appear to involve oxygen-centered radicals.

Ken Busch pointed out that given the complexity of the reactions involved in liquid SIMS, it is possible to find evidence to support almost any kind of reaction. Furthermore, the intensity of ions characteristic of certain kinds of damage may be time dependent. Evidence of ion damage may be suppressed for one sample depending upon additives present in the sample. A good example was hypoxanthine. Reduction is apparent in LSIMS spectra of hypoxanthine/glycerol solutions when p-toluene sulfonic acid is present, but if HCl is substituted for the p-toluene sulfonic acid, no reduction is apparent in the LSIMS spectrum.

Peter Todd addressed the difference between "reversible" and "irreversible damage". The distinction is based upon how the mass spectrum of a solution changes with time and primary ion current density. A reduced primary ion intensity will often lead to an increase in relative abundance of analyte-characteristic ions, an effect that can be reversed by increasing the primary current density. This appears to be due to a combination of surface erosion, analyte damage at the surface, and perhaps sample charging, but in general reflects the competitive effects of the various reactions involved in LSIMS. Cumulative damage is apparent in the generation of new peaks in the mass spectrum, whose intensity continuously increases with time.

The workshop, "High Mass Ions and Quadrupole Mass Spectrometry" was attended by about one hundred fifty persons. Jack Henion outlined the experimental setup for Ion Spray Mass Spectrometry, which is a form of pneumatically assisted electrospray. The technique requires liquid effluent flow through a center capillary and simultaneous "sheath gas" N_2 flow from the annular region between the center capillary and a second coaxial capillary. Flow rates of the effluent is 40 - 50 $\mu\text{L}/\text{min}$ and 250 mL/s . for the sheath gas. By this method droplets of about 5 μm . are formed. A pressure of about 1 ATM is maintained in the source into which the effluent flows. This pressure prevents discharge when the coaxial capillary system is charged to a potential of ± 3000 V. with respect to a slightly off-axis counterelectrode and subsequent skimmer. This part of the system acts as an interface to the mass spectrometer which is maintained at a pressure of 10^{-3} torr. Dry N_2 is introduced as a collision gas between the counterelectrode and the skimmer to reduce clustering. This permits higher flow rates than might otherwise be used. Consequently direct coupling between liquid chromatograph and mass spectrometer is possible using this technique. The system is apparently very easy to construct and permits generation of ions having

molecular weights in excess of 10^4 . It is particularly suitable for biomedical applications. High charge states permit transmission through the quadrupole mass spectrometer. Limitations to the technique include a limited dynamic range in concentration (10^3) and orifice clogging at high concentrations. Furthermore, Jack pointed out that the system has been developed empirically, and a thorough understanding of the effects and causes of variations in operating procedures is lacking.

In the same workshop, Julius Perel outlined his work on improving efficiency in detecting high mass ions in quadrupole mass spectrometry. The thrust of his work involved using a post-acceleration dynode between the quadrupole mass analyzer and the continuous dynode electron multiplier (CDEM). He indicated that sensitivity could be improved by up to a factor of 100 for higher mass ($m/z > 500$) ions using this approach. Further research involving lowering the work function and modifying the ion optics of the dynode - CDEM region promise further improvements.

Peter J. Todd

ENVIRONMENTAL INTEREST GROUP REPORT

Approximately 155 attendees met on Thursday, May 25, 1989 from 1:00 - 2:15 PM to participate in the annual business meeting and a workshop titled "Environmental Applications of Liquid Chromatography/Mass Spectrometry."

The business meeting consisted of a discussion of symposia topics, plenary speakers, and workshop topics for the 1990 meeting in Tucson. The consensus favored a symposium of invited and contributed papers on "Development of Liquid Chromatography (LC)/Mass Spectrometry (MS) Methods for the Determination of Non-Gas Chromatographable Compounds in Environmental Samples."

The workshop was moderated by W. L. Budde, and consisted of brief opening statements by the discussion leaders Thomas Behymer, Jack Henion, Robert Voyksner, and Larry Slivon. In keeping with the interactive and informal atmosphere of a workshop, a number of those present contributed to the lively discussion, especially Marvin Vestal who presented results from a new design particle beam interface.

Thomas Behymer (EPA, Cincinnati) led the discussion on the carrier effect of less volatile substances and coeluting compounds on more volatile compounds in particle beam interfaces. Most quantitative data available was obtained by the EPA-Cincinnati group using ammonium acetate as the carrier. Much more data is needed to fully document this effect.

Jack Henion (Cornell University) led the discussion of the ion spray/atmospheric pressure ionization mass spectra of compounds of environmental interest, especially the intractable sulfonated azo dyes.

