THE 37th ASMS CONFERENCE ON MASS SPECTROMETRY AND ALLIED TOPICS
May 21 - 26, 1989

TABLE OF CONTENTS

INTRODUCTION	iv
ASMS BOARD OF DIRECTORS	v
ASMS COMMITTEES	v
CORPORATE MEMBERS	vi
ASMS INTEREST GROUPS	viii
LISTING OF EXTENDED ABSTRACTS	ix
Plenary Lectures	1
Monday Morning	
Symposium: Advances in Instrumentation	22
Symposium: Introduction to Alternative Ionization Techniques	36
Symposium: Elemental Analysis	46
Monday Afternoon	
Symposium: Advances in Instrumentation	60
Symposium: Air Monitoring by Mass Spectrometry	72
Biochemistry I	82
Monday Posters	
LC/MS I	106
Clusters, Inorganic, Surface Analysis	155
Ion-Activation-Dissociation	214
Polymers	258
Fuels in Geosciences	294
Ion-Molecule Reactions	313
Computational	344
Tuesday Morning	
LC/MS	365
Ionization/Activation	387
Symposium: Isotope Measurements	411
Tuesday Afternoon	
Symposium: Formation & Analysis of Multicharged Ions	425
Symposium: MS/MS in Environmental Applications	436
FT/MS and Ion Traps	449
Symposium: Historical Developments in Instrumentation & Techniques	470
Tuesday Posters	
Ionization Methods	527
Isotope Ratios	588
Reaction Mechanisms	600
Pharmacology/Drugs	676
Oligosaccharides/Lipids	720

Wednesday Afternoon	
Symposium: Next Generation of Environmental Contaminants	798
Symposium: Lasers in Mass Spectrometry	812
Ion Molecule Reactions	824
Wednesday Posters	
Peptides and Proteins	844
LC/MS II	927
Instrumentation	1017
Thursday Morning	
Symposium: Tandem MS in the Solution of Peptide & Protein Structural Problems	1122
Inorganic Elemental Analysis and Instrumentation	1133
Symposium: Comparison of Ionic Reactions in Gas Phase & in Solution	1157
Thursday Afternoon	
Symposium: State of the Art Research in Mass Spectrometry	1165
Biochemistry II	1175
Symposium: Organometallic Mass Spectrometry	1198
Thursday Posters	
FT/MS and Ion Traps	1210
Metabolism and Toxicology	1280
Ion Molecule Reactions	1363
Environmental	1402
Friday Morning	
Symposium: Separations and Peptides	1472
Environmental Applications	1478
Fundamental Ion Chemistry Clusters and Surfaces	1498
INDEX OF AUTHORS	1517
INDEX OF SUBJECTS	1536
MINUTES OF THE ASMS BUSINESS MEETING	1545
SALARY SURVEY	1548
COMMITTEE, INTEREST GROUP AND WORKSHOP REPORTS	
Analytical Utility of High and Low Energy Collision Regimes	1550
Biomedical Interest Group	1551
Budget Blues or Where Do I Get Money to Buy a New Multiplier	1552
Desorption Processes Interest Group	1554
Environmental Interest Group	1556
Fundamentals of Peptide Sequencing	1557
History of Mass Spectrometry Interest Group	1559
Instrument-Dependent CAD Databases	1560
Instrumentation and Ion Physics Interest Group	1562
Laser Desorption of Biomolecules. How Does It Work?	1563
Young Mass Spectrometrists Interest Group	1564
1989 ASMS MEMBERS AND CONFERENCE ATTENDEES	1565

INTRODUCTION

By action of the ASMS Board of Directors, this official record of the annual meeting will henceforth be known as the Proceedings instead of the more informal term "bound volume". Thus, the 1989 designation is Proceedings of the 37th ASMS Conference on Mass Spectrometry and Allied Topics.

The extended abstracts that comprise the bulk of the Proceedings provide a valuable and timely view of the most current research in this very dynamic field. A large number (more than 90 %) of those presenting papers and posters at the conference contribute extended abstracts to the Proceedings. Extra space has been allotted to Plenary lecturers and symposia speakers to provide more details of their presentations. New this year is an index of subjects. Also included in the Proceedings are workshop and interest group reports and a directory of names, addresses, and telephone numbers of 1989 members and conference attendees.

The efforts of Judith A. Watson and her staff of Professional Association Management, Inc. in compiling the Proceedings and arranging for timely printing and distribution in a cost effective manner are gratefully acknowledged. The work presented here also reflects the hard work and creativity of the Vice-President for Programs, Robert C. Murphy, in arranging the technical program.

The Proceedings find a greater audience each year and form a valuable asset to the members of the Society. No doubt there are ways it could be improved, and suggestions or comments directed toward making this a more useful resource are invited.

Willard W. Harrison
Editor and Member-at-Large
ASMS Board of Directors

CITATION NOTICE

This volume contains the extended abstracts of papers presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics. The material is not copyrighted and appearance of material in this volume does not jeopardize the author's right to publish the information in scientific journals.

Reference to individual abstracts contained in this volume should be cited as follows:

Author(s); title; Proceedings of the 37th ASMS Conference on Mass Spectrometry and Allied Topics, Miami Beach, Florida, May 21-26, 1989.

ASMS INTEREST GROUPS

The following is a brief description of the role of each interest group as provided by their coordinators.

Academic Laboratory Managers, *Thomas R. Sharp*

The problems and solutions encountered by those responsible for academic service mass spectrometry facilities.

Biomedical Applications, *Richard M. Caprioli*

Mass spectrometric relevance to biological and medical systems, including areas such as enzymology, macromolecular sequencing, metabolic screening, natural products, etc.

Computer Applications, *Jon D. Onstot*

Enhancement of the science of mass spectrometry by exploitation of computer technology either through electronic data acquisition, data processing, artificial intelligence or other technologies.

Desorption Ionization, *Peter J. Todd*

Investigation of, and applications for, processes by which gas phase ions are generated from condensed phases.

Elemental Analysis, *Gary M. Hieftje*

The application of mass spectrometry to elemental analysis, including applications to organic and inorganic samples, the use and development of isotope ratio technology and the development of instrumentation and methodology for elemental mass spectrometry.

Environmental Applications, *William L. Budde*

The development and application of mass spectrometry and related techniques to the qualitative and quantitative analysis of environmental systems.

Fundamentals, *Douglas P. Ridge*

The chemistry of gas phase ions including structural, spectroscopic, thermodynamic and kinetic properties and their influence on other areas of mass spectrometry.

History of Mass Spectrometry, *Michael A. Grayson*

The collection and archiving of information about the development of mass spectrometry, its practitioners, and its instrumentation.

Instrumentation and Ion Physics, *Scott A. McLuckey*

Techniques for forming, transporting, analyzing, and detecting charged particles with the goal of improving mass spectrometry as a research tool.

Isotopic Applications, *Lawrence W. Green*

The application and development of isotope ratio mass spectrometry in all areas of science, including (but not limited to) archeology, atmospheric science, geology, medicinal chemistry, and nuclear science.

Pharmacology, *James Vrbanc*

The structural and quantitative analysis of drugs and their metabolites, and of endogenous bioactive compounds and their metabolites.

Physical Organic, *Brian Chait*

The physical and chemical processes involved in the production of neutral and ionized organic molecules, their subsequent interaction with neutral and charged entities, and their fragmentation.

Surface Science, *Robert W. Odom*

The application of mass spectrometry to the study of the elemental and chemical composition and structure of solid surfaces and the characterization of atomic and molecular adsorbates.

Young Mass Spectrometrists, *Julie A. Leary*

The support and advancement of mass spectrometrists in the early stages of their careers.

PROCEEDINGS OF THE 37TH ASMS CONFERENCE TECHNICAL SESSIONS

PLENARY LECTURES

FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY: PRECEPTS AND PROSPECTS *MARSHALL, A.G.	1
MOLECULAR ION SPECTROSCOPY: THE THIRD GENERATION *SAYKALLY, R.J.	6
MASS SPECTROMETRY: HOW DID WE GET HERE AND WHERE ARE WE GOING? *MCLAFFERTY, F.W.	8
ONE MAN'S JOURNEY IN MASS SPECTROMETRY *BEYNON, J.H.	16

MONDAY ORAL SESSIONS

Symposium: Advances in Instrumentation

IONIZATION BY POSITRONS: WHAT'S THE MATTER WITH ANTIMATTER? *MCLUCKEY, S.A., GLISH, G.L., DONOHUE, D.L., HULETT, L.D. AND MCKOWN, H.S.	22
ION/SURFACE COLLISIONS: INSTRUMENTATION AND APPLICATIONS *COOKS, R.G., HABIBI-GOUDARZI, S., MORAND, K.L., SCHEY, K.L. AND SCHWARTZ, J.C.	25
ARRAY DETECTORS FOR MAGNETIC MASS SPECTROMETERS *BIEMANN, K.	27
CAPILLARY ELECTROPHORESIS/FLOW FAB/MS *MINARD, R.D., CURRY, P. AND EWING, A.G.	30
ANALYSIS OF DATA RATE REQUIREMENTS FOR HIGH PERFORMANCE GC/MS: THE CASE FOR TOFMS WITH TIME-ARRAY DETECTION *ENKE, C.G., WATSON, J.T., ALLISON, J. AND HOLLAND, J.F.	32
ISOTOPE-RATIO-MONITORING GAS CHROMATOGRAPHY MASS SPECTROMETRY *HAYES, J.M., FREEMAN, K.H., RICCI, M.P., STUDLEY, S.A., MERRITT, D.A., BRAND, W.A. AND HABFAST, K.	33
COUPLING PLANAR CHROMATOGRAPHIES WITH MASS SPECTROMETRY, AND MASS SPECTROMETRY WITH OPTICAL SPECTROSCOPIC IMAGING *BUSCH, K.L.	35
MASS RANGE EXTENSION IN QUADRUPOLE ION TRAPS KAISER, R.E., COOKS, R.G. AND *HEMBERGER, P.H.	60
ION INJECTION INTO ION TRAPS *YOST, R.A. AND PEDDER, R.E.	62
TWO-DIMENSIONAL FT/MS *GAUMANN, T.	65
NEW METHODS OF ION ISOLATION AND EXCITATION IN FT/MS *CODY, R.B.	68

A TRIPLE STAGE QUADRUPOLE GLOW DISCHARGE MASS SPECTROMETER: THE DISSOCIATIVE REMOVAL OF POLYATOMIC INTERFERENCES *HARRISON, W.W. AND KING, F.L.	70
--	----

Symposium: Introduction to Alternative Ionization Techniques

A PRIMER ON ELEMENTAL MASS SPECTROMETRY: ICPMS(SOLUTIONS) VS GDMS(SOLIDS) *HARRISON, W.W.	36
RIMS AND TIMS AND APPLES AND ORANGES - A COMPARATIVE SUMMARY *MOORE, L.J.	38
PRODUCTION OF IONS FROM CHARGED LIQUID DROPLETS IN ELECTROSPRAY, THERMOSPRAY, AND RELATED TECHNIQUES *VESTAL, M.L.	41
DESORPTION TECHNIQUES: HOW THEY ARE DIFFERENT *COTTER, R.J.	43

Symposium: Elemental Analysis

INTERACTIONS OF SOLIDS, LIQUIDS, AND VAPORS IN ICP-MS: POTENTIAL FOR ADVANCES ZHU, G., PAN, C. AND *BROWNER, R.F.	46
PLASMA MASS SPECTROMETRY FOR CHROMATOGRAPHIC DETECTION *CARUSO, J.A., SHEPPARD, B., CREED, J., SUYANI, H. AND DAVIDSON, T.	48
STRUGGLING TO REDUCE MOLECULAR ION INTERFERENCES IN INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY (ICP-MS) *DOUGLAS, D.J.	50
TIME RESOLVED STUDIES IN GLOW DISCHARGE MASS SPECTROMETRY *HARRISON, W.W. AND KLINGLER, J.A.	52
NEW DEVELOPMENTS IN SOURCES FOR PLASMA-SOURCE MASS SPECTROMETRY *HIEFTJE, G.M., CHAMBERS, D., JIN, Q. AND ROSS, B.	54
ION KINETIC ENERGIES IN THE LOW-PRESSURE ZONES OF AN INDUCTIVELY COUPLED PLASMA MASS SPECTROMETER *CHAMBERS, D.M. AND HIEFTJE, G.M.	56
SAMPLE AEROSOL, PLASMA GAS COMPOSITION AND SAMPLER-SKIMMER GEOMETRY EFFECTS IN INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY (ICP-MS) *HORLICK, G.	58

Symposium: Air Monitoring by Mass Spectrometry - Present & Future

EXPECTED REGULATORY AND GUIDANCE REQUIREMENTS FOR CONTROL OF AIR TOXICS *WOOD, G.	72
ROLE OF MASS SPECTROMETRY IN EXPOSURE ASSESSMENT PROGRAMS *PELLIZZARI, E.D.	74
DIRECT AIR MONITORING USING AN ION TRAP MASS SPECTROMETER *GLISH, G.L. AND MCLUCKEY, S.A.	77
ATMOSPHERE ANALYSIS ON BOARD SUBMARINES *WYATT, J.R. AND KOSLIN, M.E.	80

Biochemistry I

A RAPID IMMUNOAFFINITY CLEANUP/GC-MS METHOD FOR DETERMINATION OF 3-METHYLADENINE IN URINE *FRIESEN, M., SHUKER, D.E.G., GARREN, L. AND PREVOST, V.	82
ISOLATION AND CHARACTERIZATION OF AN UNUSUAL NUCLEOSIDE FROM HUMAN URINE *CHHEDA, G.B., DUTTA, S.P., TWOREK, H.A., BHARGAVA, A.K., TAKITA, H., ANTKOWIAK, J.G. AND PATRZYC, H.B.	84
LASER IONIZATION FOURIER TRANSFORM MASS SPECTROMETRY FOR THE ISOMERIC DIFFERENTIATION OF ALKYLATED NUCLEOSIDES *HETTICH, R.L. AND BUCHANAN, M.V.	86
FAB/MIKES ANALYSIS OF CYCLIC NUCLEOTIDES AND RELATED COMPOUNDS NEWTON, R.P., WALTON, T.J., *BRENTON, A.G., HARRIS, F.M., GHOSH, D., KINGSTON, E.E., BEYNON, J.H., JENKINS, A. AND SALVAGE, B.J.	88
AN INVESTIGATION OF IONIZATION MECHANISMS DURING LIQUID SECONDARY ION MASS SPECTROMETRY (LSIMS): EVIDENCE FOR ONE-ELECTRON REDUCTION *LARAMEE, J.A., ARBOGAST, B. AND DEINZER, M.L.	90
QUANTIFICATION OF EPOXYEICOSATRIENOIC ACID BY CAPILLARY COLUMN CHROMATOGRAPHY/NEGATIVE ION CHEMICAL IONIZATION MASS SPECTROMETRY *BLAIR, I.A., CAPDEVILA, J. AND YAMASHITA, K.	92
IDENTIFICATION OF CARROT PHOSPHOINOSITOLS BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY *VAN BREEMEN, R.B., WHEELER, J.J. AND BOSS, W.F.	94
ENHANCED DETECTION OF DIAGNOSTIC ACYLCARNITINES IN PLASMA AND TISSUE UTILIZING FAB COUPLED WITH TANDEM MASS SPECTROMETRY *MILLINGTON, D.S., NORWOOD, D.L. AND KODO, N.	96
SEQUENCE SPECIFIC PEPTIDE FRAGMENTATION OBSERVED USING MS/MS/MS SCAN MODES *SCHEY, K.L., SCHWARTZ, J.C. AND COOKS, R.G.	98
TANDEM MASS SPECTROMETRY OF MULTIPLY CHARGED PEPTIDES AND PROTEINS *BARINAGA, C.J., UDSETH, H.R. AND SMITH, R.D.	100
STRUCTURE DETERMINATION OF NOVEL CYCLIC PEPTIDES BY USING TANDEM MASS SPECTROMETRY *CERNY, R.L., GROSS, M.L., PETTIT, G.R., KAMONO, Y. AND HERALD, C.H.	102
HIGH VS LOW ENERGY CID OF PEPTIDE IONS ALEXANDER, A.J., THIBAUT, P., *BOYD, R.K., CURTIS, J.M. AND RINEHART, K.L.	104

MONDAY POSTER SESSIONS

LC/MS I

ANALYSIS OF SYNTHETIC PEPTIDE MIXTURES AND PROTEIN DIGESTS BY CZE/CF-FAB/MS *MOORE, W.T., MARTIN, M., DAGUE, B., CAPRIOLI, R.M., WILSON, K.J. AND MORING, S.E.	106
SENSITIVITY ENHANCEMENT OF PARTICLE BEAM LC/MS *WILLOUGHBY, R.C., BUCHNER, J.D. AND SHEEHAN, E.W.	108

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

PARTICLE BEAM LC/MS BY FAB *SANDERS, P.R.,WILLOUGHBY, R. AND MITROVICH, S.	110
DETERMINATION OF ALKYL BENZENESULFONATES BY CAPILLARY ZONE ELECTROPHORESIS - MASS SPECTROMETRY *VASSILIADOU, M.,MILLS, T.M. AND MISSLER, S.R.	112
CAPILLARY ZONE ELECTROPHORESIS AND CAPILLARY LIQUID CHROMATOGRAPHY COUPLED WITH SECTOR MASS SPECTROMETRY USING COAXIAL CONTINUOUS FLOW FAB INTERFACES *MOSELEY, M.A.,DETERDING, L.J.,TOMER, K.B.,BRAGG, N. AND JORGENSEN, J.W.	114
CAPILLARY ZONE ELECTROPHORESIS-MASS SPECTROMETRY OF PEPTIDES AND PROTEINS *LOO, J.A.,UDSETH, H.R. AND SMITH, R.D.	116
ANALYSIS OF TRYPTIC DIGESTS BY ON-LINE ZONE ELECTROPHORESIS TANDEM MASS SPECTROMETRY *HUANG, E.,COVEY, T. AND HENION, J.	118
THE ON-LINE COMBINATION OF CAPILLARY ISOTACHOPHORESIS WITH MASS SPECTROMETRY *UDSETH, H.R.,LOO, J.A. AND SMITH, R.D.	120
CHROMATOGRAPHY AND MASS SPECTROMETRY OF DOMOIC ACID, A MARINE NEUROTOXIN *PLEASANCE, S.,QUILLIAM, M.A.,LEBLANC, Y.,SIM, P.G.,THIBAUT, P. AND MEI, X.	122
QUALITATIVE AND QUANTITATIVE DATA OBTAINED FROM PACKED COLUMN SUPERCRITICAL FLUID CHROMATOGRAPHY/MASS SPECTROMETRY USING THERMOSPRAY JOSEPH, R.S.I.,*LANT, M.S. AND WOOLGAR, P.	124
HIGH TEMPERATURE VAPORIZATION EFFECTS IN PARTICLE-BEAM MASS SPECTROMETRY *HARRIS, W.E. AND BROWNER, R.F.	126
IN VITRO ANALYSIS OF ANTIMETABOLITES IN BLOOD PLASMA BY MAGIC LC/MS *HARRIS, W.E. AND BROWNER, R.F.	128
AEROSOL TRANSPORT STUDIES IN PARTICLE-BEAM MASS SPECTROMETRY *EDMAN, K.R.,KIRK, J.D. AND BROWNER, R.F.	130
FAST ATOM BOMBARDMENT: BROADENING THE CAPABILITIES OF PARTICLE-BEAM LC/MS *KIRK, J.D. AND BROWNER, R.F.	131
LC/API/MS BY PARTICLE BEAM LIQUID CHROMATOGRAPHY *SHEEHAN, E.W.,LO, H.H. AND WILLOUGHBY, R.C.	133
OPTIMIZATION AND EVALUATION OF PARTICLE BEAM HPLC/MS PERFORMANCE FOR THE ANALYSIS OF PESTICIDE COMPOUNDS AND METABOLITES *SMITH, C.S.,KNOX, P.C. AND VOYKSNER, R.D.	135
THE APPLICATION OF PARTICLE BEAM HPLC/MS TO THE ANALYSIS OF DERIVATIZED AND UNDERIVATIZED PROSTAGLANDINS *SCHILLING, A.B.	137
CHARACTERIZATION OF FLAVORS AND AROMAS BY GC/MS AND PARTICLE BEAM LC/MS *MARECIC, T.,SHEEHAN, E.W. AND DILTS, M.J.	139
DEVELOPMENT OF AN INTERNAL STANDARD AND A PERFORMANCE TEST MIXTURE FOR PARTICLE BEAM LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY SYSTEMS *BEHYMER, T.D.,BELLAR, T.A. AND BUDDE, W.L.	141
VARIOUS ASPECTS OF IONSpray MASS SPECTROMETRY/MASS SPECTROMETRY *SIU, K.W.M.,GARDNER, G.J. AND BERMAN, S.S.	143

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

IONSpray MASS SPECTROMETRY FOR THE ANALYSIS OF MARINE TOXINS *QUILLIAM, M.A. AND THOMSON, B.	145
A NON-AEROSOL VAPORIZATION INTERFACE FOR LC/MS AND LC/MS/MS *SLIVON, L.E., KENNY, D.V. AND SEVERANCE, R.A.	147
ATMOSPHERIC PRESSURE SPRAY IONIZATION FOR LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY (LC/MS) *SAKAIRI, M. AND KAMBARA, H.	149
SHEET DIRECT INSERTION MEMBRANE PROBE FOR SELECTIVE INTRODUCTION OF ORGANIC COMPOUNDS INTO A MASS SPECTROMETER BIER, M.E., *KOTIAHO, T. AND COOKS, R.G.	151
MATRIX-FREE FAB ANALYSIS UTILIZING THE MOVING BELT LC/MS INTERFACE *BAKER, T.R., KYRANOS, J.N. AND VOURES, P.	153

Clusters, Inorganic, Surface Analysis

COLLISION INDUCED DISSOCIATION STUDIES OF TRANSITION METAL OXIDE CLUSTERS *MALEKNIA, S.D. AND LAUDE, D.A.	155
CLUSTER ION FORMATION BY DIRECT LASER VAPORIZATION AND PARTICLE BOMBARDMENT *CALLAHAN, J.H., ROSS, M.M. AND BARONAVSKI, A.P.	157
FTMS STUDIES OF CARBON CLUSTER ANIONS MCELVANY, S.W.	159
DISSOCIATION AND REACTIVITY OF COBALT AND MOLYBDENUM OXIDE CLUSTER IONS *CASSADY, C.J. AND MCELVANY, S.W.	161
REACTIVITY OF BISMUTH CLUSTER IONS *ROSS, M.M., WYSOCKI, V.H. AND MCELVANY, S.W.	163
CLUSTER FORMATION IN THE FAST ATOM BOMBARDMENT (FAB) MASS SPECTRA OF DIOXOURANIUM (VI) DINITRATE AND DIACETATE *JENNINGS, K.R., KEMP, T.J. AND READ, P.A.	165
FORMATION OF CARBON CLUSTERS FROM LASER ABLATION OF POLYMERS *CREASY, W.R. AND BRENNAN, J.T.	167
TANTALUM CARBIDE CLUSTER IONS: PRODUCTION, DISSOCIATION, AND REACTIVITY *CASSADY, C.J. AND MCELVANY, S.W.	169
SAMPLE INTRODUCTION CHARACTERISTICS OF FLOW INJECTION WITH ICP-MS *ZHU, G., PAN, C. AND BROWNER, R.F.	171
COLLISION-INDUCED DISSOCIATION OF SOME RUTHENIUM COMPLEXES *LIANG, X. AND FREAS, R.B.	173
PURITY OF 1% SILANE AND 1% DICHLOROSILANE IN HYDROGEN *REENTS, W.D., GREEN, M.L. AND BRASEN, D.	175
APPLYING THE CONCERTED ISOTOPE PATTERN-EXACT MASS METHOD OF ESTABLISHING ELEMENTAL COMPOSITION *BLOM, K. AND CUMMISKEY, J.	176
INORGANIC FINGERPRINT OF RAT TISSUES *GELINAS, Y., FERRARIS, J. AND SCHMIT, J-P.	178
ELEMENTAL COMPOSITION OF MILK: FROM THE COW TO THE CONSUMER *MARTINEZ, C., AMER, M.A., GOSWAMI, T. AND SCHMIT, J-P.	180

THE DETERMINATION OF LOW-ABUNDANCE OXYGEN IN FLUORINE GAS MIXTURES *CISPER, M.E. AND HEMBERGER, P.H.	182
MATRIX EFFECTS ON THE FAST ATOM BOMBARDMENT MASS SPECTRA OF PALLADIUM COMPLEXES *MALLIS, L.M. AND SCOTT, W.J.	184
FAST ATOM BOMBARDMENT ANALYSIS OF SPECIES FORMED BY THE INSERTION OF CARBON DISULFIDE INTO Mn-H BONDS SCHAUER, S.J., EYMAN, D.P. AND *MALLIS, L.M.	186
EVALUATION OF A DOUBLE-QUADRUPOLE SPECTROMETER SYSTEM FOR GLOW DISCHARGE MASS SPECTROMETRY DUCKWORTH, D.C. AND *MARCUS, R.K.	188
THE RELATIVE ROLE OF PENNING IONIZATION IN GLOW DISCHARGE DEVICES SERXNER, D., SMITH, R.L. AND *HESS, K.R.	190
SEPARATION OF ATOMIZATION AND IONIZATION PROCESSES IN GDMS *BARSHICK, C.M. AND HARRISON, W.W.	192
STUDIES OF THIN FILMS IN GLOW DISCHARGE MASS SPECTROMETRY *RATLIFF, P.H. AND HARRISON, W.W.	194
ANALYSIS OF POWDERED METAL OXIDES USING RADIO FREQUENCY GLOW DISCHARGE MASS SPECTROMETRY *KLINGLER, J.A. AND HARRISON, W.W.	196
GETTERS AS PLASMA REAGENTS IN GLOW DISCHARGE MASS SPECTROMETRY *MEI, Y. AND HARRISON, W.W.	198
KINETICS OF ETHYLLIDYNE FORMATION USING LITD/FTMS *PETTIETTE-HALL, C.L., LAND, D.P., MCIVER, R.T. AND HEMMINGER, J.C.	200
CALCULATIONS OF THE TEMPERATURE JUMP AND DESORPTION PROBABILITY IN LASER-INDUCED THERMAL DESORPTION *WANG, D.T-S., HEMMINGER, J.C. AND MCIVER, R.T.	202
TIME-OF-FLIGHT SECONDARY ION MASS SPECTROMETRY (TOF-SIMS) OF POLYMER MATERIALS *VANLEYEN, D., NIEHUIS, E., HAGENHOFF, B. AND BENNINGHOVEN, A.	204
THE EFFECTS OF POLYATOMIC PRIMARY IONS ON THE YIELD AND EXTENT OF FRAGMENTATION OF SECONDARY IONS IN MOLECULAR SECONDARY ION MASS SPECTROMETRY *HAND, O.W., MAJUMDAR, T.K. AND COOKS, R.G.	206
ORGANIC SURFACE ANALYSIS WITH A TIME-OF-FLIGHT SECONDARY ION MICROSCOPE *SCHUELER, B., SANDER, P. AND ODOM, R.W.	208
EVIDENCE FOR ION NEUTRALIZATION BY ELECTRON TUNNELING IN THE DESORPTION OF SPECIES FROM POLYMER SURFACES *NORD, R.F. AND MACFARLANE, R.D.	210
ENHANCEMENT OF STATIC FAB SPECTRAL DATA OF AZO SULFONATED DYES NG, K., *SHIMANSKAS, C., KARLINER, J. AND JHO, C.	212

Ion Activation-Dissociation

ON THE DYNAMICS OF LOW AND MEDIUM ENERGY COLLISION INDUCED DISSOCIATION OF IONS *SHUKLA, A.K., QIAN, K., HOWARD, S.L., ANDERSON, S.G. AND FUTRELL, J.H.	214
--	-----

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

DETECTION OF LONG-LIVED EXCITED STATES OF POLYATOMIC IONS IN MOLECULAR BEAM STUDIES OF COLLISION-INDUCED DISSOCIATION PROCESSES *QIAN, K., BIGGERSTAFF, J., ANDERSON, S., HOWARD, S., SHUKLA, A. AND FUTRELL, J.	216
ANGLE AND ENERGY RESOLVED COLLISION-INDUCED DISSOCIATION STUDIES OF THE PROPANE MOLECULAR ION *ANDERSON, S.G., SHUKLA, A.K., LEHMAN, T.H. AND FUTRELL, J.H.	218
ACCELERATION REGION PROCESSES MARCH, R.E. AND *HUGHES, R.J.	220
A COMPARISON OF INTERNAL ENERGIES OF IONS FORMED BY CHARGE INVERSION COLLISIONAL ACTIVATION AND DIRECT EXCITATION BY COLLISIONAL ACTIVATION *STROBEL, F., BRICKER, D.L. AND RUSSELL, D.H.	222
REINVESTIGATION OF KINETIC ENERGY LOSS ACCOMPANYING COLLISION ACTIVATION OF CHLOROPHYLL A USING A FLOATED CELL ALEXANDER, A.J., BOYD, R.K. AND *THIBAUT, P.	224
INTERNAL ENERGY UPTAKE OF SURVIVAL IONS IN KILOVOLT COLLISIONS ALEXANDER, A.J., BOYD, R.K., *THIBAUT, P. AND TOMER, K.B.	226
REFLECTION OF POLYATOMIC IONS UPON COLLISIONS WITH SURFACE *HABIBI-GOUDARZI, S. AND COOKS, R.G.	228
EVALUATION OF PHOTON INDUCED DISSOCIATION IN A FOUR-SECTOR MASS SPECTROMETER *MARTIN, S.A., HILL, J.A., KITTRELL, C. AND BIEMANN, K.	230
MEASUREMENTS OF DAUGHTER ION MASS SPECTRA IN A REFLECTING TIME-OF-FLIGHT MASS SPECTROMETER *TANG, X., ENS, W., MAYER, F., MAO, Y., POPPE, N. AND STANDING, K.G.	232
CHARGE SEPARATION AND ELECTRON CAPTURE INDUCED DISSOCIATION OF DOUBLY CHARGED PORPHYRIN IONS *VAN BERKEL, G.J., GLISH, G.L. AND MCLUCKEY, S.A.	234
DISSOCIATION OF LARGE IONS IN FTMS *WANG, B.H., WILLIAMS, E.R., HENRY, K.D. AND MCLAFFERTY, F.W.	236
ENERGETICS OF CHARGE-REMOTE FRAGMENTATION: A FURTHER INVESTIGATION *GIBLIN, D. AND GROSS, M.L.	238
CHARGE-REMOTE FRAGMENTATIONS OF A SERIES OF HOMOCONJUGATED OCTADECADIENOIC ACIDS: A CA MS/MS STUDY *CROCKETT, J.S. AND GROSS, M.L.	240
STRUCTURAL INFORMATION DERIVED FROM KINETICS OF DISSOCIATION REACTIONS *RUSSELL, D.H. AND SELLERS-HANN, L.	242
INFLUENCE OF CATIONIZING METAL IONS UPON FRAGMENTATION IN FOLIC ACID DERIVATIVES *JONES, A.D., CLIFFORD, A.J. AND BILLS, N.D.	244
CONTROLLED ENHANCEMENT OF STEROCHEMICAL EFFECTS BY MS/MS/MS: ACCESS TO ENDOTHERMICALLY FORMED DAUGHTER IONS *COLE, R.B., PREVOST, C. AND TABET, J.C.	246
COLLISIONALLY ACTIVATED DISSOCIATION OF LASER-DESORBED N-ALKYLPYRIDINIUM CATIONS *WATSON, C.H., KATRITZKY, A.R., DEGA-SZAFRAN, Z. AND EYLER, J.R.	248
TWO-LASER INFRARED MULTIPHOTON DISSOCIATION OF GASEOUS IONS STUDIED BY FTICR *WATSON, C.H. AND EYLER, J.R.	250

DETERMINATION OF INTERNAL-ENERGY AND ENERGY DISSIPATION RATES IN N-BUTYLBENZENE IONS BY COMPETITIVE PHOTODISSOCIATION *UECHI, G.T. AND DUNBAR, R.C.	252
TIME RESOLVED PHOTOFAGMENTATION OF THIOPHENOL IONS IN AN ICR MASS SPECTROMETER *FAULK, J.D. AND DUNBAR, R.C.	254
FRAGMENTATION MECHANISMS FOR HIGHLY FUNCTIONALIZED IONS: THE FAB MASS SPECTRA OF SOME CARDIAC GLYCOSIDES REVISITED SCHULTZ, G.,LIGHT, K. AND *ALLISON, J.	256

Polymers

LASER ABLATION MASS SPECTRA OF HIGH MOLECULAR WEIGHT POLYMERS DETERMINED BY FOURIER TRANSFORM MASS SPECTROMETRY *BRENNAN, J.T. AND CREASY, W.R.	258
FOURIER TRANSFORM SPECTRA OF POLYBUTADIENES AND POLYISOPRENES *CHOWDHURY, A.K. AND WILKINS, C.L.	260
LASER DESORPTION FT/ICR MASS SPECTRA OF POLYAMIC ACIDS *WEBER, W.D.	262
IDENTIFICATION OF POLYIMIDES BY MASS SPECTROMETRY *CHACE, M. AND PLAT, M.	264
EI AND CI SFC/MS OF ISOCYANATE PREPOLYMERS *CARY, A.S.	266
PHOTO- AND THERMAL DEGRADATION OF IODONIUM SALTS: COMPLICATIONS WITHIN SECONDARY ION MASS SPECTROMETRY AND FAST ATOM BOMBARDMENT MASS SPECTRA *SCHURZ, H.H. AND BUSCH, K.L.	268
IDENTIFICATION OF POLYMER INTERMEDIATES BY LINKED SCAN FAST ATOM BOMBARDMENT MASS SPECTROMETRY *KYRANOS, J.N.,VOUROS, P. AND HAGNAUER, G.L.	270
THE CHARACTERIZATION OF AROMATIC POLYMERS BY FIELD DESORPTION MASS SPECTROMETRY ROLLINS, K.,*SCRIVENS, J.H.,TAYLOR, M.,MAJOR, H.J. AND BATEMAN, R.H.	272
THE CHARACTERIZATION OF SYNTHETIC LUBRICANT FORMULATIONS BY FIELD DESORPTION MASS SPECTROMETRY ROLLINS, K.,TAYLOR, M.,*SCRIVENS, J.H. AND ROBERTSON, A.	274
MASS SPECTRAL CHARACTERIZATION OF COMPOUNDS FORMED DURING HIGH TEMPERATURE OXIDATION OF STYRENE BASED POLYMERS USING THERMAL CHROMATOGRAPHY *SUTTON, C. AND ZUMBERGE, J.E.	276
MASS SPECTRAL STUDY OF THE THERMAL BEHAVIOR OF POLYMERS OF OXALIC ACID WEININGER, S. AND *YEOMANS, W.	278
THERMAL DEGRADATION OF POLY[bis(PHENOXY)-PHOSPHAZINE] POLYMERS MAYNARD, S.J.,*SHARP, T.R. AND HAW, J.F.	280
THERMAL STABILITY OF ETFE COPOLYMER SYSTEMS *MORELLI, J.J.,FRY, C.,WOLF, C.J.,GRAYSON, M.A. AND LIND, A.C.	282
LIQUID CARBON DIOXIDE VS SOLVENT EXTRACTION OF ORGANIC POLYMER ADDITIVES FOR MASS SPECTRAL ANALYSIS *MILLER, M.L.	284

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

STEPWISE PYROLYSIS OF POLYMERIC MATERIAL BY ON-LINE PYROLYSIS/GC/MS CHUNG, H.L.,*MOORE D.S. AND ALDRIDGE, J.C.	286
BULK POLYMER ANALYSIS USING LASER IONIZATION MASS SPECTROMETRY (LIMS) AND PATTERN RECOGNITION TECHNIQUES *ODOM, R.W. AND DI BROZOLO, F.R.	287
STUDY OF REDOX PROPERTIES OF POLY-3-METHYLTHIOPHENE FILMS BY Cf-252 PLASMA DESORPTION MASS SPECTROMETRY *AI, J. AND MACFARLANE, R.D.	289
WATCHING REACTIONS WITH K+IDS *SIMONSICK, W.J. AND FULGINITI, M.	291
PYROLYSIS GAS CHROMATOGRAPHY MASS SPECTROMETRY OF POLYARYLACETYLENE RESINS *EASTON, M.P. AND GILMARTIN, D.	293

Fuels in Geosciences

PHOTOIONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY OF ORGANIC COMPOUNDS FROM MANTLE MINERALS AND METEORITES *BECKER, C.H. AND TINGLE, T.N.	294
HYDROCARBON-TYPE ANALYSIS BY FIELD IONIZATION MASS SPECTROMETRY *GALLEGOS, E.J.	296
THE ON-LINE DETERMINATION OF WATER BY MASS SPECTROMETRY *CRAWFORD, R.W., COBURN, T.T. AND ALCARAZ, A.	298
NAPHTHENIC ACIDS IN PETROLEUM BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY *FAN, T.P.	300
DEVELOPMENT OF ITD BASED GC/MS TECHNIQUES FOR RAPID PROFILING OF MICROBIAL CELL WALL LIPIDS *TAGHIZADEH, K., MEUZELAAR, H.L.C. AND HATCHER, H.H.	302
LASER PYROLYSIS MASS SPECTROMETRY OF SINGLE LEVITATED COAL PARTICLES MASWADEH, W., ROBERTS, K.A., MCCLENNEN, W.H., MEUZELAAR, H.L.C. AND *ARNOLD, N.S.	304
THE USE OF A HYBRID MASS SPECTROMETER IN DETERMINING BIOMARKER COMPOUNDS IN CRUDE OIL EXTRACTS WEIR, O. AND *WOOD, D.	306
THERMAL SLICING AS A TOOL TO STUDY THE THERMAL DECOMPOSITION OF COALS & KEROGEN *ZUMBERGE, J.E. AND SUTTON, C.	308
MASS-SPECTROMETRIC ANALYSIS OF HIGH-BOILING WAXES SEPARATED FROM SLUDGE FORMED DURING STORAGE OF CRUDE OIL IN UNDERGROUND RESERVOIRS *GRIGSBY, R.D., THOMSON, J.S., VOGH, J.W., WOODWARD, P.W. AND GILES, H.N.	310
FREE-RADICAL CHEMISTRY IN SUPERCRITICAL FLUIDS *OLESIK, S.V. AND PEKAY, L.	312

Ion Molecule Reactions

ADDUCTS OF d5 AND d10 TRANSITION METAL CATIONS WITH ALKANES: AB INITIO AND EXPERIMENTAL STUDIES *BEAUGRAND, C., BERTHIER, G., SUARD, M., MESTDAGH, H. AND ROLANDO, C.	313
GAS-PHASE ION-MOLECULE REACTIONS OF Cu+ AND C7H8 ISOMERS: A CA MS/MS STUDY *MACMILLAN, D.K., HAYES, R.N. AND GROSS, M.L.	315
LIGAND FLUXIONALITY AND CLUSTERING REACTIONS OF TRANSITION METAL CARBONYLS: Fe(13CO)+ CLUSTERING WITH Fe(CO)5 *KERELY, E.L. AND RUSSELL, D.H.	317
LIGAND EXCHANGE REACTIONS OF IONIC TRANSITION METAL CARBONYL CLUSTERS: REACTIONS FOR Cr2(CO)y+ AND Fe2(CO)y+ *SELLERS-HANN, L. AND RUSSELL, D.H.	319
DYNAMICS AND THERMODYNAMICS OF LASER ABLATED METAL IONS BY HIGH PRESSURE MASS SPECTROMETRY *BOUCHARD, F., MCMAHON, T.B. AND HEPBURN, J.W.	321
ION-MOLECULE CHEMISTRY OF METHYL, CYCLOPENTADIENYL CHROMIUM DINITROSYL *COMISAROW, M.B. AND CHEN, S-P.	323
THE PROPER CONSTRUCTION OF EQUILIBRIUM "LADDER" SCALES *SORENSEN, D.M. AND BARTMESS, J.E.	325
THE STRUCTURE OF THE (M-H) ANIONS OF NITROMETHANE AND METHYLNITRITE *THOMAS, D. AND BARTMESS, J.E.	326
THERMOCHEMISTRY FOR REACTIVE NEUTRAL SPECIES FROM APPEARANCE ENERGY MEASUREMENTS IN A FLOWING AFTERGLOW-TRIPLE QUADRUPOLE INSTRUMENT *PAULINO, J.A. AND SQUIRES, R.R.	327
DETERMINATION OF STABILITY AND STRUCTURE OF CLUSTER IONS C1-(RH) (C1- ATTACHED WITH ALKANES) *LI, C. AND MCMAHON, T.B.	329
FOURIER TRANSFORM ION CYCLOTRON RESONANCE INVESTIGATION OF HYDROGEN BONDING IN ALCOHOL-FLUORIDE ADDUCT IONS *WILKINSON, F.E. AND MCMAHON, T.B.	331
A HIGH PRESSURE MASS SPECTROMETRIC DETERMINATION OF EQUILIBRIUM ISOTOPE EFFECTS OF ASSOCIATION AND EXCHANGE REACTIONS OF F- AND RO- WITH SIMPLE OH/OD LABELLED ALCOHOLS *SZULEJKO, J.E., WILKINSON, F.E. AND MCMAHON, T.B.	333
STRUCTURES AND ENERGETICS OF NO3- FORMED IN A GLOW DISCHARGE IONIZATION SOURCE *FLURER, R.A., MCLUCKEY, S.A. AND GLISH, G.L.	335
RATE ENHANCEMENT OF -ELIMINATION REACTIONS BY DIPOLE-ANION INTERACTIONS *SUMPTER, T. AND BARTMESS, J.E.	337
AN FTMS STUDY OF ALKANE ELIMINATIONS FROM GAS PHASE IONS *AHMED, M.S., GIAM, C.S. AND MCADOO, D.J.	338
ASSIGNMENT OF HYDROXYHYDANTOIN ISOMERS BY LINKED SCAN, TANDEM, AND HIGH RESOLUTION MS	340

*ONISKO, B. AND LEWIS, S.

THE TRIMETHYLSILYLUM (Me₃Si⁺) AFFINITY OF ALKYLAMINES 342
STONE, J.A. AND *LI, X.

Computational

NON-FT/ICR/MS: AUTOREGRESSION AND BAYESIAN SPECTRAL ANALYSIS FOR ICR MASS 344
SPECTROMETRY
MEIER, J.E. AND *MARSHALL, A.G.

MSCOINT: A COMPUTER PROGRAM DEVELOPED FOR THE INTERPRETATION OF 346
COLLISIONALLY ACTIVATED MASS SPECTRA
*ZIDAROV, D. AND BERTRAND, M.J.

AN AUTOMATED CHEMICAL STRUCTURE ELUCIDATION SYSTEM (ACES) FOR MS/MS 348
SPECTRA
*HART, K.J. AND ENKE, C.G.

MASSPEC- A GRAPHICS BASED DATA SYSTEM FOR CORRELATING A MASS SPECTRUM 350
WITH A PROPOSED STRUCTURE
*SIEGEL, M.M. AND GILL, G.

MACPROMASS-A COMPUTER AID FOR THE ANALYSIS OF MASS SPECTRAL DATA OF 352
PEPTIDES AND PROTEINS
*LEE, T.D. AND VEMURI, S.

IMPROVED RETRIEVAL OF HIGH RESOLUTION UNKNOWN MASS SPECTRA WITH EXACT 354
MASS-PROBABILITY BASED MATCHING
*LOH, S. AND MCLAFFERTY, F.W.

QUALITATIVE EFFECTS OF ION ABUNDANCE TUNING ON MASS SPECTRAL MATCHING 356

TUESDAY ORAL SESSIONS

LC/MS

REAL-TIME REACTION MONITORING BY CONTINUOUS INTRODUCTION ION SPRAY TANDEM 365
MASS SPECTROMETRY
*LEE, E.D., MUCK, W. AND HENION, J.D.

DETERMINATION OF CHARGE STATE OF IONS IN THERMOSPRAY MASS SPECTROMETRY 367
*CHAN, K., WINTERGRASS, D., HO, T. AND STRAUB, K.

THERMOSPRAY LC/MS USING A QUADRUPOLE ION TRAP 369
KAISER, R.E., LAMMERT, S.A., WILLIAMS, J., COOKS, R.G. AND *ZAKETT, D.

MASS SPECTROMETRIC INSIGHTS INTO BIOLOGICAL REDOX REACTIONS *VOLK, K.J., BRAJTER-TOTH, A. AND YOST, R.A.	371
MASS-FLOW ENHANCEMENT APPROACHES IN LC/MS *VAN DER GREEF, J., NIESSEN, W.M.A. AND TJADEN, U.R.	373
MASS SPECTROMETRIC DETECTION FOR HIGH PERFORMANCE ANION EXCHANGE LIQUID CHROMATOGRAPHY *SIMPSON, R.C., FENSELAU, C.C., LEE, Y.C., TOWNSEND, R.R. AND COTTER, R.J.	375
DEVELOPMENTS IN SUPERCRITICAL FLUID CHROMATOGRAPHY MASS SPECTROMETRY *NIESSEN, W.M.A., VERHEIJ, E.R., VAN DER HOEVEN, R.A.M., TJADEN, U.R. AND VAN DER GREEF, J.	377
OPTIMIZATION AND APPLICATIONS OF PARTICLE BEAM HPLC/MS FOR COMPOUNDS OF PHARMACEUTICAL INTEREST *VOYKSNER, R.D., KNOX, P.C. AND SMITH, C.S.	379
INTERMEDIATE TERM STABILITY OF ION INTENSITIES AND ELECTRON IMPACT MASS SPECTRA WITH PARTICLE BEAM LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY SYSTEMS BELLAR, T.A., BEHYMER, T.D. AND *BUDDE, W.L.	381
INCORPORATION OF MS/MS DETECTION FOR THE CHARACTERIZATION OF TRYPTIC DIGESTS BY CONTINUOUS FLOW FAB LC-MS *ACKERMANN, B.L., CHEN, T-M. AND COUTANT, J.E.	383
TANDEM MASS SPECTROMETRY FOR THE ANALYSIS OF BIOMOLECULES VIA COAXIAL CONTINUOUS FLOW-FAST ATOM BOMBARDMENT AND CAPILLARY ZONE ELECTROPHORESIS *DETERDING, L.J., MOSELEY, M.A., TOMER, K.B. AND JORGENSEN, J.W.	385

Ionization/Activation

SURFACE-CATALYZED REACTIONS OF AROMATIC AMINES WITH OXYGEN AND NITROGEN IN NCI MASS SPECTROMETRY *STEMMLER, E.A. AND BUCHANAN, M.V.	387
IONIZATION EFFICIENCIES IN AN ELECTROSPRAY SOURCE WONG, S.F., MANN, M., MENG, C.K. AND *FENN, J.B.	389
SPECULATION ON THE MECHANISM(S) OF ELECTROSPRAY IONIZATION *SMITH, R.D., UDSETH, H.R., LOO, J.A., EDMONDS, C.G. AND BARINAGA, C.J.	391
VISCOSITY EFFECTS IN FAST ATOM BOMBARDMENT SPECTRA SHIEA, J-T. AND *SUNNER, J.	393
ON THE DISSOCIATION AND FORMATION DYNAMICS OF CLUSTER IONS IN FAST ATOM BOMBARDMENT MASS SPECTROMETRY *BERTRAND, M.J., PERREAULT, H. AND ZHA, Q.	395
SOLUTE INTRODUCTION AND LIQUID SECONDARY ION EMISSION *TODD, P.J.	397
NEGATIVE MOLECULAR IONS FROM SAMPLES ADSORBED ON NITROCELLULOSE FOR keV AND MeV PARTICLE BOMBARDMENT *ENS, W., STANDING, K.G., SUNDQVIST, B.U.R. AND HAKANSSON, P.	399
ELUCIDATION OF ELECTRONIC AND VIBRATIONAL ENERGY LEVELS OF MOLECULAR IONS BY HIGH RESOLUTION TRANSLATIONAL ENERGY SPECTROSCOPY HAMDAN, M. AND *BRENTON, A.G.	401

FRAGMENTATION OF DISTONIC RADICAL IONS BY LOW-ENERGY COLLISION-INDUCED DISSOCIATION *WYSOCKI, V.H. AND KENTTAMAA, H.I.	403
TANDEM MASS SPECTROMETRY OF LARGE BIOMOLECULES: WHAT IMPEDES ITS USE FOR STRUCTURAL CHARACTERIZATION? *RUSSELL, D.H.	405
ANALYSIS OF THE FRAGMENTATION INDUCED BY FAB VS PHOTODISSOCIATION IN A Q-FTMS AND LONG-LIVED METASTABLES FORMED VIA FAB *LEBRILLA, C.B., WANG, D.T-S. AND MCIVER, R.T.	407
EXCITED STATE PROTON TRANSFER IN LASER MASS SPECTROMETRY *CHIARELLI, M.P., SHARKEY, A.G. AND HERCULES, D.M.	409

Symposium: Isotope Measurements

FAB MASS SPECTROMETRIC TECHNIQUES INCREASE PRACTICALITY OF AND ACCESS TO TRACE METAL ANALYSIS IN MAN *FENNESSEY, P.V. AND MILLER, L.V.	411
NEW DEVELOPMENTS IN NEGATIVE THERMAL IONIZATION MASS SPECTROMETRY AND ITS APPLICATIONS *HEUMANN, K.G., KOPPE, M. AND WACHSMANN, M.	414
HIGH SENSITIVITY ISOTOPE DILUTION (IDMS) USING THERMAL IONIZATION, RESONANCE IONIZATION, AND SECONDARY IONIZATION MASS SPECTROMETRIES--TIMS, RIMS AND SIMS *FASSETT, J.D., MAYO, S., SIMONS, D.S., WALKER, R.J. AND KELLY, W.R.	417
RIMS APPLIED TO ENVIRONMENTAL AND NUCLEAR RESEARCH *SCHWEIKHARD, L.	419
SYNTHETIC SILICON ISOTOPE MIXTURES FOR ABSOLUTE ISOTOPE ABUNDANCE RATIO MEASUREMENTS *LENAERS, G., MURPHY, T.J., VALKIEERS, S. AND DE BIEVRE, P.	422

Symposium: Formation and Analysis of Multicharged Ions

FACILITATING DESORPTION OF MULTIPLY CHARGED IONS *COOK, K.D. AND REYNOLDS, J.D.	425
SOME MASS SPECTROMETRIC IMPLICATIONS OF MULTIPLY CHARGED IONS *FENN, J.B., MANN, M., MENG, C.K., WONG, S.F. AND WEBER, R.S.	428
ELECTROSPRAY PRODUCTION AND COLLISION INDUCED DISSOCIATION OF LARGE MULTIPLY CHARGED IONS *SMITH, R.D., UDSETH, H.R., BARINAGA, C.J. AND EDMONDS, C.G.	430
ROLE OF ELECTRON TUNNELING IN THE FORMATION OF MULTIPLY-CHARGED IONS AT SURFACES *MACFARLANE, R.D., NORD, R. AND BUNK, D.	432
MULTIPLY CHARGED NEGATIVE IONS: A CRITICAL REVIEW *COMPTON, R.N.	434

Symposium: MS/MS in Environmental Applications

LC/MS/MS AND CZE/MS/MS DETERMINATION OF ENVIRONMENTALLY IMPORTANT COMPOUNDS *HENION, J. AND CONBOY, J.	436
APPLICATIONS OF TRIPLE QUADRUPOLE GC/MS/MS TO THE DETERMINATION OF DIOXINS IN COMPLEX ENVIRONMENTAL SAMPLES *REINER, E.J., SCHELLENBERG, D.H., TAGUCHI, V.Y., MCCURVIN, D.M. AND CLEMENT, R.E.	438
CHOOSING BETWEEN HRMS AND MS/MS: ENVIRONMENTAL APPLICATIONS *TONDEUR, Y. AND CHARLES, M.J.	441
DEVELOPMENT OF A MOBILE ION TRAP MASS SPECTROMETER SYSTEM FOR ENVIRONMENTAL MONITORING *MEUZELAAR, H.L.C., MCCLENNEN, W.H., ARNOLD, N.S. AND MASWADEH, W.	444
ANALYSIS OF XENOBIOTIC CONJUGATES BY MS/MS *TOMER, K.B.	446

FT/MS and Ion Traps

HIGH MASS REMEASUREMENT ENHANCEMENT OF FOURIER TRANSFORM MASS SPECTRA *WILLIAMS, E.R., HENRY, K.D., WANG, B.H. AND MCLAFFERTY, F.W.	449
TWO DIMENSIONAL FT-ICR AND ITS REALIZATION ON A PC BASED INSTRUMENT *GUAN, S. AND JONES, P.R.	451
MINIMIZATION OF SPACE CHARGE EFFECTS IN AN FTICR TRAPPED ION CELL *LAUDE, D.A., MALEKNIA, S. AND HOGAN, J.D.	453
EXACT AND NEARLY EXACT INTERPOLATION OF APODIZED FT-ICR SPECTRA *COMISAROW, M.B. AND KEEFE, C.D.	455
AN EXTERNAL ION SOURCE PROVIDING ION ACCUMULATION AND TRAPPING OF IONS WITH BROAD ENERGY RANGE FOR ION CYCLOTRON RESONANCE SPECTROMETRY BAMBERG, M. AND *WANCZEK, K.P.	456
THE EFFECTS OF PRESSURE ON ION EXCITATION IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE (FT-ICR) SPECTROMETRY *RUSSELL, D.H., KERLEY, E.L., HANSON, C.D. AND CASTRO, M.E.	458
SIMULATED RESONANCE EXCITATION OF TRAPPED IONS *MARCH, R.E., MCMAHON, A.W., LONDY, F.A., ALFRED, R.L., VEDEL, F. AND TODD, J.F.J.	460
NEGATIVE ION CHEMICAL IONIZATION IN AN ION TRAP MASS SPECTROMETER USING REAGENT ANIONS INJECTED FROM AN EXTERNAL ION SOURCE *ECKENRODE, B.A., GLISH, G.L. AND MCLUCKEY, S.A.	462
DAUGHTER ION FORMULA DETERMINATION BY MS _n EXPERIMENTS ON NATURALLY OCCURRING ISOTOPES GLISH, G.L., *ASANO, K.G. AND MCLUCKEY, S.A.	464
HOW TO USE A STANDARD QUADRUPOLE FILTER AS A TWO DIMENSIONAL ION-TRAP BEAUGRAND, C., *DEVANT, G., ELABBASSI, B., JAOUEN, D., MESTDAGH, H. AND ROLANDO, C.	466

INJECTION OF IONS INTO A QUADRUPOLE ION TRAP FROM A CHEMICAL IONIZATION SOURCE USING A DC QUADRUPOLE	468
*PEDDER, R.E., YOST, R.A. AND WEBER-GRABAU, M.	

Symposium: Historical Developments of Instrumentation and Techniques

A HISTORICAL REVIEW OF THE ON-LINE COMBINATION OF CHROMATOGRAPHY WITH MASS SPECTROMETRY	470
*MCFADDEN, W.H.	
THE DEVELOPMENT OF SELECTIVE METHODS OF IONIZATION	474
*MUNSON, B.	
THE HISTORY OF QUADRUPOLE MASS SPECTROMETRY DEVELOPMENT	479
*DAWSON, P.H.	
A HISTORY OF GC/MS INTERFACES	485
*GRAYSON, M.A.	
THE DEVELOPMENT OF METHANE CHEMICAL IONIZATION MASS SPECTROMETRY	491
*MUNSON, B.	
CHEMICAL IONIZATION WITH TETRAMETHYLSILANE, PAST AND PRESENT	493

A RESOURCE FOR BIOMEDICAL MASS SPECTROMETRY	517
*SHERMAN, W.R. AND BIER, D.M.	
MASS SPECTROMETERS IN SPACE. ROCKETS TO SATELLITES TO MARS 1960-1976	523
BIEMANN, K., *FENNESSEY, P.V., FLORY, D.A., NIER, A.D.C. AND RUSHNECK, D.A.	

TUESDAY POSTER SESSIONS

Ionization Methods

POTASSIUM ION IONIZATION OF DESORBED SPECIES (K+IDS) BY FAB: A USEFUL METHOD FOR PROBING THE SELVEDGE REGION, AND FOR OBTAINING MOLECULAR WEIGHT INFORMATION	527
*SCHULTZ, G. AND ALLISON, J.	
THE CHARGE STRIPPING OF ALKALINE EARTH SPECIES GENERATED BY SOLID FAB	529
*CALDWELL, K.A. AND GROSS, M.L.	
ON PERFORMED IONS AND ION-MOLECULE REACTIONS IN FAB	531
SHIEA, J., NESTOR, J. AND *SUNNER, J.	