Robert Voyksner (Research Triangle Institute) led the discussion of techniques for the optimization of signal intensity in particle beam interfaces. This discussion included comparisons of spectra obtained using electron ionization, positive and negative chemical ionization, and thermospray. As always, some ionization techniques work better with some compounds than others.

Larry Slivon (Battelle Columbus Laboratories) described a new design LC/MS interface, and showed results of measurements of caffeine by direct LC injections of 5:1 aqueous dilutions of Diet Coke, Caffeine-Free Diet Coke, Dr. Pepper, and Battelle vending machine coffee.

One conclusion of the workshop was that there is a need for far more mass spectrometric data on compounds after separation with an LC column, and more quantitative information including precision, accuracy, detection limits, calibration stability, etc.

William L. Budde

FUNDAMENTALS OF PEPTIDE SEQUENCING BY MASS SPECTROMETRY

Pharmacology Interest Group Workshop Report

This workshop considered general aspects of peptide sequencing by mass spectrometry and was aimed at those scientists not necessarily highly experienced in this rapidly evolving area. The workshop was well attended and the audience posed numerous questions to the speakers. At this meeting it was also announced that at a meeting of the interest group chairmen and the Vice President for Programs, the decision was made that since the subject matter encompassed by the Pharmacology Interest Group, formerly Quantitative Organic Analysis, directly overlaps with the subject matter of the Biomedical Interest Group, formerly Qualitative Organic Analysis, these groups will be combined in the future and will be called the Biomedical Interest Group. Suggestions for the content of next year's ASMS Conference were solicited. Speakers were Steve Martin of Genetics Institute, Donald Hunt of The University of Virginia, Terry Lee of Beckman Research Institute and Frank Crow of The Upjohn Company.

Steve Martin presented an overview of the role of MS in protein sequencing and how this technology fits into the overall scheme of elucidating protein structure and complements other more traditional techniques. The most important advantage MS offers over other techniques is the ability to detect posttranslational modifications (e.g., N-acetylation, O-sulfation, methylation, etc.). Other advantages include the ability to analyze mixtures, rapid acquisition of data, sensitivity, and lack of ambiguity in data interpretation. Dr. Martin noted that when using the four-sector tandem instrument at M.I.T., usually 1 nmole was required to obtain useful sequence information but as little as 10 pmole has been observed to be sufficient.

Don Hunt described the procedure used in his laboratory for obtaining sequence information using a triple quadrupole tandem instrument. Usually 0.5 to 2 nmole of starting material was digested and fractionated using microbore HPLC. Half of the sample was propylated or methyl esters were formed (to facilitate spectral interpretation). It was stated that mass spectral analysis was usually completed in about 3 hours. Data identifying MH^+ was obtained with between 10-50 pmole and CAD spectra were obtained on 10-200 pmole. Manual interpretation of the data required between 2 to 3 days and typically 40-70% of the amino acid sequence for a 50k dalton protein was obtained in 4-5 days. Dr. Hunt stated that, in general, handling of the sample has been observed to be more problematic than the analysis. Other specific aspects of the methodology employed at the University of Virginia included a 6 kV cesium ion gun, a small amount of thioglycerol (enough to last approximately 40 seconds) on a gold plated probe, parent ion resolution of between 3-10 daltons, 2 mtorr of argon: xenon (2:1, approximately 10 collisions), collision energies between 15 and 40 eV (higher energies at higher mass), tuning of Q3 at less than unit resolution and scanning at 300 amu/sec, and the use of a 15 kV conversion dynode.

Terry Lee described methodology for the determination of peptide sequences using a double focusing sector instrument. If sample supply is not limited then complete sequence information has been obtained using this approach. Using B/E linked scans and background subtraction of the glycerol/thioglycerol matrix spectrum, sequence information was obtained on approximately 200 pmole peptide. This approach was observed to work well without the use of CAD up to 10 amino acid residues as a result of metastable decompositions. In general this methodology has been observed to be less sensitive than when using triple quadrupole or four-sector mass spectrometers.

**Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL**

Frank Crow presented an overview of investigations of the utility of TSP-MS and TSP-MS-MS in peptide sequence determination that he and Russel Robins have carried out over the past few years. Problems that were encountered initially included poor sensitivity, greatly attenuated response at high masses, and unstable source conditions. Several modifications to the standard manufactures TSP ion source aimed at increasing high mass response were made. These included using a needle repeller positioned approximately one mm directly behind the sampling cone, tightening of the source which allowed for higher flow rates, decreasing the size of the jet orifice, and use of a postcolumn cross gradient to stabilize ion source conditions. It was stated that this cross gradient (usually 75% aqueous, total flow of 3 ml/min) has been observed to be important for the successful analysis of peptide mixtures by TSP-MS. The mass spectrum obtained following TSP-MS-MS analysis of a doubly charged peptide ($MH_2^{++} = 1042$) was discussed and it was stated that this approach could allow for the MS-MS analysis of higher molecular weight peptides.

The Upjohn Company

HISTORICAL INTEREST GROUP REPORT — June 1989

The Historical Interest Group organized the *Symposium on the Historical Development of Instrumentation in Mass Spectrometry* for the 1989 Meeting in Miami Beach. A morning session covered four broad areas of development: 1) Combined Inlet Systems for Mass Spectrometry, 2) Alternative Ionization Techniques, 3) The Quadrupole Mass Filter, and 4) Computers in Mass Spectrometry with one oral presentation on each topic. The afternoon featured a poster session of nine authors, highlighting selected portions of the general topics outlined above. The poster "*Mass Spectrometers in Space, Rockets to Satellites to Mars: 1960-1976*" was presented, even though it had been inadvertently omitted from the final program. Poster authors were present with their work throughout Tuesday afternoon, but the posters remained in place through Thursday afternoon to provide interested parties an adequate opportunity to view them. Poster authors were asked to contribute their posters to the Historical Interest group for archival storage and use at a later date.

A meeting of the Interest Group was held Tuesday evening and ideas for the 1990 program were formulated. Suggestions for plenary speakers and workshop topics have been forwarded to the Vice-President for Programs. It was decided not to organize a symposium for the coming year.

A number of activities occurred during the year:

Center for the History of Chemistry :

ASMS is in the process of formally affiliating with the Beckman Center for the History of Chemistry in Philadelphia. Approval of affiliation was granted at the ASMS Board meeting in Miami Beach prior to the conference. The Historical Interest Group Chairman will be the focal point for interaction between the Society and the Center; and Member-at-Large, Mike Story, has been appointed liaison with the ASMS Board for the coming year.

Affiliation with the Center provides three resources to ASMS:

- A proper, permanent archival facility for papers and small physical items.
- A professional resource to consult with Interest Group members on the details of collecting papers and objects of historical value.
- Ready access to the Center's growing collection of materials for our members.

To all of our members who have papers, photos, manuals, data, literature or other items of historical value which they are considering donating to the Society, I encourage you contact me and do so now. You can dismiss any uncertainty which you may have had about the ultimate fate of such donations. If you are in the Philadelphia area, I encourage you to stop and visit the Center. It should be remembered that the Center represents a facility primarily for the collection of PAPERS and not EQUIPMENT.

Other ongoing projects during the past year are :

- Continuation of the 'Roots' survey of members.
- The collection of oral histories from:
 - John Beynon
 - O. P. Tanner
 - Al Nier
 - Bill Sherman
- The collection of photos of historical value.
- Consultation with the Smithsonian on the acquisition of a mass spectrometer for their collection.

A nucleus of interested individuals is at the heart of the Historical Interest Group. The activities enumerated above should continue throughout the coming year. Particularly, the collection of materials suitable for archival placement with the Center for the History of Chemistry should have a high priority among Interest Group members.

Respectfully submitted,

Michael A. Grayson
Chairman, Historical Interest Group
McDonnell Douglas Research Laboratories (314) 233-2541

WORKSHOP: "INSTRUMENT-INDEPENDENT CAD DATABASE"

(Attendance: ca. 80)

ORGANIZER: Richard I. Martinez, National Institute of Standards and Technology
(NIST; formerly National Bureau of Standards)

SPONSOR: Measurements and Standards Committee of ASMS.

SUMMARY:

The purpose of this Workshop was to assess whether or not the MS/MS community wants (and/or needs) a standardized, instrument-independent CAD database, and, if so, to discuss what standardized operating conditions and database format(s) one should use. The consensus of the participants who submitted written comments for this report can be summarized as follows: (a) it is important to generate instrument-independent spectra; (b) it is desirable to have a database of standard CAD spectra; and (c) the participants would contribute standard CAD spectra for inclusion in a NIST database.