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

MITIGATION OF BEAM-INDUCED REDUCTION IN DESORPTION IONIZATION MASS SPECTROMETRY *REYNOLDS, J.D. AND COOK, K.D.	533
EFFECT OF SORBITOL CRITICAL BEHAVIOR ON FAB TOTAL ION CURRENT *BENNETT, B.D. AND DAY, R.	535
EFFECTS OF SAMPLE PROBE SURFACE TEMPERATURE ON THE DETECTION OF PEPTIDES BY FAB/MS *PAPAYANNOPOULOS, I.A. AND BIEMANN, K.	537
NON-IONIC SURFACTANTS USED AS INTERNAL STANDARDS FOR EXACT MASS MEASUREMENTS IN FAB MASS SPECTROMETRY *SIEGEL, M.M., TSAO, R., OPPENHEIMER, S., CHANG, T.T. AND DEVASTRO, J.	539
LIQUID CHROMATOGRAPHY/HIGH PRESSURE FAST-ATOM BOMBARDMENT MASS SPECTROMETRY *THOMPSON, T., FINK, S.W. AND FREAS, R.B.	541
PEPTIDE DIMERIZATION REACTIONS IN THERMOSPRAY AND FAST-ATOM BOMBARDMENT IONIZATION *FINK, S.W., DYCKES, D.F. AND FREAS, R.B.	543
EFFECT OF PEPTIDE HYDROPHOBICITY ON MOLECULAR ION YIELDS IN NITROCELLULOSE ADSORPTION, PLASMA DESORPTION MASS SPECTROMETRY *WANG, R., CHEN, L. AND COTTER, R.J.	545
ION VS NEUTRAL DESORPTION IN PLASMA DESORPTION MASS SPECTROMETRY *COTTER, R.J. AND WANG, R.	547
FACTORS AFFECTING EH ION SOURCE FLOW AND EMISSION STABILITY: RELEVANCE TO MASS SPECTROMETRY *MAHONEY, J.F., PEREL, J., LEE, T.D. AND LEGESSE, K.	549
DISTINGUISHING ISOMERIC AND ISOBARIC IONS BY THERMOSPRAY MS PRECEDED BY ELECTROCHEMICAL ELECTROLYSIS *GETEK, T.A., KORFMACHER, W.A. AND FREEMAN, J.P.	551
CO ₂ AS A MODERATING GAS IN ELECTRON CAPTURE CHEMICAL IONIZATION *MOLLEKEN, M.E. AND HARRISON, A.G.	553
USE OF CO ₂ AS A BUFFER GAS IN HIGH PRESSURE ELECTRON CAPTURE MASS SPECTROMETRY. THE ELIMINATION OF UNUSUAL IONS *SEARS, L.J. AND GRIMSRUD, E.P.	554
SENSITIVITY STUDY OF PERFLUOROCARBONS AND PERFLUOROCARBONS CONTAINING NON-FLOUROCARBON GROUPS *HUANG, S., DESPOT, K., KLEIN, D.H. AND BIERL, T.W.	556
COMPARISON OF GAS PHASE AND LIQUID PHASE IONIZATION: CHEMICAL IONIZATION AT ATMOSPHERIC PRESSURE VS FIELD ASSISTED ION EVAPORATION *COVEY, T.R., SUSHAN, B.I., THOMSON, B.A. AND HENION, J.D.	558
FIELD IONIZATION AT LOW VOLTAGE *COGGIOLA, M.J. AND SPINDT, C.A.	560
LD/FTMS. A STUDY OF VARIABLES AFFECTING PERFORMANCE WEIL, D.A., CAMPANA, J.E., WELLER, R.R. AND *BJARNASON, A.	562
MULTIPHOTON IONIZATION OF LARGE MOLECULES: STUDY OF FRAGMENTATION AS FUNCTION OF PHOTON ENERGY AND INTENSITY *HOLLE, A., FREY, R., KAMINSKI, H., WEISS, G., FRANZEN, J. AND KOCH, D.	564
DESORPTION OF SMALL BIOMOLECULAR IONS BY UV LASER IRRADIATION *MAYER, F., ENS, W., MAO, Y., TANG, X. AND STANDING, K.G.	566

**Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL**

PULSED LASER INDUCED ELECTRON GENERATION FOR ELECTRON IONIZATION MASS SPECTROMETRY BEAVIS, R.C., ROHWER, E.R., LINDNER, J., KOSTER, C., GROTEMEYER, J. AND SCHLAG, E.W.	568
WAVELENGTH DEPENDENCE IN THE DESORPTION OF NEUTRAL MOLECULES LINDNER, J., GROTEMEYER, J. AND SCHLAG, E.W.	570
RESONANCE ENHANCED MULTIPHOTON IONIZATION DETECTION OF THE THERMAL DECOMPOSITION PRODUCTS INDUCED BY LASER DESORPTION OF OLIGOPEPTIDES LI, L. AND LUBMAN, D.M.	572
FRAGMENTATION OF CATIONIZED BIOMOLECULES IN LASER DESORPTION USING A CO ₂ LASER EMARY, W.B. AND COTTR, R.J.	574
ISOTOPE ANALYSIS IN INVOLATILE SAMPLES BY LASER DESORPTION ELECTRON IMPACT YUAN, Z.-M., FENSELAU, C., MARTIN, W.B. AND COTTER, R.J.	576
AN EFFECTIVE METHOD FOR ASSISTING LASER DESORPTION OF NON-VOLATILE COMPOUNDS ZHAO, S., SHARKEY, A.G. AND HERCULES, D.M.	578
CHARACTERIZATION OF A GLOW DISCHARGE PLASMA AS A FUNCTION OF SAMPLING ORIFICE POTENTIAL TAYLOR, W.S., DULAK, J.G. AND KETKAR, S.N.	580
ELECTROHYDRODYNAMIC EMISSION MASS SPECTRA OF PEPTIDES LEE, T.D., LEGESSE, K., MAHONEY, J.F. AND PEREL, J.	582
POSITRON IONIZATION MASS SPECTROMETRY DONOHUE, D.L., HULETT, L.D., GLISH, G.L., MCLUCKEY, S.A. AND MCKOWN, H.S.	584
ELECTROSPRAY IONIZATION-MASS SPECTROMETRY OF LARGE BIOMOLECULES LOO, J.A., BARINAGA, C.J., EDMONDS, C.G., UDSETH, H.R. AND SMITH, R.D.	586

Isotope Ratios

ISOTOPE RATIO MEASUREMENTS BY RESONANCE IONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY WITH A COPPER VAPOUR LASER PUMPED DYE LASER SYSTEM GREEN, L.W., SMYTH, M.H. AND SOPCHYSHYN, F.C.	588
DIODE LASER APPLICATION TO RESONANCE IONIZATION MASS SPECTROMETRY SMITH, D.H., YOUNG, J.P. AND SHAW, R.W.	590
MEASUREMENT OF MAGNESIUM ISOTOPIC RATIOS IN THE STUDY OF CELLULAR MAGNESIUM FLUXES VIEIRA, N.E., MONTES, J.G., SJODIN, R.A. AND YERGEY, A.L.	592
THE IMPORTANCE OF ABUNDANCE SENSITIVITY IN THE MEASUREMENT OF LARGE ISOTOPE RATIOS CANTLE, J.E. AND PALACZ, Z.A.	594
THE EFFECT OF ULTRA-HIGH VACUUM ON THERMAL IONIZATION PROCESSES TACKETT, J.R., ELLEFSON, R.E. AND WIEDENHEFT, C.J.	595
EVALUATION OF MEMORY EFFECT IN THE DETERMINATION OF ALTERED ISOTOPE RATIOS OF METALS BY GAS CHROMATOGRAPHY-MASS SPECTROMETRY AGGARWAL, S.K., KINTER, M., WILLS, M.R., SAVORY, J. AND HEROLD, D.A.	597
MEASUREMENT OF TRACES OF CHD ₃ IN CD ₄ MAMER, O.A. AND KOCH, H.	599

Reaction Mechanisms

EI INDUCED FRAGMENTATION OF 2-ARYLOXY-3-CYCLOHEXYL-6-(1,1-DIMETHYLETHYL)-3, 4-DIHYDRO-2H-1,3,2-BENZOXAZA PHOSPHORINE-2-OXIDES *RAJU, C.N., DASS, C. AND REDDY, G.S.	600
MASS SPECTRAL FRAGMENTATION OF 2,10-DICHLORO-6-ARYLOXY-DIBENZO [d,g] [1,3,6,2] DIOXATHIAPHOSPHOCIN-6-OXIDES REDDY, C.D., ANURADHA, D., *REDDY, G.S. AND DASS, C.	602
MASS SPECTRAL FRAGMENTATION OF SOME 1,4-DITHIANE-1,1-DIOXIDE AND 1,1,4,4-TETROXIDE AND RELATED HETEROCYCLIC COMPOUNDS REDDY, D.B., SEENAIHAH, B., REDDY, M.V.R. AND *REDDY, G.S.	604
PHENYL AND PYRIDYL GROUP MIGRATION ON ELECTRON IONIZATION OF ENAMIDES DERIVED FROM 1,3-BENZOTHAZINES AND ISOQUINOLINES MACLEAN, D.B., WANG, J., FODOR, L. AND *SMITH, R.W.	606
INVESTIGATION OF THE HINDRED AMINE LIGHT STABILIZER MECHANISM USING ISOTOPIC LABELING *NG, K., PIATEK, B., GANDE, M. AND KLEMCHUK, P.	608
1,2-SHIFTS, IN C ₃ H ₈ O ⁺ IONS *HUDSON, C.E. AND MCADOO, D.J.	610
THE OXIRANE ISOMERS CH ₂ OCH ₂ , OCH ₂ CH ₂ , AND CH ₃ OCH AND THEIR IONIZED COUNTERPARTS *WESEMIOTIS, C., LEYH, B., FURA, A. AND MCLAFFERTY, F.W.	612
TRIMETHYLSILYL GROUP MIGRATIONS AND EPOXIDE RING FRAGMENTATIONS IN THE MASS SPECTRA OF DERIVATIZED CHOLESTEROL OXIDATION PRODUCTS *ANNAN, M., WASILCHUK, B., LEQUESNE, P.W. AND VOURES, P.	614
SUBSTITUENT EFFECTS IN THE MASS SPECTRA OF SUBSTITUTED DIPHENYL-1-PHENYLAMINO-1-PHENYLMETHANEPHOSPHONATES AL-RAHI, M., *JAYASIMHULU, K., SMITH, S.J. AND ZIMMER, H.	616
REARRANGEMENTS OF FLUORINE-CONTAINING CATIONS *SHALER, T.A., STAMS, D.A. AND MORTON, T.H.	618
BENZOPHENONE IMINE FORMATION FROM BENZOPHENONE OXIME *MA, Y.C. AND MUNSON, B.	620
DEUTERIUM ISOTOPE EFFECT IN SOLID PROBE MS ANALYSIS *WANG, J.-S. AND QUA, A.	622
THE ELECTRON IONIZATION MASS SPECTRA OF NOVEL 2,3:4,5-BIS-O-(1-METHYLETHYLIDENE)- D-FRUCTOPYRANOSE DERIVATIVES AND RELATED SUGAR SULFAMATES *CALDWELL, G.W. AND MASUCCI, J.A.	624
THE INVESTIGATION OF [M-35] ⁺ IONS IN 2-ALKYL-4,6-DINITROPHENOLS *RILEY, J. AND MARBURY, D.	626
THE GAS-PHASE REACTION OF THE CYCLOPROPANE RADICAL CATION AND CYCLOPROPANE: FORMATION OF THE HEXAMETHYLENE DISTONIC ION *WARNER, C.D., HAYES, R.N. AND GROSS, M.L.	628
MASS SPECTROSCOPIC STUDY OF SOME FLUOROCARBONS *HUANG, S. AND TUINMAN, A.	630

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

A STUDY OF THE FRAGMENTATION PATHWAY OF A SERIES OF FROG ALKALOIDS OF THE PUMILIOTOXIN CLASS *PU, Q-L., PANNELL, L.K., FALES, H.M. AND MASON, R.T.	632
CLEAVAGE MECHANISMS OF CHROMIUM- DIKETONATES BY ELECTRON IONIZATION *WENCLAWIAK, B.	634
FUNDAMENTAL STUDIES OF CHEMICAL IONIZATION MECHANISMS OF PORPHYRINS AND METALLOPORPHYRINS *BEATO, B.D. AND YOST, R.A.	636
STUDIES OF THE ION/MOLECULE REACTION OF ESTERIFICATION BY ION TRAP MASS SPECTROMETRY *CHANG, J.S-C. AND YOST, R.A.	638
IONIC DISSOCIATION OF 7-R-O-METHYLNORGAROL AND ITS DEGRADATION PRODUCTS *NISHIMURA, T., ROBINS, R.H., CROW, F.W. AND SONODA, A.	640
PHOTOCHEMICALLY-INDUCED REACTION OF CHLORPROTHIXENE WITH OXYGEN UNDER METHANE NEGATIVE CHEMICAL IONIZATION CONDITIONS *FUKUDA, E.K., CALLERY, P.S. AND DAVIS, P.P.	642
THE METHANE CHEMICAL IONIZATION MASS SPECTRA OF A SERIES OF URETHANES WRIGHT, A.D., BOWEN, R.D. AND *JENNINGS, K.R.	644
REACTIONS OF BIDENTATE LIGAND ANIONS WITH LEWIS ACIDS AS PROBES OF POTENTIAL ENERGY SURFACES *BABCOCK, L.M. AND TAYLOR, W.S.	646
PROTONATION ON PHENOXY OXYGEN IN METHANE CHEMICAL IONIZATION OF ALKYL PHENYL ETHERS *KONDRAT, R.W., STAMS, D.A. AND MORTON, T.H.	648
OBSERVATION OF DIAZONIUM ION-CROWN ETHER MOLECULAR COMPLEXES IN THE GAS PHASE BY FIELD DESORPTION AND FAST ATOM BOMBARDMENT MASS SPECTROMETRY *LAALI, K. AND LATTIMER, R.P.	650
DIFFERENCES IN THE MECHANISM OF FORMATION OF PARENT-MOLECULAR IONS IN CHEMICAL IONIZATION AND FAST ATOM BOMBARDMENT MASS SPECTROMETRY *ZHA, Q. AND BERTRAND, M.J.	652
MECHANISMS OF THERMALLY ANALOGOUS COLLISION-INDUCED CHARGE-REMOTE FRAGMENTATIONS *CONTADO, M.J., ADAMS, J., JENSEN, N.J. AND GROSS, M.L.	654
COLLISION-INDUCED DISSOCIATION OF MULTIPLY-CHARGED DIATOMIC CATIONS *HARBOL, K.L. AND KISER, R.W.	656
THE ROLE OF GAS-PHASE BASICITY AND SURFACE ACTIVITY IN THE FORMATION OF FAB AND PD MASS SPECTRA *KEOUGH, T. AND LACEY, M.P.	658
UNIMOLECULAR DISSOCIATION OF METASTABLE $[Mn_2(CO)_{10}]^+$ *LIANG, X. AND FREAS, R.B.	660
MASS SPECTROMETRY OF RHODIUM CHELATES: HYDROGEN TRANSFER DURING ION DECOMPOSITION *WESTMORE, J.B. AND STERN, G.A.	662
MASS SPECTRAL STUDIES OF IRIIDIUM COMPLEXES OF 2,4-PENTANEDIONE, 1,1,1-TRIFLUORO-2,4-PENTANEDIONE AND 1,1,1,5,5,5-HEXAFLUORO-2,4-PENTANEDIONE *STERN, G.A. AND WESTMORE, J.B.	664

STRUCTURAL IMPLICATIONS REGARDING PHOTOFRAGMENTATION OF 12-CROWN-4 FROM PHOTOIONIZATION MASS SPECTROMETRY *MOINI, M., ALLISON, J. AND LEORI, G.E.	666
A COMPETITION BETWEEN TWO ISOMERIZATION PROCESSES IN UNIMOLECULAR DISSOCIATION *ZHA, Q., BERTRAND, M.J., NISHIMURA, T. AND MEISELS, G.C.	668
HIGH MASS CARBON CLUSTER FORMED FROM POLYCYCLIC AROMATIC HYDROCARBONS OBSERVED BY LASER MASS SPECTROMETRY *LINEMAN, D.N., VISWANADHAM, S.K., SHARKEY, A.G. AND HERCULES, D.M.	670
THE KINETIC ENERGIES OF IONS FORMED BY RESONANT AND NON-RESONANT MULTIPHOTON IONIZATION *ZIMMERMAN, J.A. AND O'MALLEY, R.M.	672
FRAGMENTATION OF THE PARENT ION OF METHYL ESTERS AND KETONES BY MS/MS IN AN ION-TRAP MASS SPECTROMETER: CHANGE IN MECHANISM WITH CHAIN LENGTH *MASON, R.T., FALES, H.M., PANNELL, L.K. AND PU, Q.-L.	674

Pharmacology/Drugs

MASS SPECTROMETRIC TECHNIQUE APPLIED TO ASSIGNMENT OF STRUCTURES IN THREE OR FOUR STEP - LACTAM SYNTHESSES *DAY, R.A. AND BENNETT, B.	676
RAPID IDENTIFICATION OF URINARY METABOLITES OF ADINAZOLAM IN HUMANS USING TANDEM MASS SPECTROMETRY *VRBANAC, J.J., PENG, G.W. AND O'LEARY, I.A.	678
EFFECT OF PHTHALATE IMPURITIES ON PEAK AREAS DURING NEGATIVE ION METHANE GC/MS ANALYSIS OF NABILONE AND DEUTERATED NABILONE IN HUMAN PLASMA SAMPLES *DHAHIR, P.H., BARTON, R., WOLEN, R.L. AND BREAU, A.P.	680
HYBRID MS/MS OF AROMATIC DIAMIDINO ANALOGS *MARBURY, G.D., CHARLES, J.C., BELL, C., HALL, J.E. AND TIDWELL, R.	682
A SELECTED CAD-DAUGHTER ION RECORDING ASSAY FOR FLUPHENAZINE *EDOM, R.W., MCKAY, G., HAWES, E.M. AND MIDHA, K.K.	684
PURIFICATION OF INHIBITORS OF OUABAIN BINDING FROM BOVINE POSTERIOR PITUITARIES USING HIGH PRESSURE LIQUID CHROMATOGRAPHY & MASS SPECTROMETRY *MCQUADE, P.S., LABELLA, F.S. AND STANDING, K.G.	686
THE STRUCTURE ELUCIDATION AND MASS SPECTROMETRY OF PENICILLINIC ACID THIOLACTONES *CHESS, E.K., PEREIRA, D. AND SMITH, W.J.	688
MASS SPECTROMETRY OF MITOMYCIN C AND SELECTED ANALOGS *HAMMARGREN, W.M., IYENGAR, B.S., REMERS, W.A. AND SCHRAM, K.H.	690
MASS SPECTROMETRY IN PREHISTORIC RESEARCH *ORLEY, C.O. AND MESTER, M.	692
ANALYSIS OF BLOODROOT EXTRACT USING TLC/SIMS, HIGH RESOLUTION MS, AND MS/MS *DOHERTY, S.J. AND BUSCH, K.L.	694
DERIVATIZATION OF PUTATIVE BRADYKININ METABOLITES FOR GC-MS ANALYSIS *VRBANAC, J.J., BALLARD, K.D. AND KNAPP, D.R.	696

APPLICATION OF AUTOMATED GC/MS/MS FOR THE QUANTITATIVE DETERMINATION OF NE-11740 IN PLASMA *DOBSON, R.L.M., NEAL, D.M., DEMARK, B.R. AND WARD, S.R.	698
CHARACTERIZATION OF DERIVATIVES OF CHIRAL ANTIARRHYTHMIC DRUGS AND THEIR METABOLITES USING FAB-MS *SWEETMAN, B.J., PRAKASH, C. AND BLAIR, I.A.	700
NEGATIVE ION FAST ATOM BOMBARDMENT MASS SPECTROMETRIC ANALYSIS OF PLATINATED OLIGONUCLEOTIDES *MARTIN, L.B., SCHREINER, A.F. AND VAN BREEMEN, R.B.	702
GAS CHROMATOGRAPHY-ION TRAP MASS SPECTROMETRY DETERMINATION OF ARECOLINE IN HUMAN PLASMA *SHETTY, H.U., GREIG, N.H., SONCRANT, T.T. AND RAPOPORT, S.I.	704
SELECTED REACTION MONITORING FOR RAPID QUANTITATION OF DEXAMETHASONE IN PLASMA *KAYGANICH, K.A., HEATH, T.G. AND WATSON, J.T.	706
NEGATIVE CHEMICAL IONIZATION VERSUS ELECTRON IMPACT IONIZATION DETECTION OF SCOPOLAMINE BY GC/MS IN HUMAN AND RAT PLASMA *DEUTSCH, J., SONCRANT, T.T., GREIG, N.H. AND RAPOPORT, S.E.	708
STRUCTURE ELUCIDATION OF ISOMERIC HYDROXY-ALOINS AND OXANTRHONE GLUCOSYLES BY THE USE OF HIGH RESOLUTION AND TANDEM MASS SPECTROMETRY *SCHRODER, E. AND RAUWALD, U.	710
SELECTIVE DETECTION OF SULFUR-CONTAINING COMPOUND BY REACTION INTERFACE/MASS SPECTROMETRY AND ITS APPLICATIONS TO DRUG METABOLISM *MOINI, M., CHACE, D.H. AND ABRAMSON, F.P.	712
DETECTION OF ¹⁴ C-LABELED DRUGS AND THEIR METABOLITES BY CAPILLARY GAS CHROMATOGRAPHY - REACTION INTERFACE / MASS SPECTROMETRY (GC-RIMS) *CHACE, D.H. AND ABRAMSON, F.P.	714
MASS SPECTROMETRIC STUDIES ON AZIDOTHYIMIDINE (AZT) USING FAB, THERMOSPRAY, PLASMASPRAY AND MS-MS *ROBOZ, J., LAPPIN, G. AND NIEVES, E.	716
USE OF PYROLYSIS CI/MS OVER THREE DIFFERENT TEMPERATURE RANGES TO IDENTIFY BACTERIA *CONWAY, D.C., LOPEZ, H. AND QUARLES, J.M.	718

Oligosaccharides/Lipids

DYNAMIC LIQUID SIMS OF UNDERIVATIZED OLIGOSACCHARIDES: IMPROVEMENTS IN MASS RANGE AND SENSITIVITY *GENO, P.W.	720
CF-FAB/MS MONITORING OF COMBINED PEPTIDASE HYDROLYSIS FOR THE CHARACTERIZATION OF SMALL AND MEDIUM-SIZED PEPTIDES *WHALEY, B.S. AND CAPRIOLI, R.M.	722
TANDEM MASS SPECTROMETRY OF LIPOSIDOMYCIN ANTIBIOTICS *NELSON, C.C., MCCLOSKEY, J.A., UBUKATA, M. AND ISONO, K.	724
STRUCTURE DETERMINATION A NOVEL ANTIFUNGAL NUCLEOTIDE ANTIBIOTIC *PHILLIPS, D.R., MCCLOSKEY, J.A., URAMOTO, M. AND ISONO, K.	726
STUDIES OF OLIGONUCLEOTIDE IONIZATION BY CONTINUOUS-FLOW FAST ATOM BOMBARDMENT *SHEIL, M.M., KOWALAK, J.A. AND MCCLOSKEY, J.A.	728

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

FAB-MS VS TIME-OF-FLIGHT SIMS: NEGATIVE ION STUDIES OF O-ALKYL DI-AND TRINUCLEOTIDES	730
*LAFORTUNE, F., BUCHKO, G., HRUSKA, F.E., SADANA, K.L., STANDING, K.G. AND WESTMORE, J.B.	
THE IDENTIFICATION OF 5,6-DIHYDROURIDINE IN NORMAL HUMAN URINE BY COMBINED GC/MS	732
*REIMER, M.L.J., SCHRAM, K.H., NAKANO, K. AND YASAKA, T.	
GC/MS ANALYSIS OF SPE ISOLATED URINARY NUCLEOSIDES	734
*MYKYTYN, V.V. AND SCHRAM, K.H.	
STRUCTURAL CHARACTERIZATION OF PENTAFLUOROBENZYL DERIVATIVES OF ALKYL AND HYDROXYALKYL MODIFIED DNA BASES	736
*ANNAN, R.S., GIESE, R. AND VOURES, P.	
FAB MASS SPECTRA OF SOME NATURALLY OCCURRING MODIFIED NUCLEOTIDES AND THEIR ANALOGS	738
DUTTA, S.P., WESOLOWSKI, J. AND *CHHEDA, G.B.	
COMPARISON OF THE MAJOR LIPIDS OF SCENT GLAND SECRETIONS FROM THE WESTERN DIAMONDBACK RATTLESNAKE (CROTALUS ATROX) AND DUMERIL'S GROUND BOA (ACRANTOPHIS DUMERILI) BY GC-MS: EVIDENCE FOR TAXONOMIC AND EVOLUTIONARY VARIATION	740
*SIMPSON, J.T., TANNER, M.J., SHARP, T.R., DAHM, K.H. AND WELDON, P.J.	
ELECTRON IMPACT MASS SPECTRA OF STEROIDS: ANDROSTANES AND DERIVATIVES	742
*SHARP, T.R., SUTTON, M., FERGUSON, A. AND MARSH, K.N.	
FATTY ACID AND HYDROCARBON CONTENT OF SALMONELLA TYPHIMURIUM BY GC/MS	744
*BEIER, R.C., OYOFI, B.A., SPATES, G.E. AND DELOACH, J.R.	
DETERMINATION OF ANOXIA-INDUCED PHOSPHOLIPASE A2 (PLA2) ACTIVATION IN FRESHLY ISOLATED RABBIT PROXIMAL TUBULES USING NICI	746
*PORTILLA, D., MILLINGTON, D.S. AND MANDEL, L.	
DIRECT ANALYSIS OF MODIFIED FATTY ACIDS THROUGH THEIR OXAZOLINE DERIVATIVES BY COMBINED IN-BEAM ELECTRON IMPACT (IBEI)-B/E LINKED SCANNING TECHNIQUE	748
*YANG, Y.M., ZHANG, J.Y. AND HUANG, Z.H.	
CHARACTERIZATION OF FATTY ACYL HYDROXYLATION OF TUMOR CELL GANGLIOSIDES BY FAB CAD MS/MS	750
*GAGE, D.A., SWEELEY, C.C., LADISCH, S. AND BECKER, H.	
EC-NI CAD MS/MS ANALYSIS OF THE FRAGMENTATION OF ABSCISIC ACID	752
*HEATH, T.G., ZEEVAART, J.A.D. AND GAGE, D.A.	
TANDEM MASS SPECTROMETRY OF UNDERIVATIZED PROSTAGLANDINS	754
*DAVOLI, E., BETTAZZOLI, L., GROSS, M.L. AND MURPHY, R.C.	
NEGATIVE ION FABMS/MS OF PLATELET ACTIVATING FACTOR	756
*CLAY, K.L. AND ZIRROLI, J.A.	
DETERMINATION OF ENDOTHELIAL CELL DERIVED PLATELET ACTIVATING FACTOR BY CONTINUOUS FLOW FAB/TANDEM MS WITH SELECTED REACTION MONITORING	758
*HAROLDSEN, P.E., TAYLOR, A.A. AND GASKELL, S.J.	
ANALYSES FOR LEUKOTRIENES USING CONTINUOUS FLOW FAST ATOM BOMBARDMENT/TANDEM MASS SPECTROMETRY	760
*RAFTERY, M.J., ORKISZEWSKI, R.S. AND GASKELL, S.J.	
LIPID OXYGENATION OF POLYUNSATURATES BY HUMAN AND RAT PLATELETS	762
*KIM, H-Y., KARANIAN, J.W. AND SALEM, N.	

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL .

NOVEL METABOLITES OF LTB ₄ FROM GUINEA PIG EOSINOPHILS *MATHEWS, W.R., GUIDO, D.M., SUN, F.F., CZUK, C.I. AND TAYLOR, B.M.	764
CHARACTERIZATION OF A-RING HYDROXY METABOLITES OF VITAMIN D BY CID ANALYSIS OF "STANDARD" IONS YOUNG, D., *VOUROS, P. AND HIGUCHI, T.	766
STRUCTURAL DETERMINATION OF MODIFIED CHLOROPHYLLS BY USING TANDEM MASS SPECTROMETRY *GRESE, R.P. AND GROSS, M.L.	768
DERIVATIZATION OF GANGLIOSIDES AND THEIR ANALYSIS BY HIGH PERFORMANCE TANDEM MASS SPECTROMETRY VATH, J.E., DOMON, B. AND *COSTELLO, C.E.	770
ANALYSIS OF CAROTENOID COMPOUNDS BY ELECTRON CAPTURE NEGATIVE ION MASS SPECTROMETRY *LUSBY, W.R., KHACHIK, F. AND BEECHER, G.R.	772
ETHANOL INDUCED CHANGES IN CENTRAL NERVOUS SYSTEM PROSTAGLANDIN PRODUCTION *YERGEY, J.A. AND HEYES, M.P.	774
BACTERIAL PHOSPHOLIPID ANALYSIS BY FAB/MS/MS: CHARACTERIZATION OF THE EFFECTS OF GROWTH CONDITIONS *COLE, M.J. AND ENKE, C.G.	776
ANALYSIS OF BACTERIAL CELL WALL GLYCOLIPIDS BY LASER DESORPTION AND PLASMA DESORPTION MASS SPECTROMETRY *EMARY, W.B., WANG, R., CHEN, L. AND COTTER, R.J.	778
TANDEM MASS SPECTROMETRY OF ERGOSTEROL AND RELATED COMPOUNDS *KINOSHITA, T., NAGAKI, H. AND NAKAMURA, T.	780
PEPTIDE MAPPING AND CARBOHYDRATE STRUCTURAL ANALYSIS OF RECOMBINANT SOLUBLE CD4 BY MASS SPECTROMETRY *HEMLING, M.E., CARR, S.A., ROBERTS, G.D. AND DODIA, V.	782
CONTROLLED FRAGMENTATION OF PERACETYLATED OLIGOSACCHARIDES IN 252Cf PLASMA DESORPTION MASS SPECTROMETRY *ADURU, S. AND CHAIT, B.T.	784
STRATEGIES TO DISTINGUISH CARBOHYDRATE SEQUENCE IONS *ORLANDO, R., MURPHY, C. AND FENSELAU, C.	786
LSIMS ANALYSIS OF OLIGOSACCHARIDES AS NEOGLYCOLIPID DERIVATIVES *LAWSON, A.M., CHAI, W., CASHMORE, G., STOLL, M., HOUNSELL, E.F. AND FEIZI, T.	788
CHARACTERIZATION OF OLIGOSACCHARIDES FROM MUCIN GLYCOPROTEINS BY LSIMS USING AN AUTOMATED TLC TARGET STAGE *LAWSON, A.M., CHAI, W., STOLL, M., HOUNSELL, E.F., FEIZI, T., BATEMAN, R.H. AND MAJOR, H.J.	790
ORIGIN OF THE (M-H) ⁺ IONS IN THE FAST ATOM BOMBARDMENT MASS SPECTRA OF SOME CYCLIC SUGARS *ZHA, Q. AND BERTRAND, M.J.	792
SEQUENCE ANALYSIS OF HIGHLY SULFATED, HEPARIN-DERIVED OLIGOSACCHARIDES USING FAST ATOM BOMBARDMENT MASS SPECTROMETRY *MALLIS, L.M., WANG, H.M., LOGANATHAN, D. AND LINHARDT, R.J.	794
PORPHYRIN PYRROLE SEQUENCING BY LOW ENERGY CID OF (M+7H) ⁺ GENERATED IN SITU DURING AMMONIA CHEMICAL IONIZATION VAN BERKEL, G.J., *TUINMAN, A.A., GLISH, G.L. AND MCLUCKEY, S.A.	796

WEDNESDAY ORAL SESSIONS

Symposium: Next Generation of Environmental Contaminants

AZODYES: ENVIRONMENTAL CONCERNS, ANALYTICAL CHEMISTRY, & MASS SPECTROMETRY *BUDE, W.L.	798
POSSIBLE WIDESPREAD ENVIRONMENTAL CONTAMINATION BY BROMO AND BROMOCHLORO DIOXINS AND DIBENZOFURANS *SOVOCOL, G.W. AND DONNELLY, J.R.	800
ALKYLINS; GOOD FOR ANTIFOULING PAINT, NOT SO GOOD FOR OYSTERS *GREAVES, J.	803
THE ROLE OF MASS SPECTROMETRY IN THE ANALYSIS OF EXPLOSIVES *MCLUCKEY, S.A. AND GLISH, G.L.	806
THE IDENTIFICATION OF BIZARRE ALKYLPHENOLS IN THE DETROIT RIVER CARTER, D., SHIRAISHI, H. AND *HITES, R.A.	809

Symposium: Lasers in Mass Spectrometry

LASER IONIZATION MASS SPECTROMETRY (LIMS): TECHNIQUE AND APPLICATIONS *ODOM, R.W. AND EVANS, C.A.	812
CO ₂ AND EXCIMER LASER DESORPTION AND PHOTODISSOCIATION IN A FTMS NUWAYSIR, L.M. AND *WILKINS, C.L.	816
MECHANISTIC STUDIES IN LASER IONIZATION MASS SPECTROMETRY WILKERSON, C.W., YANG, M., COLBY, S.M. AND *REILLY, J.P.	819
LASERS AND QUADRUPOLE FOURIER TRANSFORM MASS SPECTROMETRY APPLIED TO PROTEIN SEQUENCE ANALYSIS *SHABANOWITZ, J., HUNT, D.F., GRIFFIN, P.R. AND ZHU, N.Z.	821

Ion Molecule Reactions

PHOTOINDUCED ION MOLECULE REACTIONS IN THE GAS PHASE USING FTMS GORD, J.R. AND *FREISER, B.S.	824
DEPENDENCE OF CAR SPECTRA OF DIASTEREOMERIC MH ⁺ IONS UPON INITIAL INTERNAL ENERGY *TABET, J.-C.	826
EFFECTIVE ION TEMPERATURES IN A QUADRUPOLE ION TRAP NOURSE, B.D., *KENTAMAA, H.I. AND COOKS, R.G.	828
MECHANISTIC AND ENERGETIC IMPLICATION OF KINETIC ENERGY RELEASE DISTRIBUTIONS FOR REACTIONS OF TRANSITION METAL IONS WITH SMALL MOLECULES *BRODBELT-LUSTIG, J., VAN KOPPEN, P.A.M., BEAUCHAMP, J.L. AND BOWERS, M.T.	830
HYDROGEN BONDED, BONDED AND BONDED COMPLEXES (X.A)- FROM X- AND A, WHERE X- = CH ₃ O-, F-, Cl-, Br-, I-, AND A = SUBSTITUTED BENZENES AND QUINONES *PAUL, G.J.C. AND KEBARLE, P.	832

UNIMOLECULAR REARRANGEMENTS IN THE GAS PHASE: RING OPENING OF CYCLOPROPYL ANIONS CHOU, P. AND *KASS, S.	834
A THEORETICAL STUDY OF NUCLEOPHILIC SUBSTITUTION REACTIONS IN THE GAS PHASE *HIERL, P.M., MEYER, S. AND SIGLER, J.	836
SELECTIVITY AS A FUNCTION OF ANIONIC BASE PROPERTIES IN THE REACTIONS OF DIMETHYL SULFITE *GRABOWSKI, J.J. AND LUM, R.C.-J.	838
GAS-PHASE NUCLEOPHILIC ADDITION REACTIONS OF NITRILES: A CA MS/MS STUDY OF THE THORPE REACTION *HAYES, R.N. AND GROSS, M.L.	840
GAS-PHASE REACTIONS OF FIRST-ROW TRANSITION METAL IONS (Sc ⁺ -Zn ⁺) WITH PHENYL HALIDES *BJARNASON, A.	842

WEDNESDAY POSTER SESSIONS

Peptides and Proteins

ELECTROSPRAY IONIZATION MASS SPECTROMETRY OF SMALL OLIGONUCLEOTIDES *EDMONDS, C.G., BARINAGA, C.J., LOO, J.A., UDSETH, H.R. AND SMITH, R.D.	844
FAB TANDEM MS OF PROTEASE AUTOLYSIS PRODUCTS *VESTLING, M.M. AND FENSELAU, C.	846
SEQUENTIAL MASS SPECTROMETRY ON A HYBRID TANDEM INSTRUMENT OF BEqQ CONFIGURATION *THORNE, G.C. AND GASKELL, S.J.	848
APPLICATIONS OF STABLE ISOTOPES AND TANDEM MASS SPECTROMETRY TO THE CHARACTERIZATION OF REACTIVE METABOLITE PEPTIDE INTERACTIONS *PEARSON, P.G., SLATTER, J.G., HAN, D.-H. AND BAILLIE, T.A.	850
ALTERNATE MASS SPECTROMETRIC METHODS FOR PEPTIDE SEQUENCE DETERMINATION *BOLGAR, M.S., DIDONATO, G.C., JOHNSON, J.H., TYMIK, A.A., UNGER, S.E. AND WARRACK, B.M.	852
SELECTIVE IDENTIFICATION OF DISULFIDE-CONTAINING PEPTIDES BY ELECTROCHEMICAL HPLC AND FAB/MS *SUN, Y., ANDREWS, P.C. AND SMITH, D.L.	854
AMINO-TERMINAL DERIVATIZATION OF PEPTIDES YIELDS IMPROVED CAD SPECTRA *STULTS, J.T., HALUALANI, R. AND WETZEL, R.	856
INVESTIGATION OF THE FRAGMENTATION OF PEPTIDES AS A FUNCTION OF COLLISION ENERGY IN A FOUR-SECTOR TANDEM MASS SPECTROMETER *MARTIN, S.A.	858
EFFECT OF TRIFLUOROACETIC ACID ON THE REDUCTION OF DISULFIDE BRIDGES IN PEPTIDES ANALYZED BY FAB/MS *VISENTINI, J., GAUTHIER, J. AND BERTRAND, M.J.	860
A MASS SPECTROMETRIC TECHNIQUE FOR DETECTING AND LOCATING ERRORS IN SYNTHETIC PEPTIDES *CHOWDHURY, S. AND CHAIT, B.T.	862
PULSED ION BOMBARDMENT TIME-OF-FLIGHT MASS SPECTROMETER WITH OPTIMUM SENSITIVITY FOR PEPTIDES IN 1-2 PICOMOLE RANGE *KATTA, V. AND CHAIT, B.T.	864

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

THE EFFECT OF PRIMARY IONIZATION ON THE MS/MS SPECTRA OF SMALL PEPTIDES USING A TRIPLE QUADRUPOLE MS *ROBINS, R.H. AND CROW, F.W.	866
THREE DIMENSIONAL CELLULAR MAPPING OF ANTIBODY-ANTIGEN INTERACTIONS BY SECONDARY ION MASS SPECTROMETRY LEE, J.J., LINTON, R.W., *VOYKSNER, R.D., HUNTER, J.L. AND WILSON, D.C.	868
TOPOGRAPHY OF MEMBRANE-BOUND PROTEINS: PHOTOAFFINITY STUDIES OF COLICIN Ia *FALICK, A.M., MEL, S.F., STROUD, R.M. AND BURLINGAME, A.L.	870
DERIVATIZATION AS AN AID TO PEPTIDE MAPPING BY LSIMS FALICK, A.M. AND *MALTBY, D.A.	872
LIQUID SECONDARY ION MASS SPECTROMETRIC (LSIMS) MASS MAPPING OF HUMAN HEMOGLOBIN FROM RED BLOOD CELLS MODIFIED IN VITRO BY STYRENE-7,8-OXIDE *KAUR, S., BURLINGAME, A.L., HOLLANDER, D. AND HAAS, R.	873
IDENTIFICATION OF POST-TRANSLATIONAL ARTIFACTS IN THE PRODUCTION OF BIOSYNTHETIC HUMAN GROWTH HORMONE BECKER, G.W., GILLIAM, J.M. AND *OCCELOWITZ, J.L.	875
OLIGOPEPTIDE FRAGMENTATION VIEWED AS CONSTANT NEUTRAL LOSS *MURPHY, C.M., ORLANDO, R.C., FENSELAU, C.C. AND COTTER, R.J.	877
INVESTIGATION OF ARTIFACTS FORMED DURING CYANOGEN BROMIDE DIGESTION OF PROTEINS *GOODLETT, D.R., CREECH, J. AND VAN BREEMEN, R.B.	879
NITRO-PHENYLISOTHIOCYANATE AS A REAGENT FOR PEPTIDE SEQUENCING BY NEGATIVE ION MASS SPECTROMETRY *WAIDYANATHA, S. AND ANDEREGG, R.J.	881
QUANTIFICATION OF SUBSTANCE P BY FAB-MS *KUSMIERZ, J. AND DESIDERIO, D.M.	883
QUANTIFICATION OF BETA-ENDORPHIN IN HUMAN PITUITARY BY FAB *DASS, C., KUSMIERZ, J. AND DESIDERIO, D.M.	885
MATRIX REACTIONS AND THEIR EFFECTS ON THE ISOTOPIC PEAK RATIOS OF PEPTIDES MEASURED BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY *VISENTINI, J., THIBAUT, P. AND BERTRAND, M.J.	887
ANALYSIS OF CANCER CELL LINES FOR THE PRESENCE OF PEPTIDE GROWTH HORMONES AND OTHER PEPTIDES BY ION EVAPORATION IONIZATION/TANDEM MASS SPECTROMETRY *TRESTON, A., KASPRZYK, P., CUTTITTA, F., COVEY, T. AND MULSHINE, J.	889
ANALYSIS OF PHOSPHORYLATED AND SULFATED PEPTIDES BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY *GUIDO, D.M. AND MATHEWS, W.R.	891
CESIUM ION LIQUID (SIMS) AND CALIFORNIUM-252 PLASMA DESORPTION MASS SPECTROMETRY STUDIES OF SOME NATURAL AND RECOMBINANT PROTEINS PRAMANIK, B.N., *TSARBOPoulos, A., SIEGEL, M., REICHERT, P., DAS, P., BARTNER, P., HER, G., TSAO, R., DOELLING, V. AND TROTTA, P.P.	893
SOLVING DIFFICULT PEPTIDE STRUCTURAL PROBLEMS BY TANDEM MASS SPECTROMETRY *BEAN, M.F., CARR, S.A., ESCHER, E., JOHNSON, W. AND MOORE, M.	895
NEW TECHNIQUES IN THE HYBRID TANDEM MASS SPECTROMETRY OF PEPTIDES *ORKISZEWSKI, R.S., THORNE, G.C., DOURDEVILLE, T.A. AND GASKELL, S.J.	897

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

BRAIN CALBINDINS AND A MONOCYTE CHEMOTACTIC AGENT; STRUCTURAL ANALYSIS BY TANDEM MASS SPECTROMETRY *MCCORMACK, A.L., HUNT, D.F., SHABANOWITZ, J., ZHU, N.Z. AND GRIFFIN, P.R.	899
TOF-SIMS AND FAB OF MODIFIED PEPTIDES: A COMPARISON OF SENSITIVITIES HAGENHOFF, B., *NIEHUIS, E., BENNINGHOVEN, A., WUNSCH, C. AND MUSCHE, H.	901
STRUCTURAL CHARACTERIZATION OF LENS PROTEINS BY FAB/MS *LEEDS, J., QIN, W. AND SMITH, D.L.	903
COLLISION-INDUCED DISSOCIATION OF MULTIPLY CHARGED PEPTIDES *COVEY, T.R., CONBOY, J.J. AND HENION, J.D.	905
COLLISION-INDUCED DECOMPOSITIONS OF PEPTIDE IONS CATIONIZED WITH ALKALINE EARTH AND ALKALI METALS *TEESCH, L.M. AND ADAMS, J.	907
PD/FAB-MAPPING OF BOVINE NEUROPHYSINS *FEISTNER, G.J., HOJRUP, P., EVANS, C.J., BAROFSKY, D.F., ROEPSTORFF, P. AND FAULL, K.F.	909
RESOLUTION AND IDENTIFICATION OF DERIVATIZED ENANTIOMERS OF α -AMINO ACIDS ON A CHIRAL DIAMIDE PHASE BY GC/MS *CHANG, J.S.-C. AND LIN, S.-R.	911
IDENTIFICATION OF AN AMINO ACID REPLACEMENT IN A MUTANT PHYCOCYANIN BY MS/MS WITH A HYBRID INSTRUMENT *WILLIAMS, T., SWANSON, R., WILBANKS, S., ZHOU, J., BRYANT, D., GLAZER, A.N. AND LEARY, J.A.	913
FAST ATOM BOMBARDMENT MASS SPECTROMETRIC CHARACTERIZATION OF RECOMBINANT HUMAN CYCLOPHILIN *LARSEN, B.S., LISCHWE, M., DAVIS, G. AND GALBRAITH, W.	915
MODIFIED PHENYLISOTHIOCYANATES FOR PEPTIDE SEQUENCING BY NEGATIVE ION CHEMICAL IONIZATION MASS SPECTROMETRY *GHOSH, A. AND ANDEREGG, R.J.	917
LSIMS ON MULTIPLE CYSTINE-LINKED PEPTIDES FROM RECOMBINANT HIRUDIN VARIANT 2-Lys (rHV2-Lys 47) DIGESTION LEPAGE, P., ROITSCH, C., ACKER, M., BITSCH, F. AND *VAN DORSSELAER, A.	919
CONFIRMATION OF INDOLE-3-ACETIC ACID BOUND TO ZEIN LEVERONE, L.A., CARUSO, J.L. AND *JAYASIMHULU, K.	921
CHARACTERIZATION OF PHENYLGLYCIDYL ETHER NUCLEOSIDE ADDUCTS USING FAB/MS/MS CLAEREBOUDT, J., *ESMANS, E.L., VAN DEN EECKHOUT, E.G., BAETEN, W. AND CLAEYS, M.	923
INTERCHAIN DISULFIDE BOND FRAGMENTATIONS OF DIMERIC PEPTIDES BITSCH, F., HIETTER, H. AND *VAN DORSSELAER, A.	925

LC/MS II

QUANTIFICATION OF 1,25-DIHYDROXY-VITAMIN D ₃ BY STABLE-ISOTOPE DILUTION USING COMBINED HIGH PERFORMANCE LIQUID CHROMATOGRAPHY THERMOSPRAY MASS SPECTROMETRY *WATSON, D., SETCHELL, K., ROSS, R. AND BJORKHEM, I.	927
--	-----

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

THE ANALYSIS OF NONIONIC, CATIONIC, ANIONIC AND AMPHOTERIC SURFACTANTS USING THERMOSPRAY MS/MS AND FAB MS/MS *MABUD, Md.A., DREIFUSS, P.A., KILLINGER, W.E. AND SMITH, M.W.	929
THERMOSPRAY LC/MS INTERFACE FOR TIME-OF-FLIGHT MASS SPECTROMETRY *YERGEY, A.L. AND LAMPE, F.W.	931
USE OF DEUTERATED SOLVENTS IN THERMOSPRAY LC/MS TO DISTINGUISH CLUSTER COMPOSITION, ADDUCT FORMATION, DIMERIZATION AND EXCHANGEABLE PROTONS GOODWIN, R.M. AND *BREAU, A.P.	933
OPTIMIZATION OF SENSITIVITY AND INFORMATION OF THERMOSPRAY LC/MS *NIESSEN, W.M.A., HEEREMANS, C.E.M., VAN DER HOEVEN, R.A.M., TJADEN, U.R. AND VAN DER GREEF, J.	935
THE EFFECT OF ION SOURCE CONFIGURATION ON THE GAS-PHASE IONIZATION AND ION-EVAPORATION COMPONENTS OF THERMOSPRAY *MCLEAN, M.A. AND VESTAL, M.L.	937
DESIGN AND PERFORMANCE OF A NEW COMBINED THERMOSPRAY-EI LC-MS SYSTEM *VESTAL, M.L., WINN, D. AND WILKES, J.G.	939
APPLICATION OF THERMOSPRAY HPLC/MS TO ORGANIC SYNTHESIS *YANG, L.	941
OPTIMIZATION OF ON-LINE ENZYMATIC HYDROLYSIS HPLC/MS FOR PEPTIDE MAPPING AND DISULFIDE BOND LOCATION *VOYKSNER, R.D., CHEN, D.C. AND SWAISGOOD, H.E.	943
ANALYSIS OF ANTIBIOTICS USING SUPERCRITICAL FLUID EXTRACTION WITH SUPERCRITICAL FLUID CHROMATOGRAPHY/MS AND HPLC/MS TECHNIQUES *VOYKSNER, R.D., RAYMER, J., VELEZ, G. AND TYCZKOWSKA, K.	945
ANALYSIS OF CATIONIC HEAVY METAL ALKYLATES BY THERMOSPRAY LC/MS *LINSCHIED, M.	947
HPLC-MS ANALYSIS OF COCONUT AMINE SALTS *YELLE, L.M. AND FARROW, P.E.	949
ANALYSIS OF ENVIRONMENTALLY SIGNIFICANT COMPOUNDS BY THERMOSPRAY EI LC-MS *WINN, D. AND VESTAL, M.L.	951
PEPTIDE MAPPING USING THERMOSPRAY LC/MS/MS *KANAI, M. AND RUDEWICZ, P.	953
A FACILE METHOD FOR THE PREPARATION AND LC/MS CHARACTERIZATION OF BENZYLOXYCARBONYL METHYL ESTERS DERIVATIVES OF REDUCED GLUTATHIONE, CYSTEINE AND CORRESPONDING XENOBIOTIC-THIOETHER CONJUGATES *RASHED, M.S., TALAAT, R.E. AND BAILLIE, T.A.	955
STRUCTURE DETERMINATION OF IMPURITIES IN A SYNTHESIS OF A PROTECTED DIAZABICYCLOHEPTANE BY LC/MS *ROSNACK, K.J., STROH, J.G. AND COHEN, M.J.	957
INVESTIGATION OF PRAVADOLINE METABOLITES BY THERMOSPRAY MASS SPECTROMETRY *JOHNSON, J.A., GONYEA, G.J. AND BAKER, J.F.	959
METABOLISM AND CARCINOGENICITY OF HAIR DYES: A TSP LC/MS STUDY *PARKER, C.E., TOMER, K.B., KARI, F.W., DRISCOLL, S.M. AND RUDD, K.M.	961
A COMPARISON OF MASS SPECTROMETRY OF DYES GENERATED BY PARTICLE BEAM AND THERMOSPRAY LC/MS YINON, J., JONES, T.L. AND *BETOWSKI, L.D.	963

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

A STUDY OF CHLORINATED HERBICIDES BY HPLC/THERMOSPRAY/MASS SPECTROMETRY (HPLC/TSP/MS) *JONES, T.L., BETOWSKI, L.D. AND YINON, J.	965
THERMOSPRAY LC-MS ANALYSIS OF AN INSECTICIDE CONTAINING A SERIES OF NEREISTOXIN ANALOGS HANSEN, E.B., GETEK, T.A., *KORFMACHER, W.A., XIA, S.J., KUO, W.S., WANG, X.T. AND CHOU, M.W.	967
GC/MS AND LC/MS IN THE ANALYSIS OF NPPD ("SPY DUST") *BURSEY, J., MOSEMAN, R., PARKER, C., TOMER, K. AND JAMESON, C.	969
A DERIVATIVE WITH ENHANCED NCI-MS SENSITIVITY FOR OLIGOSACCHARIDE SAMPLES: SYNTHESIS, SAMPLE DERIVATIZATION, AND SFC-MS SENSITIVITY STUDIES *CAESAR, J.P., SHEELEY, D.M., JOHNSON, R.S. AND REINHOLD, V.N.	971
INTERFACING CHROMATOGRAPHIC TECHNIQUES TO MULTIPHOTON IONIZATION MASS SPECTROMETRY KOSTER, C., ROHWER, E.R., *GROTEMEYER, J. AND SCHLAG, E.W.	973
SUPERCritical FLUID CHROMATOGRAPHY/CHEMICAL IONIZATION MASS SPECTROMETRY (SFC/CIMS) IN A THERMOSPRAY SOURCE *MUSSER, S.M. AND CALLERY, P.S.	975
ELECTRON IMPACT MASS SPECTRA WITH SFC/MS *CHUNG, H.L., MOORE, D.S., ALDRIDGE, J.C., GORDON, B.M. AND COLEMAN, W.M.	977
HIGH PRESSURE LIQUID NH ₃ INJECTION OF POLAR MOLECULES INTO A MASS SPECTROMETER WITH RESONANT TWO-PHOTON IONIZATION DETECTION PANG, H.M. AND *LUBMAN, D.M.	978
APPLICATION OF SUPERCRITICAL FLUID CHROMATOGRAPHY-MASS SPECTROMETRY TO N-LINKED GLYCANS *SHEELEY, D.M. AND REINHOLD, V.N.	980
SUPERCritical FLUID CHROMATOGRAPHY-MASS SPECTROMETRY FOR CHARACTERIZATION OF COMMERCIAL SURFACTANT MIXTURES *KALINOSKI, H.T. AND HARGISS, L.O.	982
ION SPRAY LC/API-MS OF MORFINANS LANTING, A., DRENTH, B.F.H., BOSMAN, J. AND *BRUINS, A.P.	984
IDENTIFICATION OF TRACE LEVELS OF UNKNOWN CONJUGATED QUINONES USING NICI ENHANCEMENT BY DIRECT LC/MS ANALYSIS *NG, K., PIATEK, B., PATRIANAKOS, C. AND KARLINER, J.	986
COMPARISON OF THERMOSPRAY AND CONTINUOUS FLOW FAB LC/MS METHODS FOR THE ANALYSIS OF ACYL-CoA COMPOUNDS *NORWOOD, D.L., BUS, C.A. AND MILLINGTON, D.S.	988
EFFICIENT INTRODUCTION OF HPLC FRACTIONS INTO A HIGH PERFORMANCE TANDEM MASS SPECTROMETER *CAPPIELLO, A., PALMA, P., PAPAYANNOPOULOS, I.A., BIEMANN, K., CRESCENTINI, G. AND BRUNER, F.	990
CONDITIONS FOR MICROBORE LIQUID CHROMATOGRAPHY OF PEPTIDES FOR CONTINUOUS-FLOW FAB PRAMANIK, B.C., DOURDEVILLE, T.A. AND *SLAUGHTER, C.A.	992
ABSORBENT EVAPORATOR FOR CONTINUOUS FLOW LIQUID SIMS *SHIH, M., WANG, T.-C.L. AND MARKEY, S.P.	994
LINKED SCAN AND CONTINUOUS FLOW FAB ANALYSIS OF NUCLEOSIDE-PAH DNA ADDUCTS *ANNAN, R.S., NELSON, R.J., GIESE, R.W. AND VOURES, P.	996

CONTINUOUS-FLOW FAST ATOM BOMBARDMENT LC/MS IN BIOANALYSIS KOKKONEN, P., NIESSEN, W.M.A., TJADEN, U.R. AND *VAN DER GREEF, J.	998
CONTINUOUS FLOW FAB-MS FOR RAPID STRUCTURAL COMPARISON OF ANALOGOUS THERAPEUTIC PROTEINS MOCK, K., FIRTH, J., EVANS, S. AND *COTTRELL, J.	1000
CF-FAB AND MICRODIALYSIS FOR ANALYSIS BLOOD LEVELS OF DRUGS IN LIVE ANIMALS: MULTIPLE DOSAGE PHARMACOKINETICS *LIN, S-N., CHANG, S. AND CAPRIOLI, R.M.	1002
ANALYSIS OF URINARY ACYLCARNITINES BY DYNAMIC FIB MS/MS *CLENCH, M., WILSON, S., WEIR, O., MILLS, G. AND WALKER, V.	1004
ANALYSIS OF PROTEOLYTIC DIGESTS AND PEPTIDE MIXTURES USING COAXIAL CONTINUOUS FLOW FAB MASS SPECTROMETRY DETERDING, L.J., JORGENSEN, J.W., MOSELEY, M.A., *PLEASANCE, S., THIBAUT, P. AND TOMER, K.B.	1006
MICROBORE AND MICROCAPILLARY HPLC ANALYSIS OF GLYCOPEPTIDE ANTIBIOTICS USING CONTINUOUS FLOW FAB LC-MS COUTANT, J.E., CHEN, T-M. AND *ACKERMANN, B.L.	1008
MICROCOLUMN LC/CONTINUOUS FLOW FAB MS - APPLICATIONS TO AGRICULTURAL CHEMICALS RESEARCH *REISER, R.W.	1010
EXAMPLES OF THE USE OF A PARTICLE BEAM INTERFACE FOR THE HPLC/MS ANALYSIS OF NON-GAS CHROMATOGRAPHABLE ANALYTES *HUGHES, B.M., MCKENZIE, D.E., DOI, J.D. AND ZINKL, M.A.	1012
LC/MS DETERMINATION OF PROTEINS AND LARGE PEPTIDES *HENION, J., COVEY, T., MUCK, W. AND HUANG, E.	1014
ANALYSIS OF ENZYMATICALLY DIGESTED PROTEINS BY ON LINE CAPILLARY HPLC/FAB/MS *BOURELL, J.H., HENZEL, W.J. AND STULTS, J.T.	1015

Instrumentation

A NEW INSTRUMENT FOR THE ANALYSIS OF HIGH MOLECULAR WEIGHT BIOMOLECULES *JARVIS, S., BATEMAN, R.H. AND GREEN, B.N.	1017
DESIGN AND PERFORMANCE OF A NEW MAGNETIC SECTOR MASS SPECTROMETER WITH DOUBLE FOCUSING DIMIDATE GEOMETRY *BERTRAND, M.J., BOTT, P.A., PORTER, C.J. AND BATEMAN, R.H.	1019
A HIGH SENSITIVITY/HIGH RESOLUTION TANDEM MASS SPECTROMETER FOR HIGH MASS BIOMOLECULES *RUSSELL, D.H.	1021
A TANDEM QUADRUPOLE MASS SPECTROMETER OF NOVEL GEOMETRY OPTIMISED FOR INTELLIGENT DATA ACQUISITION *MCDOWALL, M.A., MERREN, T.O. AND BUTLER, I.	1023
ION TRANSMISSION CONSIDERATIONS IN TANDEM QUADRUPOLE MS-MS *MCDOWALL, M.A., MERREN, T.O. AND HAMMOND, M.J.	1025
A PENTAQUADRUPOLE MASS SPECTROMETER: INSTRUMENTATION, SYSTEM CONTROL, AND APPLICATIONS TO MS/MS/MS SCANS *SCHWARTZ, J.C., SCHEY, K.L. AND COOKS, R.G.	1027

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

HIGH RESOLUTION DAUGHTER ION ANALYSIS APPLICATIONS IN HYBRID MASS SPECTROMETRY *GRANT, B.C., MCBAY, E.H., MCLUCKEY, S.A. AND GLISH, G.L.	1029
RESIDUAL GAS ANALYZERS AS INEXPENSIVE SOURCES OF MASS-SELECTED ION BEAMS *GILBERT, J. AND ALLISON, J.	1031
NEW B-Q TANDEM MASS SPECTROMETER *LAUE, H.J. AND HABFAST, K.	1033
PERFORMANCE OPTIMIZATION OF A KRATOS MS80RFAQ MASS SPECTROMETER FOR HIGH MASS OPERATION TO MASS 6,000 *HANSEN, G. AND MCKELLOP, K.	1035
INTERFACING MULTIPLE ION SOURCES WITH A QUADRUPOLE ELECTROSTATIC DEFLECTOR *MAHAFFY, P. AND LAI, K.	1037
DESIGN OF A FOCUSED CESIUM ION SOURCE FOR CONTINUOUS FLOW LIQUID SIMS WANG, T.-C.L., *MARKEY, S.P. AND BONI, R.	1039
MASS SPECTROMETRIC DETECTION OF THIN LAYER CHROMATOGRAPHY USING PULSED LASER EVAPORATION WITH UV LASER IONIZATION LI, L. AND *LUBMAN, D.M.	1041
DIRECT FAB-MS FROM EMPORE TLC SHEETS *MINARD, R.D. AND LONG, E.J.	1043
COMPARISON OF LC/MS PARTICLE BEAM SPECTRA WITH DCI AND DEI PROBE SPECTRA *DILTS, M.J. AND MARECIC, T.	1045
COMPARISON OF GC/MS AND GC/MS/MS FOR THE ANALYSIS OF CGS-18416A *HAYES, M.J., KHEMANI, L. AND GAUDRY, D.	1047
DIRECTLY COUPLED SUPERCRITICAL FLUID EXTRACTION-GAS CHROMATOGRAPHY/MASS SPECTROMETRIC ANALYSIS OF ORGANIC COMPOUNDS FROM SOLID SAMPLES *MILLER, D.J., HAWTHORNE, S.B. AND KRIEGER, M.S.	1049
DIRECT COUPLING OF SUPERCRITICAL FLUID CHROMATOGRAPHY WITH SECONDARY ION MASS SPECTROMETRY *WENCLAWIAK, B., SICHTERMANN, W. AND BENNINGHOVEN, A.	1051
AN OPTICAL CCD CAMERA INTEGRATED WITH A SECONDARY ION MASS SPECTROMETER FOR ANALYSIS OF PLANAR CHROMATOGRAMS *BROWN, S.M., DOHERTY, S.J. AND BUSCH, K.L.	1053
EVALUATION AND OPTIMIZATION OF A CCD DETECTOR FOR SIMS IMAGING *MANTUS, D.S., TURNER, L.K., LING, Y.-C. AND MORRISON, G.H.	1055
DIRECT INTERFACE OF A RUSKA THERMA-CHROM WITH AN HP 5985B GC/MS *GALE, P.J., BENTZ, B.L., WORDEN, R.D., SMITH, D., KING, D.B., SIZEMORE, E. AND IPPOLITO, M.L.	1057
A DATA SYSTEM FOR DAUGHTER ION MEASUREMENTS WITH A REFLECTING TIME-OF-FLIGHT MASS SPECTROMETER *ENS, W. AND STANDING, K.G.	1059
A NEW TIME-OF-FLIGHT SECONDARY ION MICROSCOPE *SCHUELER, B.W., REED, D.A. AND SANDER, P.	1061
GC-MS BY TIME-OF-FLIGHT MASS SPECTROMETRY WITH TIME ARRAY DETECTION *SCHULTZ, G.A., TECKLENBURG, R., HOLLAND, J.F., WATSON, J.T. AND ALLISON, J.	1063