Standardized, instrument-independent CAD spectra can be generated on XQQ (QQQ, BEQQ, etc.) tandem mass spectrometers by using the kinetics-based measurement protocol developed at NIST (1).¹ This protocol requires that measurements be made under single-collision conditions. Some workshop participants indicated they would be willing to use the single-collision conditions specified in the NIST protocol to generate standard spectra. However, most participants would prefer to explore the development of a protocol for generating standard CAD spectra under multiple-collision conditions. This latter approach would necessitate the participation of the MS/MS community in an additional round robin to explore the feasibility (or lack thereof) of measuring standardized, instrument-independent CAD spectra under multiple-collision conditions. The workshop participants indicated they were willing to participate in such a NIST-coordinated round robin.

PROCEEDINGS:

To provide a focus for the Workshop discussion, R.I. Martinez (NIST) gave an introductory presentation in which he:

- (a) reviewed the dynamical prerequisites (2) which must be observed to develop an undistorted, dynamically-correct (i.e., instrument-independent) MS/MS database (library) for XQQ instruments;²
- (b) reviewed the technical basis of the NIST kinetics-based measurement protocol (1) that has been proposed for the development of a standardized CAD database comprised of Characteristic Branching Ratios of Ionic Substructures (CBRIS Database Format (1));³
- (c) reported the results of the NIST-EPA International Round Robin for XQQ tandem mass spectrometers (>50% of QQQ instruments currently in the field can provide instrument-independent response (3), so a standardized CAD database is feasible);
- (d) presented data for the CAD of the acetone cation (m/z 58) under single-collision and multiple-collision conditions which indicated that single-collision conditions provide a unique MS/MS fingerprint characteristic of acetone, while multiple-collision conditions distort the structural information that is specific to a particular ion; and
- (e) proposed that the protocol for the second NIST round robin should consist of measuring four sets of branching ratios for the CAD of the acetone cation (m/z 58): viz., two fixed target thicknesses (corresponding to both single-collision and multiple-collision conditions) at two LAB energies (10 and 80 eV).

The participants then expressed their views (see SUMMARY). There was some confusion about the concept of a database of substructures (e.g., the CBRIS database) vs. a library of CAD spectra for source compounds (see Note 3(b)). One participant pointed out the imbalance between instrument time and analyst time when one is characterizing unknowns⁴ (viz., significantly less than 50% of instrument time is used for acquisition of the CAD spectra of unknowns, while significantly more than 50% of the analyst's time is devoted to interpretation of the CAD spectra of unknowns), and suggested that a CAD database may help to improve the correlation of analyst time to instrument time.

NOTES:

- ¹ The precepts of the NIST protocol (1) are also applicable to other types of tandem mass spectrometers which have strong focusing properties (e.g., quadrupole-hexapole-quadrupole MS/MS), so long as the energy range used for the pertinent ion chemistry is the same as for XQQ instruments.
- ² Unless the reaction dynamics of the CAD process are taken into account, results in XQQ instruments will be highly instrument dependent, even though reproducible conditions can be established for analytical purposes (with few exceptions, measurements for any given ion within any one XQQ instrument exhibit long-term reproducibility (precision) to within $\pm 10\%$; one laboratory reported this precision for 3 different XQQ instruments (QQQ, BEQQ, EBQQ)).
- ³ The main advantages of the CBRIS database format are:
 - (a) The proposed use of CBRIS in MS/MS is analogous to the use of group frequencies in infrared spectroscopy. That is, the partial cross sections for production of progeny fragment ions can characterize both known and unknown species (so long as the unknown species contain ionic substructures for which the CAD cross sections and product identities are known). Therefore, it may be possible to assign the structure of an unknown species on the basis of the absolute cross sections for the CAD of known ionic substructures.
 - (b) Characterization of an unknown compound by using CBRIS does not require that the compound be in the CBRIS database. By contrast, to characterize an unknown by spectral matching within a "library", the compound must usually be in the "library". In this regard, development of a database of CBRIS for all substructures (or a subset thereof) would be very much more tractable than the development of a library of CAD spectra for all the source compounds that contain all the substructures (or a subset thereof). For example, consider the simplistic analogy where compounds correspond to words, and substructures correspond to letters: more than 500,000 words can be composed with only 26 letters of the alphabet.
- ⁴ Major classes of MS/MS experiments include: (i) Mixture Analysis (quantitation with or without prior separation) and (ii) Structure Elucidation ("isolated" neat compound (prior separation)). For (i), precision within any one XQQ instrument is critical, and the goal is to maximize sensitivity for characteristic daughter ions; "standardized" conditions may be useful, but not necessary (different "standardized" conditions are needed for different substructure classes to compensate for differences in CAD dynamics). For (ii), the goal is to maximize structurally-significant information.