ION KINETIC ENERGY RELEASE MEASUREMENT BY POST-SECTOR BEAM DEFLECTION IN TIME-RESOLVED ION MOMENTUM SPECTROMETRY WITH TIME ARRAY DETECTION *LOPSHIRE, R.F., ECKENRODE, B.E., STULTS, J.T., ENKE, C.G. AND HOLLAND, J.F.	1065
MASS DEPENDENCE OF FOCUSING PARAMETERS IN TIME-OF-FLIGHT MASS SPECTROMETRY *ERICKSON, E.D., YEFCHAK, G.E. AND ENKE, C.G.	1067
POST SOURCE PULSE FOCUSING-A SIMPLE METHOD TO ACHIEVE IMPROVED RESOLUTION IN A TIME-OF-FLIGHT MASS SPECTROMETER *KINSEL, G.R. AND JOHNSTON, M.V.	1069
ORGANIC SECONDARY ION TIME-OF-FLIGHT MASS SPECTROMETRY WITH A FOCUSED LIQUID METAL ION PRIMARY BEAM JIANG, L.F., YEN, T.Y. AND *BAROFSKY, D.F.	1071
EXTENDED LIFETIME CONTINUOUS DYNODE ELECTRON MULTIPLIERS KURZ, E.A., LORETZ, T.J. AND *ROY, R.L.	1073
HIGH SENSITIVITY ION DETECTOR PARAMETRIC STUDY *PEREL, J., MAHONEY, J.F., LEE, T.D. AND LEGESSE, K.	1075
A FLEXIBLE ARRAY DETECTOR OF EXTENDED MASS RANGE FOR A HIGH PERFORMANCE TANDEM MASS SPECTROMETER *HILL, J.A., BILLER, J.E., MARTIN, S.A., BIEMANN, K. AND ISHIHARA, M.	1077
A VERSATILE ARRAY DETECTION SYSTEM *PESCH, R., JUNG, G., ROST, K. AND TIETJE, K.-H.	1079
DETECTION OF HIGH MOLECULAR WEIGHT IONS BY CHANNELPLATE DETECTORS *NIEHUIS, E., DEIMEL, M. AND BENNINGHOVEN, A.	1081
DEVELOPMENT OF AN ARRAY DETECTOR FOR WIDE MASS RANGE DETECTION *MUSSELMAN, B.D., DIXON, M., ELLIS, G., SATO, K. AND ISHIHARA, M.	1083
PERFORMANCE RELATED CHARACTERISTICS OF LINEAR ARRAY DETECTORS FOR MASS SPECTROMETRY *GRAY, J.W. AND HOOPER, J.B.	1085
DESIGN OF AN ION OPTICS USING A QUADRUPOLE DOUBLET(QPD) FOR ZOOMING MASS RANGE ON AN ARRAY DETECTOR *ISHIHARA, M., KUNITHIRO, F., OTSUKA, K., KAMMEI, Y., KUBOTA, E., ITAGAKI, Y., HIGUCHI, T. AND MUSSELMAN, B.C.	1087
DESIGN CONSTRUCTION AND CHARACTERIZATION OF ION DECELERATION LENSES. WHAT ARE THE SIMPLICITY/PERFORMANCE TRADEOFFS? *O'CONNOR, P. AND ALLISON, J.	1089
IONIZATION TECHNIQUES BASED ON PROPERTIES OF SUPERCRITICAL FLUIDS: II INSTRUMENTATION *LARKINS, W. AND OLESIK, S.V.	1091
HIGH ENERGY DYNODE (HED) ELECTRON MULTIPLIER DELIVERS INCREASED HIGH MASS SENSITIVITY FOR QUADRUPOLE MASS SPECTROMETERS FJELDSTEAD, J., *GOODLEY, P.C. AND HANSEN, S.	1092
ION TRAJECTORY MODELLING IN AN ION MOBILITY SPECTROMETER EMPLOYING NONLINEAR ELECTRIC FIELDS *ECKENRODE, B.A., MCLUCKEY, S.A. AND GLISH, G.L.	1094
NUMERICAL CALCULATION OF ION TRAJECTORIES IN A QUADRUPOLE MASS FILTER WITH CIRCULAR CROSS SECTION ELECTRODES *TAYLOR, L.C.E. AND SEDGWICK, R.D.	1096

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

A PC-BASED LINKED SCAN CONTROL AND DATA ACQUISITION SYSTEM CAPABLE OF REAL-TIME SIGNAL AVERAGING *MARTIN, W.B., COTTER, R.J., HENDERSON, L.E. AND FRASURE, W.	1098
AN IMPROVED INTERFACE DESIGN FOR DETERMINING RADIOISOTOPE PURITY BY RADIOGAS CHROMATOGRAPHY MASS SPECTROMETRY *KASTL, P.E., LANGVARDT, P.W., BARTELS, M.J. AND BRZAK, K.A.	1100
CHARACTERISTICS OF A HIGH RESOLUTION ICP-MS INSTRUMENT *BRADSHAW, N., SANDERSON, N.E. AND CANTLE, J.E.	1102
ICP-MS MEASURABILITY LIMITS IN CONCENTRATED SOLUTIONS *BEAUGRAND, C., DELAPORTE, T. AND DEVANT, G.	1104
PRECISE MASS MEASUREMENT OF FAB IONS USING AN ALTERNATING SAMPLE PROBE AND PEAK MATCHING ON THE KRATOS MS50 *HOGG, A.	1106
FIELD DESORPTION OF ORGANIC POLYMERS *DAVIS, S.C. AND BEATY, T.C.	1108
AN AUTOMATED SOLIDS INSERTION PROBE SYSTEM FOR AN ORGANIC MASS SPECTROMETER *SMITH, D.C., GOULD, V., MISTRY, H. AND TODD, D.E.	1110
PREDICTION OF RELATIVE SENSITIVITIES IN ELECTRON IONIZATION MASS SPECTROMETRY *ALLGOOD, C. AND MUNSON, B.	1112
INTERNAL STANDARD SYSTEM FOR USE WITH APCI MASS SPECTROMETERS *NELSON, P.R.	1114
NON-CONTAMINATING CI MASS CALIBRATION STANDARDS FOR QUADRUPOLE AND MAGNETIC INSTRUMENTS *HSU, F-F., TYLER, A.N. AND SHERMAN, W.R.	1115
THE DYNAMICS OF IONS IN THE DRIFT REGION OF A CORONA-TYPE MS SOURCE: SOME MATHEMATICAL MODELS SUNNER, J. AND *BUSMAN, M.	1118
INSTRUMENT-INDEPENDENT CAD DATABASE FOR XQQ INSTRUMENTS: CH ₃ CO+ --Ar CAD-CH ₃ + +CO *MARTINEZ, R.I. AND GANGULI, B.	1120

THURSDAY ORAL SESSIONS

Symposium: Tandem MS in the Solution of Peptide & Protein Structural Problems

STRUCTURE DETERMINATION OF PEPTIDES AND PROTEINS BY HIGH PERFORMANCE TANDEM MASS SPECTROMETRY *BIEMANN, K.	1122
PROTEIN STRUCTURAL PROBLEMS, THE ROLE OF TANDEM MASS SPECTROMETRY *HUNT, D.F., SHABANOWITZ, J., GRIFFIN, P.R., ZHU, N.Z., YATES III, J.R. AND MARTINO, P.	1125
FOUR-SECTOR MS/MS OF PEPTIDE TOXINS, INVERTEBRATE NEUROPEPTIDES AND TRYPTIC DIGESTS *RINEHART, K.L., THOMPSON, A.G., RONG, L., MILBERG, R.M. AND CURTIS, J.M.	1128

- AN INTEGRATED APPROACH TO PEPTIDE AND PROTEIN STRUCTURE ANALYSIS 1131
UTILIZING TANDEM HIGH PERFORMANCE MASS SPECTROMETRY
*CARR, S.A., BEAN, M.F., HEMLING, M.E. AND ROBERTS, G.D.

Inorganic Elemental Analysis and Instrumentation

- 252 CF-PLASMA DESORPTION MASS SPECTROMETRY OF Au67(PPH3)14C18 1133
*MCNEAL, C.J., WINPENNY, R.E.P., FACKLER, J.P. AND MACFARLANE, R.D.
- FABMS AND FABMS/MS STUDIES ON INORGANIC AND ORGANOMETALLIC COMPOUNDS 1135
*THOMPSON, A.G., RONG, L.-S., CURTIS, J.M., SUN, F., MILBERG, R.M.,
SUSLICK, K.S., BIBLE, K.C., SHAPLEY, J.R. AND RINEHART, K.L.
- FTMS STUDY OF THE ELECTRON AFFINITY OF TRANSITION METAL TRIS 1137
(ACETYLACETONATO) COORDINATION COMPOUNDS
RICHARDSON, D.E., *SHARPE, P., RYAN, M.F. AND EYLER, J.R.

Symposium: Comparison of Ionic Reactions in Gas Phase and in Solution

- AROMATIC SUBSTITUTION REACTIONS BY RADICAL CATIONS 1157
*GRUTZMACHER, H.-F. AND THOELMANN, D.
- SOLVOLYSIS AND PROTONATION: POSITIVE ION FORMATION IN THE GAS PHASE AND 1159
IN SOLUTION
*MORTON, T.H.

SOLVENT AND STRUCTURAL EFFECTS IN GASEOUS ION ENERGETICS AND REACTIONS *MCMAHON, T.B.	1160
BIMOLECULAR REACTIONS AND STRUCTURES OF IONS IN THE GAS PHASE *NIBBERING, N.M.M.	1163

Symposium: State of the Art Research in Mass Spectrometry

DRUG METABOLISM MADE EASY (SOMETIMES): THE USE OF TANDEM MS TECHNIQUES FOR RAPID STRUCTURE ELUCIDATION *STRAUB, K.	1165
ULTRAVIOLET LASER DESORPTION OF BIOMOLECULES IN THE HIGH MASS RANGE *HILLENKAMP, F. AND KARAS, M.	1168
RECENT DEVELOPMENTS IN ISOTOPE ABUNDANCE MEASUREMENTS *DELAETER, J.R.	1170
RECENT COMPUTER APPLICATIONS IN MASS SPECTROMETRY *WILKINS, C.L.	1173

Biochemistry II

FAB/MS AND FAB/MS OF PROTEOLYTIC DIGESTS OF BOVINE ALDOSE REDUCTASE *THOMPSON, A.G., RONG, L-S., MILBERG, R.M., SUN, F. AND RINEHART, K.L.	1175
MOLECULAR WEIGHT DETERMINATION OF RECOMBINANT HUMAN GROWTH HORMONE WITH AN ATMOSPHERIC PRESSURE ION SOURCE QUADRUPOLE MASS SPECTROMETER *CHAKEL, J. AND COVEY, T.	1177
QUANTIFICATION BY GC/MS OF SEPARATED ENANTIOMERS OF ARABINITOL TO AID THE DIFFERENTIAL DIAGNOSIS OF DISSEMINATED CANDIDIASIS *ROBOZ, J., NIEVES, E. AND HOLLAND, J.F.	1179
RELATIONSHIP OF THE STRUCTURE OF SUBUNIT CONTAINING PROTEINS TO THEIR ION EVAPORATION SPECTRA *COVEY, T.R., SUSHAN, B.I., BONNER, R.F. AND HENION, J.	1181
INFLUENCE OF THE RATIO OF GLYCEROL TO ANALYTE ON FAB-MS ANALYSES *HEINE, C.E., HOLLAND, J.F. AND WATSON, J.T.	1182
DIFFERENTIATION OF LEAFY SPURGE (EUPHORBIA ESULA L.) ACCESSIONS BASED ON CHEMICAL CONSTITUTION USING CURIE POINT PYROLYSIS-MASS SPECTROSCOPY-PATTERN RECOGNITION VALCARCE, R.V., *SMITH, G.G., TORELL, J.M. AND EVANS, J.O.	1184
MATRIX ASSISTED UV LASER DESORPTION OF BIOLOGICALLY INTERESTING MOLECULES *CHAIT, B.T.	1186
STRUCTURAL ANALYSIS OF COMPLEX BACTERIAL OLIGOSACCHARIDES BY TWO-AND FOUR-SECTOR LSIMS *JOHN, C.M. AND GIBSON, B.W.	1188
HIGH ENERGY CID OF OLIGOSACCHARIDES (MS-MS) USING MULTICHANNEL ARRAY DETECTION *GILLECE-CASTRO, B. AND BURLINGAME, A.L.	1190
SEPARATION OF HIGH MANNOSE OLIGOSACCHARIDE ISOMERS AND THEIR CHARACTERIZATION BY MASS SPECTROMETRY *JOHNSON, R.S., COSTELLO, C.E. AND REINHOLD, V.N.	1192

LDI-FT-ICR MASS SPECTROMETRY OF OLIGOSACCHARIDES *COMISAROW, M.B., DUTTON, G.G.S., LAM, Z., WEIL, D.A. AND BJARNASON, A.	1194
FAST ATOM BOMBARDMENT MASS SPECTRAL BEHAVIOR OF SACCHARIDES AND NUCLEOSIDES: MATRIX EFFECT *OSEI-TWUM, E.Y. AND MAMER, O.A.	1196

Symposium: Organometallic Mass Spectrometry

CHEMISTRY OF IONS DERIVED FROM METAL CARBONYLS PAN, Y.H. AND *RIDGE, D.P.	1198
"DAMAGE CONTROL" IN CHARACTERIZING COMPLEXES *COOK, K.D. AND REYNOLDS, J.D.	1201
STRUCTURE AND CHEMISTRY REVEALED BY THE MS AND MS/MS SPECTRA OF INORGANICS AND ORGANOMETALLICS *COSTELLO, C.E.	1204
MASS SPECTROMETRY OF METAL-LINKED DIMERS AND COVALENT HEME PRODUCTS *COTTER, R.J. AND CHEN, L.	1207

THURSDAY POSTER SESSIONS

FT/MS and Ion Traps

ADVANCED FEATURES OF A FAST BUFFER BOARD FT-ICR INTERFACE TO A PERSONAL COMPUTER *GUAN, S. AND JONES, P.R.	1210
ENHANCED MASS RESOLUTION OF BROADBAND FT-ICR MASS SPECTRA BY THE MAXIMUM ENTROPY METHOD (MEM) *GUAN, S. AND JONES, P.R.	1212
AN ADVANCED DATA SYSTEM FOR FT/ICR *MEEK, J.T., MILLEN, W.G., STOCKTON, G.W. AND WAYNE, R.S.	1214
A COMPARISON OF SEVERAL APODIZATION FUNCTIONS FOR SWIFT WAVEFORMS *HEARN, B.A. AND EYLER J.R.	1216
A NEW METHOD FOR GENERATING SWIFT WAVEFORMS FOR FTMS *GOODMAN, S.D.	1218
THEORY OF IMPULSE EXCITATION FOR FOURIER TRANSFORM MASS SPECTROMETRY *BAYKUT, G., MCIVER, R.T. AND HUNTER, R.L.	1220
INCORPORATION OF AVERAGED ION-ION INTERACTION INTO A MODEL FOR PEAK SHAPES IN FTMS *REMPER, D.L. AND GROSS, M.L.	1222
A MODEL FOR THE REDUCTION OF MASS MEASUREMENT ERRORS DUE TO ION-ION INTERACTION IN FTMS *YANG, S.S., REMPEL, D.L. AND GROSS, M.L.	1224
ELIMINATION OF Z-EJECTION IN FT/ICR BY RF ELECTRIC FIELD SHIMMING *WANG, M. AND MARSHALL, A.G.	1226
A SCREENED STATIC ELECTROMAGNETIC ION TRAP FOR FT/ICR: ENHANCED MASS RESOLUTION, MASS ACCURACY, MS/MS, REPRODUCIBILITY, AND UPPER MASS LIMIT *WANG, M. AND MARSHALL, A.G.	1228

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

SOLUTION OF THE EQUATIONS OF ION MOTION DURING THE ION CYCLOTRON RESONANCE EXCITATION EVENT GROSSHANS, P.B. AND *MARSHALL, A.G.	1230
A NEW METHOD FOR CALCULATING THE SIGNAL INDUCED ON ICR DETECTOR PLATES GROSSHANS, P.B., *MARSHALL, A.G. AND SHIELDS, P.	1232
PRECISION IN DETERMINATION OF RELATIVE ION ABUNDANCES FROM FT/ICR MASS SPECTRA: ABSORPTION PEAK AREA IS SUPERIOR TO PEAK HEIGHT OR COMPLEX AREA LIANG, Z. AND *MARSHALL, A.G.	1234
EFFECT OF SAMPLING RATE ON FT/ICR MASS SPECTRA: IS OVERSAMPLING OVERRATED? ALBER, G.M. AND *MARSHALL, A.G.	1236
ISOTOPE-RATIO MEASUREMENTS BY FT/ICR: ESTIMATING INITIAL AMPLITUDES AND DAMPING CONSTANTS FROM SEGMENTED TIME SERIES *MITCHELL, D.W. AND DELONG, S.E.	1238
ICR EXPERIMENTS ON SHORT-LIVED ISOTOPES AND CLUSTERS: NEW THEORETICAL AND EXPERIMENTAL RESULTS *SCHWEIKHARD, L., AUDI, G., BECKER, S.T., BLUNDSCHLING, M., BOLLEN, G., EGELHOF, P., JERTZ, R., KLUGE, H.-J., KERN, F. AND KUNZ, K.	1240
IN-SITU PYROLYSIS AND THERMAL DESORPTION IN AN ION TRAP MASS SPECTROMETER *YOUNG, S. AND COGGIOLA, M.J.	1242
ION INJECTION INTO AN FTMS *CAMPANA, J.E., SHABANOWITZ, J. AND SHOHET, J.L.	1244
EXTERNAL ION SOURCES ON ION CYCLOTRON RESONANCE (ICR) MASS SPECTROMETERS ION-OPTICAL CONSIDERATIONS *DAVIS, S.C., DERRICK, P.J. AND GREATHEAD, R.J.	1246
A SIMPLE DIFFERENTIALLY PUMPED EXTERNAL SECONDARY ION SOURCE FOR FTMS *IJAMES, C.F. AND WILKINS, C.L.	1248
NEGATIVE IONIZATION IN QUADRUPOLE ION TRAP MASS SPECTROMETRY: EFFECTS OF APPLIED VOLTAGES AND REACTION TIMES *BERBERICH, D.W. AND YOST, R.A.	1250
CALIBRATION AND ACCURATE MASS MEASUREMENT WITH GC-FTMS USING AN EXTERNAL ION SOURCE *GROSSMANN, P. AND KELLERHALS, H.P.	1252
MULTIPHOTON IONIZATION ON A FOURIER TRANSFORM MASS SPECTROMETER WITH AN EXTERNAL ION SOURCE *GROSSMANN, P., ALLEMAN, M., LOEPFE, M. AND KELLERHALS, H.P.	1254
USE OF HIGH VOLTAGE PULSES TO STUDY LASER DESORBED IONS IN A DUAL CELL FT/ICR *HONOVICH, J.P. AND MARKEY, S.P.	1256
LASER DESORPTION WITHIN THE ION TRAP CAVITY: OPTIMIZATION AND APPLICATION *HELLER, D.N., COTTER, R.J. AND UY, O.M.	1258
APPLICATIONS OF LASER DESORPTION IN AN ION TRAP MASS SPECTROMETER *GOERINGER, D.E., GLISH, G.L., ASANO, K.G. AND MCLUCKEY, S.A.	1260
AMMONIUM HYDROXIDE CHEMICAL IONIZATION MASS SPECTROMETRY *CODY, R.B.	1262
ION TRAP GC/MS/MS DETERMINATION OF EICOSANOIDS STRIFE, R.J. AND *SIMMS, J.R.	1264

ION TRAP QUANTITATIVE MS/MS ASSAYS USING RF/DC *STRIFE, R.J., SIMMS, J.R. AND LACEY, M.P.	1266
PHASE ANGLE SYNCHRONIZATION BY FREQUENCY SWEEP EXCITATION IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE *HANSON, C.D., CASTRO, M.E. AND RUSSELL, D.H.	1268
THE EFFECT OF MAGNETIC INHOMOGENEITIES ON ION PARTITIONING IN A TWO-SECTION FT-ICR CELL *KERLEY, E.L., HANSON, C.D., CASTRO, M.E. AND RUSSELL, D.H.	1270
MEASUREMENTS OF KINETIC ENERGIES OF ION MOLECULE REACTION PRODUCT IONS BY FOURIER TRANSFORM ION CYCLOTRON RESONANCE *CASTRO, M.E., KERLEY, E.L., HANSON, C.D. AND RUSSELL, D.H.	1272
A FIELD CORRECTED ION CELL FOR INCREASED PERFORMANCE IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE *HANSON, C.D., CASTRO, M.E. AND RUSSELL, D.H.	1274
PULSED ION INJECTION WITH AN EXTERNAL SOURCE TIME-OF-FLIGHT FTMS *BEU, S.C., LAUDE, D.A. AND HOGAN, J.D.	1276
ANALYTICAL APPLICATIONS OF LASER DESORPTION AND PHOTODISSOCIATION FOURIER TRANSFORM MASS SPECTROMETRY *NUWAYSIR, L.M. AND WILKINS, C.L.	1278

Metabolism and Toxicology

CONFIRMATION OF NEWLY IDENTIFIED AMPICILLIN METABOLITES *SUWANRUMPHA, S. AND FREAS, R.B.	1280
NOVEL PATHWAYS FOR THE OXIDATIVE DEGRADATION OF ALIPHATIC CHAINS IN CANNABINOID METABOLISM *HARVEY, D.J.	1282
A METHOD FOR THE IDENTIFICATION OF TETRAHYDROCANNABINOL METABOLITES BY GC/MS USING CATALYTIC HYDROGENATION *HARVEY, D.J. AND BROWN, N.K.	1284
CANNABICHROMENE METABOLISM IN THE RABBIT: A NEW METHOD FOR METABOLITE IDENTIFICATION AND THE CHARACTERIZATION OF EIGHT NEW DIHYDROXY METABOLITES *HARVEY, D.J. AND BROWN, N.K.	1286
METABOLISM OF CANNABIDIOL BY THE DOG: IDENTIFICATION OF GLUCOSE CONJUGATES AS THE MAJOR URINARY METABOLITES *HARVEY, D.J. AND SAMARA, E.	1288
TANDEM (MS/MS) MASS SPECTROMETRY UTILIZING ELECTRON IMPACT IONIZATION AND MULTIPLE REACTION MONITORING FOR THE RAPID, SENSITIVE, AND SPECIFIC IDENTIFICATION AND QUANTITATION OF MORPHINE IN WHOLE BLOOD WITH 5 METER CAPILLARY COLUMN CHROMATOGRAPHY *PHILLIPS, W.H., WADE, N., OTA, K., KITAGAWA, R., WARDEN, D., ZEHNDER, S., APPEL, T. AND DAVIS, G.	1290
AN IMPROVED METHOD FOR EXTRACTING OPIATES FROM URINE SAMPLES PRIOR TO FULL SCAN GC/MS ANALYSIS *DE KANEL, J. AND HALL, T.	1292
TRIPLE QUADRUPOLE AND QUADRUPOLE ION TRAP TANDEM MASS SPECTROMETRY (MS/MS) FOR THE DETERMINATION OF MORPHINE ALKALOIDS *JOHNSON, J.V. AND YOST, R.A.	1294

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

IDENTIFICATION OF FOUR NEW METABOLITES OF COCAINE IN HUMAN URINE SPECIMENS *ZHANG, J.Y. AND FOLTZ, R.L.	1296
CHARACTERIZATION OF URINARY METABOLITES OF NAPAMEZOLE HCl IN RATS, DOGS, MONKEYS AND HUMANS *JOHNSON, J.A., SEGER, N.A., STACK, R.F. AND BENZIGER, D.P.	1298
IDENTIFICATION OF PHASE II METABOLITES OF ANTIPSYCHOTIC DRUGS USING HPLC COMBINED WITH FAB-MS *MCKAY, G., JACKSON, C.J., SHU, Y.-Z., HUBBARD, J.W., HAWES, E.M. AND MIDHA, K.K.	1300
UTILITY OF LC-MS AND TANDEM MS FOR THE ANALYSIS OF THE RAT URINARY METABOLITES OF PYRILAMINE KORFMACHER, W.A., FREEMAN, J.P., *BLOOM, J., GETEK, T.A. AND HOLDER, C.L.	1302
CHARACTERIZATION OF THE URINARY METABOLITES OF TIBENELAST FROM MALE HUMANS USING LIQUID SECONDARY ION (LSIMS), DIRECT PROBE CHEMICAL IONIZATION (DCI) AND THERMOSPRAY (TSP) MASS SPECTROMETRY PEYTON, A.L., ZIEGE, E.A., GOODWIN, R.M. AND *BREAU, A.P.	1304
APPLICATION OF THERMOSPRAY LC-MS FOR THE ANALYSIS OF THENYLDIAMINE AND TRIPELENNAMINE AND THEIR MICROBIAL METABOLITES *KORFMACHER, W.A., GETEK, T.A., HANSEN, E.B. AND CERNIGLIA, C.E.	1306
THE DETERMINATION OF SERUM URIC ACID BY ISOTOPE DILUTION LC/MS AND LC/MS/MS *WELCH, M.J., CHRISTENSEN, R.G. AND ELLERBE, P.	1308
QUANTITATIVE DETERMINATION OF LEUCINE TRANSAMINATION IN THE FETUS FOLLOWING TRACER INFUSION OF 13-C LEUCINE *BROWN, K.A., EVANS, M.A., SCHAEFER, M.S. AND LIECHTY, E.A.	1310
ISOTOPE DILUTION METHOD FOR QUANTITATIVE GAS CHROMATOGRAPHY-MASS SPECTROMETRY OF HYDROXY AND KETO ACIDS IN URINE *OSEI-TWUM, E.Y. AND MAMER, O.A.	1312
DETERMINATION OF 13C-, 15N-, AND 2H- ENRICHMENT USING CAPILLARY GAS CHROMATOGRAPHY - REACTION INTERFACE / MASS SPECTROMETRY (GC-RIMS) CHACE, D.H. AND *ABRAMSON, F.P.	1314
QUANTIFICATION OF THIODIGLYCOL IN RAT URINE BY CAPILLARY COLUMN CHROMATOGRAPHY USING ELECTRON IONIZATION MASS SPECTROMETRY *JAKUBOWSKI, E.M., WOODARD, C.L. AND DOLZINE, T.W.	1316
APPLICATION OF FAST ATOM BOMBARDMENT AND THERMOSPRAY MASS SPECTROMETRY TO THE IDENTIFICATION OF TWO GLUCURONIDE METABOLITES OF METHAPYRILENE *LAY, J.O., GETEK, T.A., KELLY, D.W., SLIKKER, W. AND KORFMACHER, W.A.	1318
BIOACTIVATION OF 1,2-DIBROMO-3-CHLOROPROPANE TO FIVE GLUTATHIONE CONJUGATES IN VIVO: MECHANISM OF FORMATION AND DETECTION BY TANDEM MASS SPECTROMETRY *PEARSON, P.G., HOWALD, W.N. AND NELSON, S.D.	1320
A SCREENING STRATEGY FOR THE DETECTION OF DERIVATIZED GLUTATHIONE CONJUGATES BY TANDEM MASS SPECTROMETRY (MS/MS) *PEARSON, P.G., HOWALD, W.N., NELSON, S.D. AND BAILLIE, T.A.	1322
ANALYSIS OF BENZO(a)PYRENE METABOLITES BY CONTINUOUS-FLOW FAB/MS *TEFFERA, Y., BAIRD, W.M. AND SMITH, D.L.	1324
CHARACTERIZATION OF THE BILIARY METABOLITES OF THE HEPATOTOXIC MONOTERPENE PULEGONE BY TANDEM MASS SPECTROMETRY (MS/MS) *THOMASSEN, D., PEARSON, P.G. AND NELSON, S.D.	1326

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

RAPID SCREENING OF NEONATAL WHOLE BLOOD FOR VARIOUS METABOLIC DISORDERS BY FAB/MS/MS *KODO, N., NORWOOD, D.L. AND MILLINGTON, D.S.	1328
URINARY EXCRETION PATTERN OF DICARBOXYLIC ACID AND ACYL-CARNITINES IN THE PATIENTS TREATED WITH CALCIUM HOPANTENATE *MATSUMOTO, I., MATSUMOTO, M., KUHARA, T., SHINKA, T., INOUE, Y. AND OHKURA, T.	1330
CHARACTERIZATION OF ORGANIC NITROXIDE RADICALS BY MASS SPECTROMETRY *SWEETMAN, B.J., ANJANEYULU, P.S.R., BETH, A.H. AND STAROS, J.V.	1332
DETERMINATION OF INTACT STYRENE-7,8-OXIDE IN BLOOD USING AUTOMATED GAS CHROMATOGRAPHY-MASS SPECTROMETRY *LANGVARDT, P.W. AND NOLAN, R.J.	1334
MASS SPECTROMETRIC CHARACTERIZATION OF A PROPOSED PENULTIMATE METABOLITE OF LANOSTEROL DEMETHYLASE METABOLISM MCKAY, R.G., *LARSEN, B.S., FISCHER, R.T., KO, S.S., BROSZ, C., MAGOLDA, R.L. AND TRZASKOS, J.M.	1336
DETERMINATION OF RADIATION INDUCED CHOLESTEROL OXIDES BY ON-COLUMN CAPILLARY GC-MS *HARTMAN, T.G., ROSEN, R.T., MAERKER, G. AND LAKRITZ, L.	1338
CONTINUOUS FLOW L-SIMS, GC/MS AND BIOASSAY IN THE ISOLATION AND IDENTIFICATION OF PLANT TOXINS *DUNCAN, M.W., MARINI, A.M., WANG, T-C.L., SHIH, M-C. AND MARKEY, S.P.	1339
DETERMINATION OF ETHYL CARBAMATE (URETHANE) IN COMMERCIAL PROTEIN BASED CONDIMENT SAUCES (SOY SAUCES) BY GAS CHROMATOGRAPHY-MASS SPECTROMETRY *HARTMAN, T.G., ROSEN, R.T. AND LECH, J.	1341
AMMONIA CHEMICAL IONIZATION GCMS ANALYSIS OF POLYHYDROXY AMINES FROM PLANT SOURCES *APLIN, R.T., COFFEY, D.P.M., FLEET, G.W.J. AND FELLOWS, L.E.	1342
DETERMINATION OF MONO (2-ETHYL-HEXYL) PHTHALATE IN HUMAN SERUM ALBUMIN *ZAMECNIK, J., ETHIER, J-C., BLACK, D.B. AND NEVILLE, G.A.	1344
ANALYSIS AND MASS SPECTROMETRIC IDENTIFICATION OF FOOD DYES AND THEIR SUBSIDARY COLORED MATERIAL *SUZUKI, M., MASUDA, K., OKA, H. AND HARADA, K-I.	1346
MASS SPECTROMETRIC ANALYSIS OF IN VITRO METABOLITES OF FLUORINATED HERBICIDES FUJIWARA, H., SOLSTEN, R.T., *CHOTT, R.C. AND LOGUSCH, E.W.	1348
ANALYSES OF ACIDIC AND NEUTRAL CATECHOLAMINE METABOLITES IN BRAIN TISSUES, CSF, PLASMA AND URINE *CHANG, S.Y., REINHARD, J., COOPER, B. AND TAYLOR, L.C.E.	1350
QUANTITATION OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) AND THREE OF ITS METABOLITES IN RAT BRAIN BY ION TRAP MASS SPECTROMETRY *LIM, H.K. AND FOLTZ, R.L.	1352
METABOLISM OF KETOXIME ANALOGS OF BETA-ADRENERGIC BLOCKERS: GC/MS AND THERMOSPRAY LC/MS STUDIES *PROKAI, L. AND BODOR, N.	1354
FAST ATOM BOMBARDMENT OF WARFARIN AND WARFARIN METABOLITES *HILKER, D.R., ALDOUS, K.M., SPINK, D. AND KAMINSKY, L.	1356
SIMULTANEOUS PREPARATION OF ACIDIC BASIC AND NEUTRAL URINARY CONSTITUENTS FOR GC/MS *SHOEMAKER, J.D. AND ELLIOTT, W.H.	1358

SIMULTANEOUS DETERMINATION OF ACIDS AND AMINES BY GC-NCIMS *AVERY, M. AND JUNK, G.	1359
IDENTIFICATION OF MERCAPTURIC ACID METABOLITES OF ACRYLONITRILE BY TANDEM MASS SPECTROMETRY *TURNER, M.J., HELD, S.D. AND KEDDERIS, G.L.	1361

Ion Molecule Reactions II

VINYL ANION FORMATION AND REACTIVITY ANDERSON, K. AND *KASS, S.	1363
MULTIPLE, SITE-SPECIFIC REARRANGEMENTS IN THE ATMOSPHERIC PRESSURE IONIZATION MASS SPECTRA OF ALKYL PHOSPHONATE AND ALKYL PHOSPHATE ESTERS *SNYDER, A.P. AND HARDEN, C.S.	1365
A COMPARATIVE STUDY OF ISOELECTRONIC AND ISOGYRIC REACTIONS: MOLECULAR ORBITAL CALCULATIONS OF DIATOMIC HYDRIDES AND HALIDES *DEAKYNE, C.A., LIEBMAN, J.F., FRENKING, G. AND KOCH, W.	1367
LOW ENERGY CROSSED BEAM STUDIES OF THE CHARGE TRANSFER REACTION DYNAMICS OF $Ar+(2P_{3/2})$ WITH $O_2(X^3 \text{ } g^-)$ *BIGGERSTAFF, J., BIRKINSHAW, K., WANG, J., SHUKLA, A., HOWARD, S. AND FUTRELL, J.	1369
CROSS-SECTION FOR PROTON TRANSFER FROM LARGE BIOLOGICAL IONS TO SMALL MOLECULES IN THE GAS PHASE *DAVIS, S.C., DERRICK, P.J. AND GREATHEAD, R.J.	1371
FAB INDUCED CONDENSATION OF GLYCEROL WITH TETRAALKYL AMMONIUM SURFACTANTS *TUINMAN, A. AND COOK, K.	1373
FT-ICR DETERMINATION OF THE IONIZATION POTENTIALS OF CARBON CLUSTERS VIA CHARGE TRANSFER *BACH, S.B.H. AND EYLER, J.R.	1375
A CHARGE TRANSFER REACTION OF EXCITED CH_5^+ HERROLD, D., *LIN, H.Y. AND RIDGE, D.P.	1377
ON THE USE OF NEGATIVE ION CLUSTERING IN THE ANALYSIS OF SUBSTITUTED NITROBENZENES BY APIMS *ZOOK, D.R. AND GRIMSRUD, E.P.	1379
PROTON TRANSFER AND HYDROGEN HALIDE ELIMINATION REACTIONS OF HALOGENATED BENZENES FALCINI, M.R.A. AND *JENNINGS, K.R.	1381
DIFFERENTIATION OF OLEFINS AND NAPHTHENES USING ION-MOLECULE REACTIONS IN THE COLLISION CELL OF A HYBRID MASS SPECTROMETER *MISSLER, S.R. AND VASSILIADOU, M.	1383
GAS PHASE ION-MOLECULE REACTIONS OF CARBOCATIONS: RADIATIVE ASSOCIATION REACTIONS *PENTECOST, T.C. AND BABCOCK, L.M.	1385
NEUTRALIZATION-REIONIZATION STUDIES OF ISOMERIC IONS AND NEUTRALS *ZHANG, M.-Y., WESEMIOTIS, C., DRINKWATER, D.E., TURECEK, F. AND MCLAFFERTY, F.W.	1387
A PHOTOIONIZATION STUDY OF $C_4H_7^+$ IONS IN THE GAS PHASE *TRAEGER, J.C.	1389

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

DETERMINATION OF RADIATIVE ASSOCIATION RATE CONSTANTS BY FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY *FISHER, J.J. AND MCMAHON, T.B.	1391
DOUBLE IONIZATION ENERGIES OF FLUORETHANE MOLECULES MEASURED BY DOUBLE-CHARGE - TRANSFER-SPECTROSCOPY *GRIFFITHS, W.J. AND HARRIS, F.M.	1393
GAS-PHASE DEHYDROGENATION OF CYCLOALKANES TO AROMATIC HYDROCARBONS BY Os ⁺ , Os ²⁺ , Os ³⁺ TOLLENS, F.R. AND *MARSHALL, A.G.	1395
DIAMINE BASICITIES: A NEW MAXIMUM GAS-PHASE BASICITY TOLLENS, F.R., BALASUBRAMANIAN, V., FRAENKEL, G. AND *MARSHALL, A.G.	1397
THE MEASUREMENT OF ONSET POTENTIALS FOR EXOTHERMIC AS WELL AS ENDOTHERMIC PROTON TRANSFER REACTIONS WITH A TRIPLE QUADRUPOLE INSTRUMENT BURSEY, M.M., BLACKBURN, T.R., MEYERHOFFER, W.J. AND *MATTSON, W.A.	1399
HYDROGEN-DEUTERIUM EXCHANGE PROCESSES OCCURING DURING THE RETRO-DIELS-ALDER REACTION OF BETA-LACTAM ANTIBIOTICS IN A THERMOSPRAY MASS SPECTROMETER INTERFACE *SIEGEL, M.M., COLTHUP, N.B. AND KENION, G.	1400

Environmental

RAPID DETECTION AND CHARACTERIZATION OF FOSSIL-DERIVED FUELS IN WATER AND SOIL SAMPLES USING DIRECT PURGE ION TRAP MASS SPECTROMETRY WISE, M.B., *BUCHANAN, M.V. AND GUERIN, M.R.	1402
PARALLEL COLUMN CHROMATOGRAPHY-MASS SPECTROMETRY FOR THE ANALYSIS OF COMPLEX MIXTURES *QUILLIAM, M.A.	1404
THE ROLE OF MASS SPECTROMETRY IN THE CLEAN-UP OF THE SYDNEY TAR PONDS *SIM, P.G., QUILLIAM, M.A., PERREAU, H. AND ELSON, C.M.	1406
CAPILLARY GC/MS CHARACTERIZATION OF CRESOTE CONTAMINATION WITH COMPARISON TO GC/FTIR AND GC/MIP RESULTS *BRILIS, G., TETTA, D., CUMMINGS, R., POTTER, B.B., BRUMLEY, W.C., FARNHAM, I. AND PYLE, S.	1408
ANALYSIS OF FIVE- AND SIX-RING NITRO-PAHs: A COMPARISON OF EI, API AND METHANE NICI MASS SPECTROMETRY *LOPEZ-MIRANDA, A.T., KORFMACHER, W.A., ROSARIO, O. AND FU, P.P.	1410
ENVIRONMENTALLY SIGNIFICANT HALOGENATED COMPOUNDS IN FLUFF *GRANGE, A.H., DONNELLY, J.R., NUNN, N.J. AND SOVOCOL, G.W.	1412
COMPARISON OF MS/MS AND SELECTED ION RECORDING (SIR) IN THE ANALYSIS OF TCDD AND TCDF TONDEUR, Y., *WEIR, O., WOOD, D. AND CLENCH, M.	1414
ANALYSIS OF MONOBROMINATED PCDD AND PCDF IN MUNICIPAL INCINERATOR FLYASH *TONG, H.Y., MONSON, S.J. AND GROSS, M.L.	1416
EI AND NEGATIVE ION CIMS OF POLYBROMINATED FURANS IN PLASTICS *BRUMLEY, W.C., GRANGE, A., NUNN, N., DONNELLY, J., BRILIS, G.M. AND SOVOCOL, W.	1418
GC/MS METHODS UTILIZED IN A SURVEY OF SELECTED XENOBIOTIC CONTAMINANTS IN FISH FROM SITES ACROSS THE UNITED STATES *BUTTERWORTH, B.C., KUEHL, D.W., MARQUIS, P.J., LARSEN, M.L., MOZOLL, A.E. AND HOLLAND, L.G.	1420

Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL

GC/MS ANALYSIS OF HALOGENATED ORGANIC COMPOUNDS IN WATER, FISH, AND SEDIMENT SAMPLES COLLECTED NEAR AN INDUSTRIAL OUTFALL IN THE CALCASIEU RIVER ESTUARY, LOUISIANA *LEIKER, T.J., PEREIRA, W.E. AND ROSTAD, C.E.	1421
GC/MS IDENTIFICATION OF TRICHLOROPHENYL ETHANOL IN IMPORTED PEPPERS: POTENTIAL MISIDENTIFICATION AS A TRICHLOROPHENYL METHYL METHOXY BENZENE *BARRY, T.L., PETZINGER, G., CAIRNS, T. AND SIEGMUND, E.	1423
DIRECT ON-LINE VAPOR MONITORING BY TRANSFER LINE GC/MS *ARNOLD, N.S., ROBERTS, K.A., MCCLENNEN, W.H. AND MEUZELAAR, H.L.C.	1425
INLET SYSTEM FOR AUTOMATED GC/MS ANALYSIS OF COMPOUNDS IN AMBIENT AIR AS COLLECTED IN STEEL CANISTERS *CARDIN, D.B., LIN, C.C., JACOBS, D.B. AND LEV-ON, M.	1427

FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY: PRECEPTS AND PROSPECTS

Alan G. Marshall

Department of Chemistry (and Department of Biochemistry)
120 West 18th Avenue, The Ohio State University, Columbus, Ohio 43210

Perhaps more than for any other type of mass spectrometry, progress in FT/ICR¹ has been closely associated with an ever-deepening understanding of the fundamental motions of ions stimulated by an rf electric field in a static electromagnetic ion trap. In this abstract, I shall try to show how that understanding has led to an ever-improving series of excitation waveforms, detection modes, ion trap geometries, and a host of techniques for transformation and analysis of digitized data. When combined with the extensive arsenal of previously developed tools for making ions and manipulating neutrals, FT/ICR offers a family of hybrid methods spanning an extraordinary range of academic and practical applications. Experiments formerly requiring a series of collision chambers and mass analyzers can now be performed by a single mass analyzer with a sequence of events separated in *time* rather than in *space*.

The circular trajectory of an ion moving in a fixed magnetic field was well understood (in the design of magnetic sector mass spectrometers) long before Lawrence and Livingston exploited resonant excitation of that motion in their original "cyclotron".² For the next twenty years, cyclotrons were used principally for producing high-energy charged particles. In 1949, Sommer and Hipple introduced the "omegatron", the first of three basic methods for detecting ion cyclotron resonance frequency. In the omegatron,³ ions of a given m/z were coherently driven to larger ICR orbital radius by continuous application of a resonant radiofrequency electric field until the ions struck an electrode plate to produce a detectable current. Much later, Wobschall used a resonant circuit to detect the power absorbed by ions *during* continuous resonant excitation.⁴ More than 40 ICR instruments based on Llewelyn's commercial design⁵ were in use by 1974. Finally, Comisarow and Marshall⁶ separated the ICR excitation and detection events, by exciting ions to large orbits and then detecting the charge induced in detector electrodes *after* the rf excitation had been turned off. Discrete Fourier transformation of a digitized time-domain transient then yielded a broad-band spectrum of ICR frequencies (which could easily be converted to an m/z scale). More than 90 FT/ICR instruments based on that idea are now in use worldwide.

Subsequent technique development in FT/ICR mass spectrometry can be classified into several areas: (a) ionization/ion introduction methods (i.e., how to form and introduce ions into the trap); (b) ion trap improvements; (c) excitation methods; (d) detection modes; (e) data reduction methods; and (f) experimental event sequences for MS/MS and other studies of ion-molecule reaction pathways, kinetics, and equilibria. I shall now describe some of our recent contributions to many of those areas, with emphasis on the fundamentals of ion behavior in electric and magnetic fields.

Ionization techniques

Many previously developed ionization techniques (electron ionization, chemical ionization, fast atom bombardment, plasma desorption, laser desorption, photoionization, fast neutral beam, secondary ionization) have been adapted to ICR. Perhaps the most novel was "self chemical ionization"⁷ in which chemical ionization is

achieved at low pressure, simply by "incubating" the ions with their parent neutrals, with the result that protons are commonly transferred from ionized daughter fragments to neutral parent molecules to produce abundant $(M+H)^+$ ions without the addition of a chemical ionization reagent gas. In terms of technique development, our principal contributions in this area have been the interface of a fast neutral beam SF_6 source to an FT/ICR instrument,⁸ and the extension of laser desorption/ionization from the original CO_2 laser (1.06 μ) to a Nd/YAG laser at fundamental and harmonic frequencies (1064, 532, and 266 nm) for applications to analysis of drugs and polymers.⁹

Ion trap improvements

McIver's "trapped-ion cell"¹⁰ provided the first means for confining ions for extended periods (a few milliseconds to seconds) to provide for ion-molecule reactions and/or high-resolution detection. Comisarow's cubic trap¹¹ provided a good approximation to a quadrupolar electrostatic potential, and has been widely used. However, the cubic (or orthorhombic) trap configuration generates *curved* isopotential contours, with two undesirable effects. First, attempts to apply a static trapping potential along the magnetic field (z-) direction produce an outward-directed *radial* static field which shifts ICR frequencies and reduces the upper m/z limit. Even a trap with hyperbolically curved electrodes (which generate near-perfectly quadrupolar electric potential) reduces the ICR upper mass limit.¹² Second, an attempt to apply a transverse radiofrequency electric field excitation also generates a z-field which excites z-motion and can result in mass-dependent ion ejection (so that ICR relative peak areas no longer accurately represent the relative numbers of ions of those m/z-values). As reported elsewhere at this meeting, we have largely solved these problems by the use of grounded screens (to shield the trapped ions from the static trapping potential throughout most of the ion trap volume)¹³ and by rf "shimming" to reduce the z-component of the rf electric field during excitation.¹⁴ FT/ICR mass spectral peak frequencies and areas should now be essentially independent of ICR orbital radius, a major advantage for mass measurement and quantitation of relative m/z abundances.

Signal generation

The very first FT/ICR signals were excited with an rf pulse of approximately rectangular envelope.⁶ That waveform offers broad-band frequency-domain magnitude, but requires high time-domain amplitude and is non-selective over the excitation bandwidth. The d.c. or single-frequency rf-pulse idea has since been revived twice in slightly modified form as "burst"¹⁵ or "impulse"¹⁶ waveforms with essentially the same frequency-domain magnitude profiles. Frequency-sweep ("chirp") excitation,^{17,18} now employed in virtually all FT/ICR instruments, can produce power over a broad frequency range from a relatively low-amplitude time-domain waveform, but the excitation frequency-domain magnitude is neither flat nor sharply selective. In 1985, we introduced stored waveform inverse Fourier transform ("SWIFT") excitation as a means for producing optimally flat excitation power with optimally high selectivity and optimally low time-domain amplitude.¹⁹ As detailed in a recent review,²⁰ SWIFT excitation may be used for: improved quantitation of relative ion abundances; MS/MS with ultrahigh mass resolution in the first MS stage; the first truly simultaneous multiple-ion monitoring; multiple-ion ejection for enhancement of dynamic range; and all sorts of applications in which uniform selective excitation is required.

In 1984, we showed that a 180° phase shift at the midpoint of a time-domain single-frequency excitation waveform could effectively "de-excite" ions back to their starting points.²¹ That principle has since been applied by Gäumann *et al.* to develop a two-dimensional FT/ICR MS/MS technique,²² and by Russell *et al.* to produce mass-selective excitation by use of non-selective radiofrequency excitation.²³

Signal detection

For *infinitely extended* electrodes, the oscillating charge induced in the detector electrodes would be purely sinusoidal. However, for detector electrodes of *finite* dimensions, signals at odd multiples of the ICR orbital frequency are observed.²⁴ Recently, Wanczek (for a cylindrical trap)²⁵ and we (for a cubic trap)²⁶ have shown that the harmonic signal magnitudes increase with ICR orbital radius, but are typically quite small (<2%) under typical operating conditions.

All present FT/ICR instruments detect the ICR signal induced on a *single* pair of opposed electrodes. We have recently shown that a potential increase by a factor of $\sqrt{2}$ in signal-to-noise ratio results from *quadrature* detection from *two* orthogonal pairs of electrodes.²⁷ We have suggested several other applications for quadrature detection: e.g., halving the lower mass limit for a given maximum digitizer speed; and dual-range detection (say, simultaneous wide-range low-resolution, and narrow-range high-resolution).

Data reduction

FT spectroscopy differs fundamentally from other types of spectroscopy by its inherent need for *discrete* data.²⁸ As a result, the quality of an FT/ICR mass spectrum depends in detail upon how the "raw" time-domain *analog* signal is converted ("sampled") into digital data. For example, sampling at a rate less than twice per cycle of the highest frequency in the spectral bandwidth results in "foldover" ("aliasing"), so that the apparent ICR frequency (and thus the apparent m/z) can be shifted to an incorrect value. Recently, we showed how the interleaving of successive time-delayed acquisitions can be used to extend this "Nyquist" limit, thereby lowering the lower mass limit for FT/ICR.²⁹ Conversely, we have shown that intentional *undersampling* may be used to provide *simultaneous ultrahigh mass resolution* for ions of widely separated m/z -values.³⁰ In work reported elsewhere in this volume,³¹ we discuss the advantages of intentional *oversampling* (i.e., sampling more frequently than required by the Nyquist limit). Finally, the quality of an FT spectrum is determined by the *vertical* as well as the *horizontal* resolution in time-domain sampling; in the extreme limit of 1-bit vertical analog-to-digital conversion (ADC) resolution, we showed that such extremely "clipped" data can provide almost as much information as from more conventional 12-bit ADC's.³²

There is considerable current interest in *non-FT* methods for obtaining a (frequency-domain) spectrum from a discrete time-domain signal. We recently showed that the Hartley transform offers all of the advantages of fast FT data reduction without the use of mathematically complex algebra.³³ More recently, we have compared Bayesian and maximum-entropy analysis with FT data reduction, as discussed elsewhere in this volume.³⁴

The Fourier transform produces mathematically "real" and "imaginary" data sets. However, extraction of the desired absorption-mode spectrum requires accurate *phasing* of the complex spectrum. We provided the first method for broad-band phasing of FT/ICR data,³⁵ based on plots of imaginary vs. real FT spectral data.³⁶ We also pointed out that the negative-frequency spectral peaks (which themselves have no physical significance) can shift the (observed) positive-frequency peaks in an FT spectrum, thereby affecting mass calibration (in a calculable way).³⁷

Perhaps the most important issue in data reduction is the *precision* of the determined FT/ICR spectral parameters: peak frequency (from which m/z is computed); peak width (which offers a direct measure of reduced ion-molecule collision frequency); peak height (or preferably peak area, which offers a direct measure of

relative ion abundance). Under very general conditions, we have shown that frequency-domain precision is proportional to signal-to-noise ratio (as for analog data) and to the (square root of the) number of data points per peak width.^{38,39} Finally, we have used a three-point fit⁴⁰ to each magnitude-mode spectral peak to evaluate the effects of noise, zero-filling, time-domain signal truncation, and the round-off errors of the FFT algorithm itself on spectral precision.⁴¹

This retrospective survey has been devoted mainly to *technique development*. Analytical and chemical problem-solving applications based on those techniques may be found in abundance elsewhere in this volume, from a host of FT/ICR practitioners.

Molecular Ion Spectroscopy: The Third Generation

Richard J. Saykally
Department of Chemistry
University of California
Berkeley, CA 94720

Within the obvious limitations deriving from any particular system of classification, it seems reasonable to characterize the evolution of high resolution (i.e. rotationally resolved) molecular ion spectroscopy into three generations; the basis of this classification is the degree of complexity of the ions studied, which, in turn, serves to characterize the technical sophistication of the methods used to study them.

The first generation principally involved the study of diatomic ions by optical emission spectroscopy of both electrical discharges in the laboratory and of comet tails. The "Diatomic Era" yielded detailed information on the electronic and geometrical structures of approximately 50 diatomic ions as well as similar information for a few polyatomic species. The chemical information derived from seven decades of investigation is compiled in the monograph by Huber and Herzberg (1) and is described in several reviews.

The second generation of molecular ion spectroscopy, the "Polyatomic Age", was initiated by the discovery of the molecular ions HCO^+ and HNN^+ in interstellar dust clouds by microwave astronomy and by the subsequent development of laboratory microwave spectroscopy of molecular ions in electrical discharges (2-7). The quest to understand the high abundance of molecular ions in the interstellar medium provided strong motivation for the development of laboratory spectroscopy efforts. Following the pioneering microwave work of Woods and coworkers, infrared spectra of a few simple ions (HD^+ , HeH^+ , H_3^+) were obtained with laser ion beam experiments employing indirect (mass spectrometric) detection of the effects of photon absorption. The rather severe dynamical constraints involved in this approach restricted the generality of these otherwise elegant methods. In 1980, Takeshi Oka demonstrated the first use of tunable infrared laser absorption spectroscopy for measuring vibration-rotation spectra of ions (H_3^+) generated in a glow discharge. While this straightforward approach was soon extended to NeH^+ , more general application was impeded by the overwhelming interference caused by the much more abundant neutral species present in chemically complicated discharges. A sensitive, ion-selective detection method was obviously required in order to genuinely advance infrared spectroscopy of ions.

Such a method (called "Velocity Modulation Laser Spectroscopy") was developed at Berkeley by Gudeman et al. (8) in 1983. By employing the Doppler shift resulting from ion drift motion in the positive column of a glow discharge, laser absorption spectra of ions could be separated from neutral absorption features. Moreover, the anticorrelated translational motions of positive and negative ions in a discharge make it possible to unambiguously determine the sign of the charge of the absorbing ion. As a result of the development of velocity modulation, as well as several other ion selective modulation methods, approximately 60 different molecular ions have been studied with infrared laser spectroscopy by some eight different spectroscopy groups. These include some of the most fundamental ions in chemistry (e.g. H_3O^+ , NH_4^+ , CH_3^+ , NH_2^+ , OH^- , NCO^-) (9-12).

The third generation of molecular ion spectroscopy might be called "The Cluster Era". The most sophisticated spectroscopy experiments that have been developed recently have the capability to measure rotationally resolved spectra of cluster ions, such as $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$, and complicated species like nonclassical carbonium ions. Rotationally resolved laser induced-fluorescence of ions produced by laser ionization in a supersonic jet has been demonstrated by Terry Miller (13). A new experiment developed by Yuan

Lee and coworkers (14) has produced rotationally resolved IR spectra of $\text{H}_2\text{O}^+(\text{H}_2\text{O})_n$ and $\text{NH}_4^+(\text{NH}_3)_n$. This approach features production of cold ($\sim 10\text{K}$) ions in a supersonic corona discharge, trapping mass-selected ions in an octopole ion trap, and using laser photofragmentation/double resonance methods to measure the IR absorptions with mass spectrometer detection. Recently, microwave spectroscopy of a hollow cathode discharge was employed by Bogey et al. (15) to study detailed spectra of the ArH_3^+ cluster ion. This excellent work may soon be extended to other ions.

Coe et al. (16) have developed (DIBLAS) a new method called Direct Ion Beam Laser Absorption Spectroscopy for measuring very high resolution spectra of mass identified ions. In this approach, ions are extracted from a suitable source into a fast (3kV) ion beam operating near the space charge limit of current ($\sim 10^9$ ions/cm²). Infrared transitions are measured in direct absorption. Kinematic compression of the nascent velocity distributions results in linewidths which are ~ 10 times narrower than the room temperature Doppler width. Each absorption feature is mass identified with a precision of ~ 0.1 amu by the observed Doppler shift. Because the absolute densities of all ions can be determined quite readily, absolute infrared absorption strengths can be determined. Initial results have been demonstrated for HF^+ , HCO^+ , HNN^+ , H_2O^+ , and NH_4^+ . With the use of supersonic coronas as ion sources, we expect this method to be successfully applied to the study of vibration-rotation-tunnelling spectra of cluster ions like H_3O^+ . In this work, the hydrogen tunnelling migration dynamics will be studied, in addition to determining the structures and other properties of such clusters.

This work was supported by the National Science Foundation, Grant No. CHE-8612296.

MASS SPECTROMETRY: HOW DID WE GET HERE
AND WHERE ARE WE GOING?

Fred W. McLafferty, Baker Chemistry Laboratory, Cornell University,
Ithaca, New York 14853-1301.

Mass spectrometry has undergone an amazing growth over the last four decades. Possibly a perspective examination of this can provide guidance to make its future even more amazing. Certainly a hallmark of this progress has been the high creativity in, and unusual communication between, highly diverse scientific areas doing both basic and applied research in academic, government, and industrial laboratories. Breakthroughs on fundamentals of ion optics, kinetics, ionization processes, and mechanisms have depended on developments in reference data, instrumentation, and computer utilization, all of which have inspired unique applications across physics, geology, chemistry, biology, medicine, and environmental sciences. The basic chemistry found for small gaseous ions has led to mechanistic rationalizations for larger species, in turn sparking exciting developments in instrumentation to ionize increasingly large molecules, even those above 100,000 daltons. Coupling to chromatographic separation methods now accounts for the majority of analytical applications, while tandem mass spectrometry makes possible further new dimensions of information. As with GC/MS interfacing, MS/MS requires new methods to convert the mass-separated ion species into characteristic new masses for the next MS separation, while a multiplicity of such steps (MS^n) gives promise for extended characterization of the unusually large molecules that can now be ionized. Finally, automating the analytical process to take advantage of the unusually high information density of MS and its comprehensive collections of reference data has directly utilized the astonishing new capabilities of the computer revolution.

Why Is MS So Wonderful? Two basic reasons are proposed for the tremendous success and future promise of mass spectrometry: (1) the unusually high volume of data obtainable from unusually small samples, and (2) the success in converting these data into structural and analytical information, mainly through understanding of the chemistry involved and the application of modern computer technology. For (1), picogram sensitivities are now commonplace in molecular mass spectrometry, while modern carbon-14 dating of 100,000 year old samples in milligram quantities requires measurements at the attogram (10^{-18} g) level. The unusual data volume also results from the multiple dimensions of possible data. The high response per molecule and dynamic range of mass spectrometry represent its first dimension, while the number of individual masses for which such measurements can be made provide the second dimension. These latter "resolution increments" depend on both mass range and resolution. Miraculously, several research groups have now achieved ionization of molecules of larger than 100,000 molecular weight. The best resolution of a commercial instrument is provided by the Fourier-transform mass spectrometer, with values of 3×10^6 at m/z 100 and 3×10^5 at m/z 1,000 with heterodyne measurement over a limited mass range. Of course, the utility of this resolution is limited by the exact masses possible from combinations of the component isotopes of the molecular and fragment ions in the mass spectrum; for ordinary samples, this is probably around 10^6 , as our current database of 118,000 different compounds contains 35,734 different molecular formulae. The figure shows the dramatic improvement in instrumental capabilities to measure these first two dimensions over the last forty years.

ANALYTICAL MASS SPECTROMETRY

Multiple Dimensions Systems. One of the most exciting areas of mass spectrometry expansion has been into three and more dimensions of analytical data. The pioneering effort of this was gas chromatography/mass spectrometry, first made into a usable system by Roland S. Gohlke, one of the first persons I hired in the Spectroscopy Laboratory of the Dow Chemical Company. I first heard of gas chromatography at a 1954 Gordon Conference (chaired by my Cornell colleague, Don Cooke) from Drs. Wilson of ICI and DalNogare of DuPont. Gohlke soon had a prototype GC working in the laboratory, and went on to build some 200 for various parts of Dow before they were available commercially in the US. I first heard of the Bendix time-of-flight instrument from Bill Wiley at a Pittsburgh Conference, and in 1955 Gohlke and I went to Bendix in Detroit to see this amazing device that scanned 10,000 mass spectra per second; our pen and ink recorders required 30 minutes per spectrum at that time. Dow took delivery in 1956 of the third commercial instrument built by Bendix, and Gohlke had a successful GC/MS solving problems in less than a year; never mind that no one else seemed to be able to get useful data from supposed copies of his instrumentation for several years. Of course, the speed and sensitivity of MS were keys to the ultimate success of GC/MS, but other critical elements to its explosive growth in the 1970's were the unusually clever interface designs of Watson and Biemann and of Ryhage and the Stenhagens (for the latter jet separator, I believe the first all glass model was also invented by Gohlke when he went to Finnigan) and the computer acquisition and reduction of the resulting volumes of data.

The high performance liquid chromatograph burst upon the scene in this period. Here I was fortunate to become well acquainted with Jim Waters while running Dow's basic research lab in Framingham, MA, 1956-1964, as Waters had a small company making differential refractometers in the basement of the Framingham Police Station. John Brown of Dow/Texas invented gel permeation chromatography, for which the Waters RI detector was a key, and the Waters development of this technology led to their early preeminence in high-performance liquid chromatography. The first commercial LC/MS instrument employed a moving belt interface, while Mike Baldwin, Patrick Arpino, and Bob Dawkins at Cornell developed our "direct solution introduction" interface first reported in 1973. This was done with Waters as well as NIH support and first introduced commercially by Hewlett-Packard. Certainly the plethora of far better interfaces developed in the last few years, such as thermospray, flowing FAB,

particle beam (MAGIC), and electrospray should soon bring LC/MS to the importance level of GC/MS

Tandem mass spectrometry in many ways has the highest potential of all multidimensional methods, and of course can also be used in conjunction with separation methods like GC and LC. Here, however, the history is really one of the extremely slow recognition of the analytical possibilities of MS/MS observations made over many years, starting with Sir J.J. Thomson himself. In our laboratory the recognition of the

TANDEM MS; MSⁿ

J.J. Thomson (1912): "secondary rays" from collisions
in the fields; "Aston bands" (CAD).

Hipple & Condon (1945): metastable ions (MI)

Boerboom, Derrick, Nibbering, etc.

possible utility for ion structure characterization by metastable ion spectra only started with Tom Shannon in 1966 and by collisionally activated dissociation by Bill Haddon in 1968, while the utility of MI spectra for mixture analysis was reported by Tom Bryce in 1967 and of both MI and CAD spectra for sequencing of peptide mixtures by Hans Kasper-wipf, Phil Irving, and Malcolm McCamish in 1973. The true recognition of the analytical scope of MS/MS came a few years later through the pioneering efforts of Graham Cooks, as well as Frank Bockhoff in our laboratory. Cooks and Mike Gross recognized early on that further dimensions of mass spectrometry (MSⁿ) should have similarly expanded analytical utility, and he and Chris Enke have pioneered both instrumental and conceptual methods of exploiting MSⁿ. Ben Freiser and others have similarly showed MSⁿ to be a powerful tool in studying ion-molecule reactions.