**INSTRUMENTATION AND ION PHYSICS INTEREST GROUP
MEETING AND WORKSHOP REPORT**

The Instrumentation and Ion Physics Interest Group held a meeting and a workshop on Monday, May 22 from 1:00-2:15 P.M. Roughly one hundred people attended. The meeting portion of the program was used to solicit ideas for symposia, workshops, etc. for next year's program. Few suggestions were made during the meeting since it was held very early in this year's conference. A number of suggestions were submitted, however, as the week wore on. Some of the topics, which may be appropriate for a review lecture, symposium, or workshop included:

- Mobile mass spectrometers
- Ion sources for quantitative mass spectrometry
- High performance detectors
- State-of-the-art in sector technology
- Pressure measurement

Other suggestions were made which were more appropriately classified with other interest groups. All of the suggestions have been forwarded to the Board for consideration.

The workshop portion of the program was entitled "Detectors for Mass Spectrometry". The interest in the topic was reflected in the attendance. Four speakers were asked to participate by giving a brief description of the newest developments in detectors. Ken Schmidt of K+M Electronics described ceramic multipliers that can withstand high temperatures (several hundred °C) and discussed ways to evaluate detector performance. Julius Perel of Phrasor Scientific discussed their work with improving detection efficiency for high mass ions by use of low work function dynode materials and high voltages. Peter Graves of Detector Technology discussed several approaches to improving the lifetime of multipliers including segmented multipliers and multipliers with large area at the output end. He also described an approach to evaluating multiplier performance. John Hooper of Galileo Electro-Optics reviewed the detector requirements for a variety of mass spectrometry applications and described their efforts to produce detectors to meet each set of needs. The presentations were highly informative and generated more discussion than could be accommodated within the allotted time for the meeting. It was evident from some of the feedback from this workshop that many of our members (myself included) understand other aspects of mass spectrometry better than we understand multipliers. For this reason, a session on detectors may be warranted in the near future.

LASER DESORPTION OF BIOMOLECULES. HOW DOES IT WORK?

A Workshop Sponsored by the Physical Organic Interest Group.

This workshop was organized to consider the mechanisms involved in the laser desorption and ionization of biomolecules. Approximately 100 people attended the workshop which was held Tuesday evening, May 23, 1989.

Prior to the workshop a short business meeting was held of the Physical Organic Interest group. Suggestions for the 1990 meeting for symposia, included laser desorption, ionization, and photodissociation of biomolecules. The attendees were also polled regarding their feelings on the balance of oral versus poster presentations and on the program in general. The level of satisfaction was high on all counts.

Six panelists gave short presentations of various aspects of the laser desorption mass spectrometry of biomolecules.

Franz Hillenkamp considered possible mechanisms which could explain why his technique of matrix (nicotinic acid) assisted UV ($\lambda=266$ nm) laser desorption allows for the desorption and ionization of proteins with molecular weights in excess of 100,000u.

Ronald Beavis also discussed experiments on matrix assisted UV laser desorption and ionization wherein investigations were made of the types of matrices which yield intense spectra and of the sources of spectral peak broadening.

John Amster described experiments performed in a Fourier transform mass spectrometer in which organic molecules were desorbed by UV laser irradiation and were subsequently ionized by either EI or CI.

Kenneth Standing discussed results obtained in a time-of-flight analyzer using low irradiance UV laser pulses to produce ions from peptides in a regime where the ion yield exhibited a slow dependence on the irradiance.

Robert Cotter described results obtained on oligosaccharides and glycoconjugates using infrared laser desorption and ionization wherein the time evolution of the generated ions was investigated.

Peter Williams described experiments in which DNA fragments with molecular weights up to 1,000,000u were laser desorbed from a frozen water matrix and transferred to a catcher foil.

YOUNG MASS SPECTROMETRISTS INTEREST GROUP REPORT

This year's topic of discussion at the YMS Interest Group Meeting was on Careers in Mass Spectrometry. Michael Gross, Gary Glish, Barbara Larsen, and Julie Leary each gave a brief presentation and made suggestions to the audience on criteria which should be examined when making career choices. Through audience and speaker participation, several important observations were made: 1) If one really enjoys the job and is motivated, he or she will work the number of hours required to bring satisfactory results i.e.; those in industry have a tendency to work as hard and long as those in academia. 2) In most instances financial rewards were not as important as the type of work and benefits offered. 3) A Post-doctoral position was encouraged if time and finances were not pressing burdens. 4) Of those attending (approximately 200), more than 75% were graduate students and post-doctoral associates.

Suggestions for next year's meeting included how to write specifications for a mass spectrometer, a combined historical group and YMS group meeting, and a tutorial on how to obtain research funding.