Instrumentation. Instrumental advances have spearheaded much of the growth of the field since Al Nier led the World War II development yielding literally hundreds of mass spectrometers at Oak Ridge alone for isotopic assay of samples, production control of the gaseous diffusion plant, plus the 72 3-story "calutrons" that produced the ²³⁵U for the first New Mexico atomic bomb.

The development of modern computer hardware has been a tremendous boon to mass spectrometry for data acquisition and reduction, as outlined in the table. Dr. Rengachari (Babu) Venkataraghavan led our research

efforts on this from 1965 to 1977, with great contributions from Rick Klimowski, John Coutant, Paul Bente, Tim Wachs, John Michnowicz, Pete Rogerson, and others.

Focusing our attention on MS/MS instrumentation, it was just ten years ago that Peter Todd built our first tandem double focusing mass spectrometer for his Ph.D. thesis, with tremendous inputs from Mike Baldwin and Don McGilvery. For 8 kV ions, the magnets had upper mass limits of 12,500 and 5,000, but we soon found that CAD of even a 2,100 molecular weight peptide gave very poor fragmentation, that it was very difficult to obtain more than 1,000 resolution with MS-II because of the high energy spread of the collisionally produced ions, and that the required spectral scanning was wasteful of sample (luckily, the same instrument is ideal for our neutralization-reionization MS studies). However, the work of Comisarow, Marshall, Gross, Wilkins, Russell, McIver, Hunt, and others indicated that Fourier-transform is a highly promising alternative as an MSⁿ instrument. The Table summarizes key advantages of FTMS for MSⁿ studies of large molecules. For example, Evan Williams,

MSⁿ by Fourier -Transform MS

ICR + Comisarow/Marshall

Energy independent: resol. >200,000 at m/z 1300

Repetitive mass analysis: MSⁿ

Multichannel detection: e.g., m/z 90-16,000

Multichannel MS/MS: + Hadamard transform

Remeasurement of large ions: >97% efficiency

Ion photodissociation, SID, e⁻ + Mⁿ⁺

Bing Wang, and Kent Henry in our laboratory have found that large ions can be remeasured with nearly 100% efficiencies in the "quench off" mode, as the short measurement transients apparently result from loss of translational energy with minimal scattering, causing the ions to wind back to the center of the cell where they can be re-excited and remeasured. Further, Evan Williams and Stanton Loh here have developed a Hadamard-transform technique in which the secondary mass spectra of many precursor ions can be collected simultaneously, greatly improving the signal/noise ratio. Selecting half the precursor ions with Marshall's SWIFT technique and measuring their collective MS-II spectrum, from which is subtracted the MS-II spectrum of the saved remaining half of these ions, is then done for all possible combinations of precursors. The individual MS-II spectra are then calculated from the appropriate simultaneous equations, with the resulting signal-to-noise equivalent to that for one spectrum measured individually with the same amount of sample used for all MS-II spectra. Also critical for MSⁿ has been the development of methods for ion dissociation. Excimer laser photo-

Neutralization of multiply protonated ions to form unstable hypervalent ions yielding one or two fragment ions

dissociation appears especially promising, as this may cause dissociation in times short compared to that for energy randomization through the large molecule. Cooks' method of surface induced dissociation is highly promising for FTMS in preliminary experiments at Cornell and in collaboration with Hunt and Shabanowitz for singly charged ions up to mass 3,000. For multiply-charged larger ions from electrospray, both Smith and Loo, and Henion, have shown that CAD is promising, as also indicated by our experiments for SID.

The recent success of Evan Williams and Kent Henry, in collaboration with Jeff Shabanowitz and Don Hunt, in obtaining electrospray spectra of peptides of molecular weights up to 17,000 is very promising for MS^n sequencing of even larger peptides. Smith and Loo have obtained electrospray spectra of a 130,000 molecular weight peptide, but with more than a hundred charges; for the resulting m/z 800 - 1400 ions the FTMS instrument should have a resolving power of $>130,000$. Quite frankly, I am

MS^n MIXTURE SEQUENCING soft ionization

as excited about the potential of this approach to MS^n of large molecules as I have been of any new breakthrough in mass spectrometry since 1950.

MS Data $\rightarrow$ Structural and Analytical Information. Volumes and volumes of data are useless if they cannot be converted into desired information. As a chemist, one of the most rewarding aspects of mass spectrometry has always been that the most critical factor for this conversion to information is a basic understanding of the chemistry involved. Key to this is the unimolecular dissociation of singly charged cations, with exploitation of the bimolecular chemistry of cations and the chemistry of anions, multiply charged ions, and neutrals of high importance for the future. A second fortunate difference with conventional chemistry is that most of the basic data concerning unimolecular cation reactions is numerical, not bibliographic; thus, modern computer science is a powerful ally in the development of this chemistry. With the untimely deaths of my former collaborators Einar Stenhagen and Sixten Abrahamsson, the great majority of our current database of 140,000 different mass spectra of 118,000 different compounds has been collected at Cornell. Gerard Salton, Cornell's Professor of Computer Science, has been a key figure in developing statistical methods for document retrieval from libraries. We have tried to use all of his principles in our Probability Based Matching algorithm, which has undergone many improvements in the last fifteen years.

PROBABILITY BASED MATCHING

Salton has shown that reliable evaluations of retrieval performance must be two dimensional; such "recall/reliability" plots show that even early versions of PBM were superior to any other available retrieval algorithm. However, if the unknown compound is not in the reference file, of course it is hoped that PBM will show no promising retrievals; this requires an interpretive scheme, for which we have developed the Self-Training Interpretive and Retrieval System. This is cited as one of the first Artificial Intelligence systems of broad applicability in a scientific field.

Understanding Ion Chemistry. In its early years mass spectrometry was plagued with a terrible reputation concerning its capabilities for molecular structure elucidation. The quasiequilibrium theory developed by Eyring and his students demonstrated that mass spectra followed basic principles of chemical kinetics, but the conversion of organic chemists probably only began by showing that unimolecular ion reactions were

separate papers by Wesdemiotis, Turecek, Zhang, Drinkwater, Leyh, and Fura. A special bonus of these NRMS studies has been in the formation and characterization of unstable, exotic neutral species such as antiaromatic molecules, radicals, carbenes, enols, zwitterions, ylides, and hypervalent species. To prepare such neutrals it is only necessary that the corresponding cation or anion is stable. An especially promising technique is the MS/MS/MS characterization of the relative free energies of their dissociations by CAD of the neutrals, followed by reionization and isomeric characterization of the ionic products by further CAD.

Future. Thus, it would appear that in a generation or so of mass spectrometry we have gone from the reputation of "no real chemistry there" to a vital source of uniquely new chemistry. With the explosive expansion of mass spectrometry to the study of really large molecules we can look forward to further understanding of their chemistry, hopefully again to make a further contribution of real value to other areas such as biology and medicine.

One Man's Journey in Mass Spectrometry

by J.H.Beynon, Chemistry Building, University College of Swansea, Swansea SA2 8PP, U.K.

My career did not begin in mass spectrometry. When I graduated, in 1943 in the middle of the Second World War, I was immediately drafted into an Army post in which I was concerned with the design of gyroscopic stabilizers for tank guns. When I was released from war service in 1947, I was fortunate to obtain a position in the Research Department of ICI Ltd in Manchester, U.K. This was the largest chemical research unit in the British Commonwealth at that time. The Department housed 750 qualified chemists. Part of it is shown in Figure 1. It formed part of the Dyestuffs Division of the Company and made and sold over 6000 different products - dyestuffs and pigments, polymers, pharmaceuticals and various speciality chemicals such as wetting and waterproofing agents, chemicals for rubber and other auxiliary chemicals.

Fig. 1

effects they produced and not because of their chemical formulae. A dyestuff, for example, is sold on the basis of its colour, its fastness to light, its ability to bind to fabrics, etc. and it is these properties that have to be maintained constant in the commercial product sold over the years. Because impurities, sometimes even trace impurities, present in the products sold affected their properties (for example cause weakening of a polymer fibre) the analytical chemists were always looking for new, more sensitive and specific methods of analysis, infra-red absorption spectroscopy being the most versatile and up-to-date method at the time. But the wide analytical potential of mass spectrometry was not foreseen although it was as the result of one particular analytical problem that it was introduced in ICI. The Pharmaceutical group needed a method of tracking drug metabolites through the body and had decided that although radio-active labelling of drugs could be very useful analytically, it was too dangerous ever to contemplate using such compounds on human beings. Labelling with stable isotopes, on the other hand, using a mass spectrometer to make quantitative estimates of the amounts of various compounds present, could overcome the difficulty. This decision had been taken before I joined the Company and you can imagine my surprise when I arrived for work on my first day, to find on my desk a paper that read "Remit: Build a mass spectrometer."

I knew little or nothing about mass spectrometry and spent the next several weeks in the Library learning all that I could about the subject. In those days there was no computer-aided searching of the Literature so that references had to be found by laborious and painstaking search. And when a good paper was found, since photo-copying was not yet available, copious notes had to be made by hand. Although this process was slow, it meant that one read the papers thoroughly, and that by the time one's notes and sketches were finished, one understood it pretty well.

A design of mass spectrometer that appealed greatly to me had recently been published in the Journal of Scientific Instruments by Graham, Harkness and Thode and I decided to copy this design. Another Division of ICI had also decided to build a mass spectrometer and we decided to combine our resources and build two identical instruments based on the published design. We then discovered that Graham was temporarily in Britain and we engaged him as a consultant with whom we were able to have two or three meetings to obtain further details on the design. At this time Britain was still trying to recover from the effects of the Second World War. Many of the basic materials and components that we needed were in very short supply and no dollars were available to buy from the United States. A commercial mass spectrometer was already available in the United States, the famous 180° sector instrument made by CEC but there was no chance of obtaining the money to buy one of these. In Britain, Metropolitan Vickers had decided to build and sell a Nier-type instrument, but the fact that this was not expected to be ready for, perhaps, two years was a major factor in our decision to build our own machine. Another important consideration was that we felt we would be more able to maintain and develop the equipment if we succeeded in

building it ourselves.

Fig. 2

A description of our 'state-of-the-art' instrument may be of interest. The tube unit is shown in Figure 2. A flattened copper tube bent in a 90° arc carried the ions through the magnet pole-gap. Copper-to-glass seals joined it to the glass vacuum system. The electrical leads to the source and collector ends were carried on tungsten wires sealed through the glass envelope. The source slit was of fixed width, but the slit at the collector end could be opened and closed from outside the vacuum using a small magnet to rotate another magnet attached to the slit mechanism. An accelerating voltage of 2kV enabled us to reach to mass 200 at full magnetic field and the mass resolution (10% valley) was just over 200. The high voltage was developed via a mains transformer and mercury-vapour rectifiers. It supplied 0.25A of current which would almost certainly have killed anyone who touched it. It had one tremendous advantage, however. Throughout the 20 years lifetime of the instrument, it was (very fortunately, because of the difficulty of doing so) never necessary to remove the source for cleaning. Any conducting material that built up on the quartz insulators and that caused electrical breakdown, was quickly burned away by the very large current available. Every few years, we did insert a miniature scraper into the source through the hole through which the filament was mounted, loosen some of the carbon deposit and suck it out using a little vacuum pipe. It was quite a difficult job to change a filament. This involved cutting the glass envelope removing the entire re-entrant tube on which the filament was mounted, re-welding a new tungsten ribbon filament in position then re-inserting the filament holder and glass-blowing it, while holding the filament exactly in position, so that it formed a vacuum-tight seal. As a result of the carbon coating on the inside of the source and the use of an all-glass sample-handling system, there was less degradation of sample than in metal systems at the same temperature.

The collector was a Faraday cup and this was connected to an 'acorn' vacuum tube with a 10^{11} ohm resistor in a feed-back circuit. Currents down to 10^{-15} A could be measured with a time constant of about 1s. Thus it required at least 10s to scan over a single peak. When the instrument was first built, pen recorders had not become available in Britain (although the famous Speedomax recorder was available in the USA) and so our output current was fed to a galvanometer having a lamp-and-scale unit with a scale of 2m radius. On this, currents could be measured very accurately and it proved of great value in later experiments when small isotopic enrichments had to be measured. Later, we acquired a very fast potentiometric pen recorder with a 10 inch scale. The pen carriage floated between two clutches that were rotating very rapidly in opposite directions. Any out-of-balance signal was amplified and used to pull the pen carriage magnetically to one or other of the clutches which moved the pen in a fraction of a second to its new position on the chart. Problems arose, however, if the gain of the amplifier was a little too high, because this caused the system to 'hunt' and the rapidly vibrating pen became a hazard to all in the vicinity because it sprayed out ink in all directions.

The vacuum system was based on a home made, single stage, glass diffusion pump using mercury as the fluid. It had to be used in conjunction with a liquid-nitrogen cold trap and was capable of reaching a vacuum of 10^{-6} Torr after baking. The glass sample system used greaseless glass stopcocks lubricated with graphite from a 2B pencil and sealed with mercury. A diagram of one of these taps is shown in Figure 3. Another sample system based on a 'break-off' system enabled samples immersed in a low-temperature bath to be connected directly to the ion source without an intervening leak. The sample pressure

Fig. 3

was raised to the appropriate value for plotting a spectrum by carefully raising the bath temperature.

Mostly, spectra were plotted by hand. One operator would slowly rotate the knob of the 25 turn helical potentiometer that controlled the magnetic field and as each peak arrived, he would adjust the shunt that controlled the amplifier sensitivity to keep the peak on scale. He would call out the peak reading, continue scanning and then call out the zero reading following the peak. A second operator would record the readings and, using a mechanical hand calculator, normalise each peak to the base peak of the spectrum and plot the spectrum on graph paper. A complete spectrum up to, say, mass 200 would be ready in just over half an hour. The CEC instruments used in USA scanned the spectra by varying the accelerating voltage and this meant that sensitivity was reduced at the higher masses, making comparisons of standard spectra difficult on the two types of instrument.

As well as the difference in the method of scanning, there was one other major difference between the instruments used in Britain and USA. Many of those in USA had been built for one major application, the quantitative analysis of a mixture of hydrocarbons. These instruments were fitted with a computer which had a very poor performance indeed compared to modern computers, but which could nevertheless invert a large matrix much more rapidly than this could be done by hand. It is a sobering thought to all of us who earn our livings by mass spectrometry that if gas chromatography had been invented at that time, it could have analysed the mixture of hydrocarbons much more quickly and cheaply and the main commercial market for mass spectrometers would not have existed so that it is almost certain that they would not have been developed commercially and would have remained exclusively in Physics laboratories. From my own personal viewpoint the computers were responsible for one dreadful development; they needed a flat baseline to enable them to calculate abundances from the peak heights and so a 'metastable suppressor' was fitted so that no beautiful metastable peaks were seen. It is a very dangerous philosophy to try to eliminate features of a spectrum in this way because every feature adds to the sum total of information contained in the spectrum and aids in problem solving. My own motto has always been: If it wiggles, study it closely.

Accurate mass measurements could be made on these early instruments, though not many people realised the usefulness of such measurements at the time. Using an internal reference compound, measurements accurate to 50 ppm could readily be made even though the mass resolution was only of the order of 200. It is worth pointing out that this accuracy was not as high as Aston had achieved with comparable resolution some 25 years earlier, but we tended to be satisfied with it. Used in conjunction with isotopic abundance measurements it enabled the empirical formulae of many compounds sent in for analysis to be determined. Despite my feeling, held over many years that for some applications there would be great benefits to be gained by improving our accuracy of mass measurement to something closer to the 0.01 ppm that the physicists achieve, all is sacrificed at the altar of speed of production of spectra. Speed is necessary in many research problems but there are many problems in which the gain in sensitivity and precision achieved by plotting a spectrum more slowly are of vital importance. After all, a few minutes is a very short time indeed compared to say the time it takes to achieve a PhD degree.

It was clear to us that there were major advantages to be gained, in the types of problem in which we were mainly involved, if the mass resolution could be raised so as to separate the components of multiplet peaks. I achieved my first separation of a doublet in 1953 for which the value of $m/\Delta m$ was 1,000. The doublet was OH^+ and NH_3^+ and it is shown, plotted on the galvanometer lamp-and-scale unit in Figure 4. We also tried another method of obtaining good resolution which, although it worked well, has never been followed up. It is based on the fact that, in theory, a complete slit is not necessary to obtain good resolution, but only one edge of the slit. If the peak is oscillated across this slit edge, all the information contained in the ion beam can be extracted.

To do this and thereby obtain the first or second derivative of the peak shape, it is only necessary to apply a very small voltage $\sin \omega t$ to the accelerating voltage and to use a detector amplifier tuned to the frequencies ω or 2ω respectively. The

Fig. 4

were obtained in 1957; with modern electronics and phase-sensitive detection, I believe that a powerful method of overcoming the problems of opening and closing very narrow slits is available to us.

In order to increase our resolution still further, it was decided to approach Metropolitan Vickers (whose name later changed to GEC to AEI and then to Kratos) to ask if they would build a double focusing machine of Nier-Johnson geometry for it to be used to resolve the many doublet peaks being encountered in our organic chemical work. They agreed to aim for a resolution of 2,500 but would not guarantee this figure over a period of time because they expected that as soon as it became contaminated with organic material from the samples being examined, the resolution would fall. The machine, built with a 6 inch radius in the magnetic field was christened the MS8. It was delivered in 1955 and gave an immediate and sustainable resolution, after the slits had been narrowed of 13,500. It was immediately decided by the manufacturer not to build any more MS8's but to double the size and call the new instrument the MS9. The MS9 proved to be extremely successful and, in improved form, it is still in use in many laboratories worldwide. CEC had also decided to build a high resolution instrument, but of Mattauch-Herzog geometry. This was completed at almost exactly the same time as the MS8, but since this is meant to be my personal story, I will say no more about it other than that it, too, was an extremely successful and widely-used instrument.

(a)

(b)

Following this period, I was promoted within ICI, ultimately becoming the Research Manager controlling Physical Chemistry. No longer did I spend any time in the laboratories, though I did keep one assistant to indulge me in some mass spectrometry, which was now just a hobby. After 10 years of this, when I believed that my days in the front line of mass spectrometry were well and truly over, I received a tremendous surprise and a challenge. In 1968, I was approached by Purdue University and offered a Chair in their Chemistry Department to direct their mass spectrometry. ICI agreed to second me for a year and, filled with trepidation, for I had not done any practical work for a decade, I went to Purdue. In the event, I not only stayed for the year but commuted between Purdue and ICI for a further 6 years, becoming more and more of a Hoosier in the process. Throughout my time in USA I worked on yet another prototype instrument, the RMH-2 made by Hitachi. This was a very large machine, but in the event it never quite lived up to expectations as far as resolution was concerned. We modified it by putting a detector immediately after the electric sector and found that we had a new spectrum of metastable and collision-induced peaks that we called an IKE spectrum. This turned out to be a fortunate choice of name because we found that there were millions of buttons available all saying that they liked IKE. It was not long before we realised that if mass separation could precede production of the spectrum obtained by scanning the electric sector we would be able to produce complete 'fragmentation maps' which would be invaluable in the structural analysis of unknown compounds. In no time at all, we were building a reversed-geometry instrument using parts that had been donated to us by Kratos. We needed a name for the new spectra and decided to

call them MIKE spectra. Mass spectroscopists have always had a desire to invent special nomenclature and abbreviations for new techniques. So I was not at all surprised that, following the setting up of mass spectrometry nomenclature committees by IUPAC and by ASMS, both of which I chaired and both of which agreed that abbreviations should never be used unless they were defined first and both of which said that, in particular, the abbreviation MS should never be used (because it can mean so many things, such as mass spectrometer, mass spectrometry, metastable, manuscript, etc, etc) that in common usage today the MIKE technique that I have just described is lumped with others under the name MS/MS.

When I finally decided to leave the United States and return to Britain, it was to take up a Royal Society research Chair at Swansea. There, I took delivery of yet another prototype machine that we had persuaded VG to build for us, the reversed geometry ZAB-2F. This was my main instrument for the last decade of my working life and, as new attachments were invented, it soon bristled with extra sources, slits, sectors, collision cells, laser ports and so on. I had every bit as much fun on this machine (and every bit as much frustration) as on all the others. This period is only in the recent past, so that it is not appropriate to reminisce about it. Suffice it to say that I was also lucky enough to work again on a variety of topics, including building a hybrid instrument and a machine for high energy resolution, and to continue work on metastable ions on charge permutation and on the production of new ionic species. But I have already seen how the apparently quite *inexhaustible developments in mass spectrometry have quickly made much of this work obsolete.*

Throughout, I have talked about things that I have done, but I have always been part of a team and any ideas I may want to claim as my own will inevitably have been generated after constant discussions with my colleagues who will, consciously or unconsciously have helped to build up the idea in my mind. The teams to which I have belonged have included many clever and imaginative people to all of whom I owe a great deal. They are so many that I cannot list them all and I feel that it would be invidious to pick out just a few for special mention. I can only hope that while I learnt so much from them, they learnt something from me.

Looking back, it sometimes seems that whenever my research team came up with an idea, the more novel that idea was, the harder it was to get research support for it and the less likely it was that referees would recommend any ensuing paper for publication. It seems that the majority of scientists are very conservative and take a long time to accept new techniques and methods as being necessary or offering any advantages. This has been true in my own experience with such things as accurate mass measurement, high resolution and the study of metastable and collision-induced peaks. It seems hard to believe now, that when we combined gas chromatography's power as a separation technique with the mass spectrometer's power as an analytical device, in 1958 (in a very crude and unsophisticated way, I hasten to admit) we could get no support for developing the idea and a major manufacturer that we approached told us that the idea was crazy and had no commercial potential. Similarly, when we fitted an array detector to a mass spectrometer in 1975, we were told that this was an unnecessary refinement.

Fortunately, there exists a strong nucleus of innovative and adventurous scientists and they are often to be found in meetings such as this one. I can still remember my excitement when I attended my first meeting organized by ASTM Committee E-14 (the predecessor of ASMS) in San Francisco in 1955. From memory there were less than 100 people there and only about 50 papers were presented. It was possible to go to all the papers (there was no need for parallel sessions) and it was possible to get to know all the other delegates personally and to discuss their work with them. I was able to listen to talks outside my own area of knowledge and to broaden my outlook, but more importantly, it was the start of many research collaborations and of many personal friendships that have continued over the years. I also remember the hospitality suites which were in their heyday and how they helped in getting to know people. Many of you may not realise that if a suite was the focus of attention it was likely to stay open all night and to offer breakfast in the early hours of the morning.

I have never received the same stimulus from attending subsequent meetings as I got from attending my first. Indeed, I would suggest that support for young people to attend these meetings is of paramount importance even at the expense of rationing the visits by older and more experienced scientists. And to the younger people I would like to offer a few words of advice: Take the opportunity at this meeting of going to talks outside your own area and when you come across something that you don't understand or that you think is wrong,

**Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics

don't be afraid to ask questions. But at the same time, remember that just as you expect your own work to be appreciated, you should always look first for the good points in other people's work and be as constructive as possible in your criticisms. Remember, too to ask yourself questions about your own work and don't ever play down the unexpected (or un-wished-for) result. It may open up a whole new research area. Above all never get discouraged when things go wrong; misfortunes can provide you with stories to tell in your old age. I would like to end by telling you of the worst accident to befall my equipment. It happened with my old glass and metal machine when a leak appeared between the cooling coil on the diffusion pump and the main vacuum and the mass spectrometer filled up completely with water. I must confess that it took some time for us to accept that it was just one of those things that can happen when you tread the slippery path of mass spectrometry.

**IONIZATION BY POSITRONS:
WHAT'S THE MATTER WITH ANTIMATTER?**

We are currently investigating the ionization of polyatomic molecules by positrons. The positron, the electron anti-particle, has been known since the 1930s and has been studied in a variety of media [1]. The ultimate fate of the positron in matter is annihilation with an electron yielding gamma photons. The vast majority of studies of the interaction of positrons with gases has involved the detection of the gamma photons following annihilation or the detection of unscattered positrons. It is recognized that ions are formed in the interaction of positrons with gases but only very recently have the ions that are formed been studied [2,3]. This paper briefly reviews what is known about ionization by positrons and what might be expected based on positron lifetime and positron scattering cross-section studies.

The likely mechanisms for ionization by positrons are categorized below along with the positron kinetic energy region in which the cross-section for the mechanism is expected to be maximized:

1. impact ionization- $K.E. (e^+) > IP(M)$
2. positronium (Ps) formation- Ore gap (see below)
3. complex formation (positron capture)- $K.E. (e^+) < IP(M) - 6.8 \text{ eV}$
4. free annihilation- thermal energies and below

These mechanisms, the evidence for them, and the kinds of ions that may be formed from them are discussed below in turn.

Positrons with kinetic energies in excess of the ionization potential of the molecule can ionize the molecule in a fashion very similar to that for fast electrons. The field created by the fast moving positron can excite an electron sufficiently to liberate it from the molecule. This mechanism is depicted as:

We have ionized a number of compounds with 3000 eV positrons and find, as expected, that the spectra obtained from this approach are very similar to the analogous electron impact spectra. For example, Figure 1 compares mass spectra of toluene obtained by 3000 eV positrons, 2700 eV electrons, and 70 eV electrons. The only major differences between positron impact ionization and electron impact ionization are expected to appear near the threshold for ionization.

Ionization can occur below the IP of the molecule via the formation of positronium, a bound positron-electron, which has a binding energy of 6.8 eV. This process, depicted as:

is maximized when the positron kinetic energy falls within the so-called Ore

gap. The lower limit is the difference between the ionization potential of the molecule (IP(M)) and 6.8 eV. The upper limit is not well-defined. In practice it is reached when other processes, such as impact ionization, become more competitive. No mass spectra have yet been acquired that can clearly be identified as resulting from ionization via Ps formation although lifetime studies and scattering cross-section measurements clearly show that it occurs. For most organics, IP(M) is greater than 6.8 eV so that Ps formation is an endoergic charge transfer reaction. Note that equations (5) and (6) indicate fragmentation of the intermediate PsXY^+ prior to the annihilation of Ps. If the complex is sufficiently long-lived, this process can compete with annihilation.

Below the Ore gap, positron capture to form a long-lived complex (on the order of 1 ns) can occur for some molecules and is depicted as:

Schrader has predicted that some molecules can bind a positron [4]. Recently, Passner et al. have published mass spectra resulting from positron capture [3]. We have also recently begun to obtain this type of data. Figure 2, for example shows the mass spectrum obtained for toluene with < 3 eV positrons. We note no fragmentation in this data and find that the cross-section for this process is as least as great as that for ionization by 3000 eV positrons (which is on the order of a few Å²). We are intrigued by these data and intend to further explore the phenomena associated with and the potential selectivity of slow positron capture. Note again, as with the complex involving Ps, fragmentation of the e^+XY complex may compete with annihilation possibly leading to ions different from those formed from excited XY^+ .

A final mechanism of ionization by positrons involves so-called free annihilation of a positron by an electron in a molecule. This process is not preceded by Ps formation or the formation of a bound complex. The cross-section for this process is given by

$$\sigma = \pi r_0^2 c Z_{\text{eff}} v^{-1} \quad (9)$$

where r_0 is the classical radius of the electron, c is the velocity of light, v is the velocity of the positron, and Z_{eff} is the "effective" number of electrons in the molecule. Due to polarization of the electron density by the positron, Z_{eff} is larger than the actual number of electrons in the molecule. However, for molecules that do not bind the positron, the cross-section for free annihilation is expected to become significant only near thermal energies and below.

We have now begun to explore these processes. A description of the instrumentation and a longer discussion of these processes along with the presentation of the positron impact data will appear [5,6]. Our focus in the near future will be the study of the interaction of positrons of 0.1-10 eV with molecules to characterize the ions that are formed, the energetics involved, and the selectivity of this approach.

ION/SURFACE COLLISIONS: INSTRUMENTATION AND APPLICATIONS

R.G. Cooks, S. Habibi-Goudarzi, K.L. Morand, K.L. Schey and J.C. Schwartz
Purdue University, Chemistry Department, West Lafayette, IN 47907

Collisions of polyatomic ions with surfaces have become a subject of growing interest.¹⁻³ Surface-induced dissociation (SID), is a possible alternative to collision activated dissociation (CAD) or photodissociation (PD) in MS/MS experiments. Table 1 compares some characteristics of these three methods. Particular features of SID are control over the energy deposition, the relatively narrow distribution of internal energies deposited, and the modest dissociation efficiency. SID has been implemented using a hybrid BQ instrument,¹ a tandem quadrupole⁴ and a tandem time-of-flight instrument,⁵ all operated with large scattering angles (typically 90°) and energies up to several hundred eV. These experiments have demonstrated the usefulness of SID in ion structural work (Table 2). In almost all these cases SID provides better structural distinctions than CAD. Energy resolved measurements (ERMS) increase the value of ion/surface collisions for studies in ion chemistry.⁶

In addition to SID, several other reactions occur when polyatomic ions collide with surfaces (Table 3). These reactions have been investigated in some detail⁷⁻¹¹ and a specific example, the reflection spectrum of limonene, is illustrated in Figure 1. Among the interesting points evident in this spectrum is the ease with which the ion $C_8H_7^+$ undergoes reflection in competition with loss by neutralization and dissociation. By contrast $C_8H_6^+$ is readily neutralized.

Most polyatomic ion/surface collisions have been investigated using metal surfaces at 10^{-6} - 10^{-7} torr (i.e. covered by hydrocarbons) but some data on cleaner surfaces is available. Figure 2 illustrates typical results, showing large surface effects. Clearly aluminum is much less efficient than the steel target at causing dissociation. Other experiments established that clean graphite is relatively inert in terms of ion/surface reactions but effective at activation. This dimension of information remains to be explored, but fortunately for analytical purposes daughter spectra recorded by SID are highly reproducible in the usual mass spectrometer environment.

Wider use of surface-induced dissociation requires its implementation on conventional mass spectrometers, rather than special instruments with analyzers arranged at 90° to each other. To achieve this, a device can be inserted in-line into an ion beam and yet give large-angle collisions at a surface (Figure 3).¹² The performance of the in-line device, when fitted to a BEQ hybrid instrument, is illustrated in Figure 4. This example also demonstrates that SID is an attractive method of dissociating smaller biological compounds in order to obtain structural information.

Finally, it should be noted that ion/surface collisions are readily observed in a new hybrid mass spectrometer of BE/ion trap configuration. Figure 5 illustrates the daughter spectrum of the pyrene molecular ion selected with the BE portion of the instrument. The ions undergo chemical sputtering yielding alkyl fragments in competition with highly efficient SID to yield unsaturated fragments. The products of both these reactions are mass analyzed using the conventional mass-selective instability scan of the ion trap.

Table 1. Comparisons of Activation Methods

Parameter	SID (ev)	CAD (keV)	PD (uv)
Cross-section (cm ² /particle)	10 ⁻⁴	10 ⁻¹⁸	10 ⁻¹⁹
Energy Deposited	≤15 eV	≤3 eV	≤6 eV
Distribution P(E)	Narrow	Wide	Single-valued
Efficiency* (small ions)	2-10%	1%	<<1%
(biomolecules)	~20%	<1%	<<1%

ARRAY DETECTORS FOR MAGNETIC MASS SPECTROMETERS

Klaus Biemann and James A. Hill

Dept. of Chemistry, Mass. Institute of Technology, Cambridge, MA, 02139.

Historically, photographic plates have been used to simultaneously record a complete mass spectrum, even at high resolution. For this purpose, the plate was placed in the focal plane of a mass spectrometer of the Mattauch-Herzog geometry which had the unique feature of focusing ions of a wide mass range along a plane. The first commercial instrument of that type was the CEC 21-110 which had a focal range of 1:36 (for example, from m/z 20-760, depending on the accelerating voltage and magnetic field). With the advances in electronics and imaging devices, it became desirable to record the ion signals electronically and avoid the wet chemical treatment of photoplates. In the early 1970s, microchannel plates (MCP) consisting of over 1000 capillary electron multipliers per cm^2 became available in a configuration ($1/4" \times 1"$ active area) that lent itself for the recording of ion beams. Giffen *et al.* (1) at the Jet Propulsion Laboratory, Pasadena, CA, assembled 14 of these into a strip that was placed into the focal plane of a CEC 21-110 spectrometer. The burst of electrons emerging from the back of the plate whenever an ion struck the front was converted to photons, via a phosphor layer on the front of a 14" piece of fiber optics. The latter was folded in a way to generate a square field that was viewed through a lens system of a video camera, which allowed reading out the position of the illuminated lines in digital form (EOID, electro-optical ion detector). At about the same time, Tuithof *et al.* (2) placed a 1" MCP in the short focal plane of a single focusing magnetic instrument to simultaneously record a relatively narrow mass range (1:1.16). Shortly thereafter, Beynon *et al.* (3) accomplished the same for the recording of fast events utilizing 1" of the focal plane of a CEC 21-110.

The lens/video system was very inefficient and this shortcoming was eliminated by the emergence of photodiode arrays which could be mounted on the back of the fiber optics block (Fig. 1). The JPL group (4) incorporated this principle into the 14" device, which required an interdigitated fiber optics design to accommodate the physically larger photodiode arrays. This general principle of MCP, fiber optics and photodiode array has been incorporated into most array detectors used for single or double focusing (Nier-Johnson geometry) magnetic mass spectrometers. The exception is the detector employed by Owerkirk *et al.* (5) at the FOM-Institute, which senses the position of the electron burst emerging from the MCP and impacting a 45 mm array of 45 metal strips connected to a chain of resistors and capacitors. The charge differential developing at the extreme ends of the chain is related to the position of the electron beam and, therefore, that of the incident ion. This is an ion counting device, in contrast to the photodiode array. Such a device (covering a range of 1:1.1) has very recently been incorporated into a commercial mass spectrometer (Finnigan MAT 900), with additional features that allow the ion beam to be scanned across the detector (6) rather than to be recorded in consecutive steps. On the other hand, it has a relatively long "deadtime" (5 μsec); two ions arriving within a shorter time interval would appear as one signal at an intermediate position and have to be discarded.

A 1" array detector based on the EOID principle (Fig. 1) has recently been incorporated into two commercial instruments, KRATOS MS-50 (7) and the KRATOS Concept (8), covering a mass range of 1:1.04. We have constructed a 2" array detector (9,10) for the JEOL HX110/HX110 tandem mass spectrometer, which has a 3" focal plane covering a 1:1.10 range. The reduced range (1:1.066) was dictated by the availability of only a 2" array of 2048 photodiodes. Previously, all EOIDS utilized the fiber optics as a means to transmit the photon beam through the wall of the vacuum envelope of the mass spectrometer, allowing for operation of the photodiode array at atmospheric pressure. In our design, it was kept within the vacuum system to allow changing the position of the detector.

Simultaneous ion detection has the additional advantage of much higher sensitivity, compared to a conventional slit/electron multiplier system. The latter measures only that part of the ion beam which passes through the

narrow collector slit, while the rest of the spectrum ($\geq 99.9\%$ of the ion current) is lost. With the array detector covering a range of 1:1.066 (i.e., 6.6% of the mass range), we have improved the sensitivity by a factor of 50-100 (10); increasing the range would further increase the sensitivity proportionally.

The limited range over which ion beams of different mass are in focus along a linear plane in a Nier-Johnson type mass spectrometer presents a more complex data acquisition and processing problem. To record an entire mass spectrum, it has to be assembled from individual segments and the number of consecutive segments required depends, of course, on the mass range covered by the array detector and that of the spectrum. This problem is illustrated by Fig. 2.

To record a mass spectrum from m/z 60-3000 with a detector covering a range of 1:1.066, the mass spectrometer has to be stepped through 61 segments which then have to be processed to a contiguous spectrum (the 1:1.04 range of the 1" KRATOS detector requires about 100 steps). Increasing the range to 1:1.1 reduces the number of segments to 41. As can be seen from Fig. 2, this is mainly due to the fact that the range (in mass units) covered by each segment becomes progressively smaller at lower mass. To decrease the number of steps required (thus decreasing the time necessary to record the spectrum and further increase the sensitivity), it is desirable to further increase the mass range focused on the MCP. At ranges 1:1.2, 1:1.3 and 1:1.4, the number of segments decreases to 22, 15 and 12, respectively. However, to retain good resolution and mass measurement accuracy, one cannot utilize the full range at higher mass because the fixed number of 2048 photodiodes of a 2" Reticon photodiode array sets a practical limit of 300 mass units per segment in order to provide a sufficient number of data points (>6) per peak. This situation indicates that increasing the mass range focused onto the detector becomes of limited practical utility beyond a certain point. It is therefore desirable to be able to change the range from wide (at low mass) to narrower (at higher mass) to minimize the number of segments required while maximizing the quality of the resulting mass spectrum.

We have constructed such a variable range array detector (11), based on an ion optical principle proposed by Ishihara *et al.* (12), which involves placing a pair of quadrupole lenses between the magnetic field and the collector slit of the JEOL HX110 mass spectrometer. With the proper potentials on the lenses, a focal plane of varying range (theoretical maximum limited to 1:1.41 by the width of the flight tube in the magnet gap) is created in front of the collector slit, providing sufficient space for the variable angle (to vary the mass range) array detector, as illustrated in Fig. 3. Presently, we have achieved a range of 1:1.30. Little would be gained (see Fig. 2) by extending the range even further.

Although we utilize this detector mainly for the recording of tandem mass spectra (11), it is also useful for the measurement of normal FAB spectra, particularly when measuring the molecular weights of compounds of high but unknown mass. In such cases, one can step through the spectrum at the highest angle (mass range) until one encounters a signal. Stepwise reduction of the angle decreases the range covered and thus allows one to "zoom-in" on the signal for measurement of the average mass or, at higher resolution, the monoisotopic mass of the $(M+H)^+$ ion (or others). Detector angle, lens potentials and other parameters are computer controlled (11).

Capillary Electrophoresis-Mass Spectrometry

Robert D. Minard, Paul D. Curry, Jr., and Andrew G. Ewing
Chemistry Department, Penn State Univ., University Park, PA 16802

The development of electrophoresis in capillary tubes offers several exciting methods for fast, highly efficient separations of ionic species, separations of macromolecules important in the area of analytical biotechnology, and design of small volume separation based sensors. The history, principles, and applications of capillary electrophoresis have been recently documented by A.G. Ewing et. al.¹ The most common type of capillary electrophoresis in use today is capillary zone electrophoresis or CZE. Other types are capillary gel electrophoresis, micellar electrokinetic capillary chromatography, isoelectric focusing, and isotachopheresis. Of these five methods, all but one, isoelectric focussing, has been coupled with mass spectrometry.

The coupling of mass spectrometry and capillary electrophoresis has a number of constraints. Just as in LC-MS, it must allow the introduction of solutions without severely compromising the vacuum of the ion source. The ionization mode must be universal, allowing highly polar molecules to be ionized or ionic species to be transmitted. There must be a way to complete the electrophoretic circuit. It should not degrade electrophoretic resolution through either band broadening in transfer lines or pressure-induced laminar, or non-plug, flow through the separation capillary. Two approaches have evolved to date, one based on "spray" ionization sources and the other on flow FAB ionization sources.

Richard Smith and coworkers were first to report the direct coupling of CZE and a mass spectrometer using an electrospray interface.² Sensitivities were olympic, low attomole quantities of quaternary ammonium compounds being detected. Jack Henion and coworkers at Cornell used the related ionspray technique for the separation of a peptide mixture.³ Sensitivities were in the femtomole range. Both of these spray methods have the advantage that the electrophoresis capillary exists at essentially atmospheric pressure and therefore, no degradation of the separation due to the pressure-induced flow effects occurs.

A practical method for interfacing CZE with flow FAB would have wide application. It was felt that direct connection was not feasible since the vacuum in the ion source would draw buffer through the CZE capillary and degrade separation efficiency. For this reason, we designed an interface involving an open gap matrix "make-up" coupler.⁴ It had the advantage of allowing the easy completion of the electrophoretic circuit external to the mass spectrometer and ran the CZE capillary at atmospheric pressure. Although we were able to carry out electrophoretic separations, resolution was less than optimal. This system was used to demonstrate the micellar electrokinetic capillary chromatography separation of Leu and Met Enkephalin.⁵ Attempts to improve both resolution and sensitivity using this interface have not yielded very satisfactory results.

Moseley, Deterding, Tomer and Jorgenson have described an improved method of interfacing CZE and flow FAB MS. Based on their very successful capillary LC-flow FAB MS work⁶, they have now reported the direct coupling of CZE and flow FAB MS using the same on-line coaxial continuous flow interface.⁷ By using a small internal diameter capillary, 13 microns, the flow induced by the source vacuum is minimal, on the order of 3 nL per minute. The FAB water/glycerol matrix solution is introduced via a tee through a coaxial outer capillary at the rate of about 1 microliter per minute. The CZE capillary sits back about 1 mm from the end of the matrix sheath capillary and the matrix solution flows over and covers the end of the CZE capillary, thus minimizing vacuum effects. The electrophoretic circuit is completed through the source voltage power supply which was 8KV. Their results, in terms of both sensitivity and separation efficiency, are very impressive. For example, the separation of approximately 400 femtomoles each of

the two basic dipeptides, arginyl phenylalanine and lysyl alanine was reported. The number of theoretical peaks in both cases is almost 300,000. Their data also includes an example of CZE MS/MS on 130 femtomoles of peptide.⁷

For the purposes of our research at Penn State, sampling from single cells⁸, injection volumes in the picoliter range are very desirable and capillaries with less than 10 micrometer ID's are often used in the single cell work using electrochemical detection. For this reason, the Tomer/Jorgenson approach is very attractive to us and we have set out to duplicate their CZE/FFAB/MS coaxial interface design. In our preliminary work, we detected 3 picomoles of Substance P and the number of theoretical plates was about 40,000. Since this was a single component, it may have simply been drawn through the electrophoresis capillary by the source vacuum. However, changing the applied potential changed the migration time in direct proportion to the change in the voltage and, therefore, true electrophoresis was taking place. The mass spectrum showed a signal to noise ratio of over 100 to 1 for the MH⁺ ion at m/z 1348 and it seems reasonable that femtomole range sensitivities will ultimately be obtained.

ANALYSIS OF DATA RATE REQUIREMENTS FOR HIGH PERFORMANCE GC/MS: THE CASE FOR TOF-MS WITH TIME-ARRAY DETECTION

C.G. Enke¹, J.T. Watson^{1,2}, J. Allison¹, J.F. Holland²
1Department of Chemistry and 2Department of Biochemistry
Michigan State University
East Lansing, Michigan 48824

For accurate reconstruction of chromatographic peak height, area, and position, 10 data points per standard deviation unit (σ) are needed assuming a Gaussian peak. For a 1-second wide (FWHM) peak, now being achieved in high performance gas chromatography, this corresponds to 20-30 samples (data points) per second. For current scanning filter mass spectrometers, this sampling rate is achievable only with selected ion monitoring (SIM) or over a very limited mass scan range. When such rapid full mass scans are possible, the detection limits are reduced at least 1000-fold over SIM. The under sampling of scanned mass spectra also results in varying intensity distortions of the mass spectra. Such "skewed" spectra reduce the reliability of spectral matching programs and interfere with the application of "clean-up" programs to sort mixture spectra from overlapped chromatographic peaks into clean mass spectra for each component. These problems can potentially be avoided with non-scanning or array-detector mass spectrometers such as magnetic dispersion with array detector, FTMS, and time-of-flight (TOF) MS. None of these array detector MS instruments currently meets the scan rate, sensitivity, mass range, and mass resolution required by modern high-performance chromatography. We believe TOF-MS has the best chance to achieve these objectives in the near future.

A data rate of 20-30 useable full mass spectra per second requires that the ion detection rate be quite high. Specifically, at least 400 ions must be detected in the base peak alone for each scan file if its intensity is to have a precision of 5% or better. Assuming the base peak contains 1/20 of all the ion intensity in the spectrum, at least 8,000 ions must be detected per scan file for quantitation at 5% precision. In TOF-MS, an ion pulse is formed every 100 μ s to produce 10,000 transient wave forms per second at the detector, each containing full mass spectral information. With an integrating transient recorder (ITR) (1), 100 to 1000 successive transients are summed to produce 10 to 100 scan files per second. At 20 scan files/s, each of the 500 transients summed must, on average, represent 8,000/500 = 40 detected ions (minimum level for 5% precision in quantitation). For a reasonable dynamic range, the maximum ion detection rate should be at least five times the minimum quantitation level, or ~ 200 ions per transient. This eliminates the time-domain converter (arrival time detector) as a detection device since it is limited to only a few ions per transient. At the minimum detection level (S/N = 3), the ion detection rate at the arrival time of interest must be 10 times the background count rate for that mass. For a background of 10 ions/s in a given mass (time) window, the count rate for minimum detection must be 100 ions/s or one ion every 100 transients. Clearly, each ion event at the detector must advance the ADC in the transient recorder at least one count. The dynamic range of the TOF-ITR system with an 8-bit ADC would be equal to saturation rate/detection rate = $28/0.01 = 10^4$, a very good value.

The sample ionization and mass separation processes must be capable of delivering ions to the detector at the above calculated rates. At the minimum quantitation level ($\pm 5\%$), the detected ion current must be at least (8,000 ions/scan file) $\times$ (20 scan files/s) $(1.6 \times 10^{-19}/\text{ion}) = 2.6 \times 10^{-14}\text{A}$. In TOF-MS, ion pulse formation can make inefficient use of a gaseous (continuous flow) sample. The efficiency of chopping an ion beam, continuously extracted from the source, is only about 50 parts per million. The efficiency of continuous ion formation with pulsed extraction from the source can be 1% or higher. Assuming an ionization efficiency of 10^{-5} , the overall efficiency for conversion of sample molecules into detectable ions is 10^{-7} for pulsed ion storage source. The sample flow rate to the source to produce a $2.6 \times 10^{-14}\text{A}$ detected ion current would be 2.5 pmole/s. For a 1-s peak, the minimum quantitation level would thus be 2.5 pmoles and the minimum detection level, 100 fmole.

An MS chromatographic detection system of this type has been built in this laboratory around a CVC-2000 TOF instrument and an in-house integrating transient recorder. It produces 1-40 scan files per second. For time-lag focusing, unit mass resolution is obtained over a mass range of 2.5:1 for any given time lag setting (2). The detection limit is about 1 pmole at 20 scans/s, comparable to that of scanning filter instruments in SIM mode, but in our case, with near full spectral range and with no spectral skew. Novel approaches will be required in the data systems to process data at the required scan file generation rate and to review chromatographic run files with tens of thousands of scan files.

Particularly for applications in the natural sciences, there is great interest in the precise measurement ($\pm 0.001\%$ ^{13}C , 95% confidence interval) of carbon-isotopic compositions of individual organic compounds. To avoid problems associated with conventional, dual-inlet mass spectrometer systems in this application, we have extended the development of isotope-ratio-monitoring gas chromatography mass spectrometry (irmGCMS, ref. 1). A schematic diagram of the instrument is shown in Fig. 1. A vitreous silica capillary leak withdraws CO_2 , traces of O_2 , and He from a post-column combustion reactor with $V < 30\ \mu\text{L}$. Pressure in the reactor is stabilized at 1 atm and O_2 is supplied by dissociation of CuO at 800°C . Manipulation of gas flows allows diversion of solvent peaks. The ion source has a conductance of $\sim 1.6\ \text{L/sec}$ (air), about 4X greater than a conventional isotope-ratio source. The source housing is differentially pumped by a 300 L/sec turbomolecular pump. Rise times of all three collector amplifiers are carefully matched at 60 ms. A specialized data system integrates ion currents for selectable time intervals in the range 60-240 ms.

Figure 1. Isotope-ratio-monitoring gas chromatograph mass spectrometer.

Replicate injections of small peaks of CO_2 yield highly reproducible integrated ion current ratios. Specifically, for peaks containing $0.67\ \text{nmol}\ \text{CO}_2$, the measured relative standard deviation of

Figure 2. Chromatographic separation of isotopic species (see text).

45/44 ion-current ratios is $\sigma/R = 0.013\%$ (2). At the observed ionization efficiency of 6×10^{-5} ions/molecule, the shot noise limit is 0.006%. For 22 nmol peaks, $\sigma/R = 0.002\%$ (limit 0.001%).

When high-resolution capillary columns are employed, combustion of chromatographic peaks reveals significant resolution of isotopic species. Shown below in Fig. 2 are (a) ion currents and 45/44 ratio across a chromatographic peak (C_{21} , *n*-alkane, methyl-silicone column), (b) signals expected in the absence of chromatographic resolution of isotopic species, (c) signals expected for a $^{13}C^{12}C_{20}H_{44} - ^{12}C_{21}H_{44}$ separation of 30 ms. The ^{13}C -containing species elutes more rapidly. This behavior is the result of a vapor-pressure (*i. e.*, equilibrium) isotope effect. To avoid degradation of isotopic accuracy, care must be taken to integrate ion currents across the full width of chromatographic peaks. The phenomenon must also be taken into account during deconvolution of overlapping peaks.

The accuracy obtainable in measurements of isotopic compositions of individual alkanes is shown in Table 1. Isotopic compositions are presented in terms of $\delta^{13}C_{PDB}$ values and expressed in terms of permil units (‰). A standard deviation of one permil is equivalent to $\sigma/R = 0.1\%$. The uncertainties are considerably increased relative to those obtained following injection of peaks of CO_2 . Correction for CO_2 contributed by combustion of column bleed and uncertainties associated with standardization (*i. e.*, placement of the isotopic compositions relative to an isotopic standard) are primarily responsible for this degradation. In order to obtain standard peaks that do not interfere with normal alkanes, samples are spiked with perdeuterated *n*-alkanes. The δ values of the deuterio-alkanes are accurately known, and the δ values of unknown peaks are referred to them.

Acknowledgements. We appreciate financial support from Chevron Oil Field Research Corporation and provision of isotopic standards by Martin Schoell and Robert Carlson of Chevron.

Coupling Planar Chromatographies with Mass Spectrometry
and Mass Spectrometry with Optical Spectroscopic Imaging

Kenneth L. Busch

Department of Chemistry, Indiana University
Bloomington, IN 47405

Mass spectrometry has been coupled to planar separation techniques using a variety of indirect interfaces; the twenty year history of TLC/MS has been recently reviewed [1]. The capabilities of FAB, SIMS, and laser and plasma desorption for the direct sputtering of TLC plates and other chromatographic media have all been explored. At least one commercial vendor offers a probe accessory that allows the direct FAB analysis of small TLC strips. Our own work has focussed on the development of a grand scale two dimensional sample chamber that allows the full xy spatially-resolved images of samples to be recorded. Concurrent with this work has been extensive investigations into the sputtering mechanism and the details of sampling from a variety of matrices (solid and liquid).

The criteria by which the chromatography/SIMS experiment must be judged include selectivity, sensitivity, and spatial resolution, among others. The selectivity of mass spectrometric detection for chromatography/SIMS is the equivalent of any other mass spectral experiment. Secondary ion mass spectra contain even-electron ions indicative of molecular weight as well as structurally-informative fragment ions. A large collection of SIMS spectra is available in the literature for inspection. The information available from the mass spectrum is of particular use in the chromatography/SIMS experiment when allied with the ability to rescan a chromatogram. Just as in GC/MS, when all ions that comprise a mass spectrum of a pure compound must trace the same peak time profile, in TLC/SIMS, for example, all ions must follow the same xy profile. The sensitivity of the TLC/SIMS experiment has been shown to extend to about 100 pg for discrete samples with high secondary ion yields. The limit is the ability to extract the material from the chromatographic matrix efficiently and without loss of spatial resolution. In general, the sensitivity is lower due to the simple fact that the flux of sample into the source is not compressed into a short time window as with GC/MS. In the latter situation, the absolute intensity of the signal is high, but the persistence short. In chromatography/SIMS, the absolute level of the signal is lower, but the persistence longer; signal averaging increases the sensitivity of the method at the cost of increased analysis time.

Finally, the practical limits of spatial resolution in chromatography/SIMS should be discussed. In the determination of the homogeneity of sample spots, or in the deconvolution of two overlapping sample spots, the highest possible spatial resolution is sought. The liquid metal ion gun discussed in the previous section is capable of providing a focussed spot of 1 micron diameter on the surface of the chromatogram. The minimum detectable number of ions, and thus the practical lower limit of spot size for organic analysis by SIMS, can be estimated by considering the total number of molecules present in a chromatographic spot. For a spot size of 100 microns diameter, 20 microns depth, approximately 10^{14} molecules of a 300 dalton molecular weight compound are present. Assuming a 10^{-4} transmission efficiency for the secondary ion mass spectrometer, a 10^{-3} ionization efficiency, and a 25% extraction efficiency, about 2×10^7 ions will reach the detector. A spot size of 10 microns provides 10^5 ions at the detector, and a 1 micron spot provides 10^3 ions. Ten microns is a reasonable estimate of the lower practical limit in spot size that can be obtained with the chromatography/SIMS experiment, based also on the signal-to-background level that must be attained in the mass spectrum. In routine operation, the FAB and cesium ion guns have been modified to provide a spatial resolution of 0.1 mm. Since many developed spot sizes in TLC are larger than this value, this is sufficient spatial resolution for determination of spot homogeneity, and acquisition of data sufficient for the deconvolution of partially-overlapped spots.

In the last few years, we have developed a number of methods for the application of extraction matrices to the surface of a planar chromatogram, and have explored the sputtering of ions from solid matrices, from liquid matrices, and from matrices that are not quite either. We have shown explicitly that these methods do not cause changes in the spatial orientation of the developed spots on the chromatogram. We have recently developed a surface tracking capillary that is used to bring liquid directly into the vacuum and onto the surface of the chromatogram while sputtering is taking place. The polarity of the solvent can be adjusted as the xy coordinates of the plate are changed to provide varying extraction efficiencies. Experiments also show that the transient matrix does not change the dimensions of the developed spots.

For simple mixtures, the time required to bring sample spots to the point of analysis is not excessively long, especially with automated sample positioning with the piezoelectric translation stages. For more complex mixtures, and larger chromatograms, scan lines can be followed that ultimately intersect sample spots of interest, but overall, the measurements require excessively long periods of time for sample spot siting and analysis. Practically, almost all chromatograms are pre-screened visually before placement within the mass spectrometer. If the sample spots can be visually located, the placement of the sample spot within the point of instrument focus can be monitored through the viewports and plexiglass window of the SIMS instrument. A hand-held UV/vis lamp is also used to illuminate thin layer chromatograms with a fluorescent binder. Dark sample spots on the uniformly fluorescing background are noted by pencil marks, visible again through the ports or windows of the SIMS instrument. Finally, reversible iodine staining, with marking of the sample spots, is also used in preliminary siting of sample spots.

Each of these exercises suggest that an optically-based imaging system should be integrated with the SIMS analysis of chromatograms. Separate imaging of a thin layer chromatogram on a commercial scanning densitometer could be used, with optical spectroscopy data generated in the first xy measurements ultimately correlated with the mass spectra of the organic compounds in a separately determined xy plane. A more satisfactory approach is to simply replace the mass spectrometer with the optical imaging detector, and to leave the sample (in this case, a thin layer chromatogram) in a common coordinate system. Both optical image and mass spectrometric data are then correlated directly in the xy planar coordinates. Reduced sample chromatogram handling also reduces sample contamination and sample degradation.

In the second generation chromatography/SIMS instrument, the quadrupole is replaced by a modern charge-coupled device camera. Sample spots on a thin layer chromatogram are located in visual light, in UV/vis irradiation, or with reversible general and specific color developing reagents. Once the chromatogram is placed on the piezoelectric sample stages of the sample cell, both optical data and mass spectral data are measured within the same planar coordinates. Three detection schemes are sufficient to detect all compounds. With TLC plates coated with a fluorescent coating, illuminating the plate with 254 nm UV light yields a bright plate with dark spots corresponding to the component spots. If a particular compound does not occlude the fluorescence of the plate, and hence is not detectable by this method, the compound may iodine stain. Exposing the plate to iodine vapors turns the component spots brown. Visible light can now be used for the detection, and the iodine pumps away rapidly in the vacuum of the mass spectrometer. If iodine staining fails, a specific color-developing reagent can be used. For instance, reacting polycyclic aromatic hydrocarbons with 2,4,7-trinitro-9-fluorenone yields purplish spots.

The CCD camera can provide data complementary to the mass spectrometry data. For instance, compounds such as polysulfonated dyes are difficult to sputter with SIMS or FAB, but provide a strong visual signal. For some highly colored compounds, the high sensitivity of the charge-coupled device lends to very low detection limits. Figure 3 shows a row-plot of approximately 390 pg of oxazine 4 perchlorate, a laser dye, detected using 366 nm UV radiation. This signal to noise ratio, along with the fact that this row-plot only intersects 1/25th of the total sample, corresponds to a detection limit of about 7 pg (24 femtomoles!). The CCD camera is also being used in current experiments to monitor the sample droplet as it is sputtered, using dyes to monitor diffusion rates from within the bulk and across the surface.

A PRIMER ON ELEMENTAL MASS SPECTROMETRY
ICPMS (SOLUTIONS) VS GDMS (SOLIDS)

W.W. Harrison
Department of Chemistry
University of Florida
Gainesville, FL 32611

By far the largest number of mass spectrometry applications involve organic samples, yet there exist important needs in elemental analysis that are being met more and more by rapidly growing new mass spectrometric methodology. The two major techniques considered in this report are inductively coupled plasma mass spectrometry (ICPMS) and glow discharge mass spectrometry (GDMS). Each is a form of atomic mass spectrometry, in that the ideal ion source would reduce the analytical sample to simple atomic ions. Unlike organic applications, some form of relatively high energy is required to create the atomic reservoir and to effect ionization.

EXPERIMENTAL

Quadrupole based instruments are used with both ICPMS and GDMS, although a magnetic sector unit is the chief commercial unit for the latter. Figure 1 shows one type of GDMS instrument.

Figure 1. Cross section schematic of a glow discharge mass spectrometer.

The low resolution of quadrupoles can cause problems if polyatomic species occur at the same nominal mass as atomic ions. Even the sector instrument cannot resolve many of the more common problems, although in general this source is not particularly prone to form polyatomics.

RESULTS AND DISCUSSION

Elemental mass spectrometry has many advantages in the competitive trace element analysis field. Spectra are quite simple, compared to optical emission spectra, as exemplified in Figure 2.

Figure 2. ICPMS spectrum of molybdenum solution.

Elemental mass spectrometry is also very sensitive. Both techniques commonly exhibit ppb detection limits. Solution sensitivity is often given in parts-per trillion. Experimental simplicity is also often cited as an advantage, at least in comparison to many other techniques of comparable sensitivity. Both metals and nonmetals can be determined, as opposed to primarily metals in optical emission and adsorption. Matrix effects, while certainly not absent, are at a minimal level, particularly with GDMS. The isotopic information obtainable with each technique also stands as an advantage relative to other trace element methods.

The applications to which these two techniques have been directed are ever growing. ICPMS is useful for solution samples or any materials that can be easily dissolved. High acid or solids content in the solutions can, however, cause problems in trace analysis. GDMS is particularly valuable for samples that profit from analysis directly in the solid form. For example, the analysis of high purity metals is a major application, since no contamination-mixing is required. Table I shows results of an analysis of high purity indium.

Table I. Impurities detected in high purity indium by GDMS.
Values in ppm. (VG Isotopes)

	Sample I (99.9999%)	Sample II (99.999%)
Mg 24	0.017	0.013
Al 27	0.056	1.40
Si 28	0.020	0.15
P 31	0.006	0.003
S 32,34	0.70	0.5
K 39	0.76	0.26
Ca 44	0.23	0.26
Fe 56,54	1.46	1.80
Cu 63,65	0.12	0.15
Zn 64,66	0.018	0.006
Cd 111,112	0.015	0.027
Sb 121,123	0.17	0.018
Te 125,126	0.018	0.035
Tl 203,205	0.33	0.81
Pb 206,208	0.45	3.76
Bi 209	0.004	0.033

Nonmetal samples, such as geological materials, can be analyzed by either technique, although with additional steps. For ICPMS, often difficult dissolutions are required with attendant problems. GDMS needs a conducting sample, so some metal matrix must be mixed with the sample before it is compacted into a suitable electrode, with the possibility of introducing impurities. Still, excellent results have been obtained with each technique for such difficult sample types, given the proper analytical preparation.

RIMS and TIMS and APPLES and ORANGES - A COMPARATIVE SUMMARY Larry J. Moore, Washington Regional Center, Atom Sciences, Inc., College Park, MD 20742

Thermal ionization mass spectrometry (TIMS) has a long and distinguished record in the performance of precise and accurate isotope ratio measurements for those elements amenable to the variant forms of the thermal ionization mechanism. Within the last several years laser resonance ionization mass spectrometry (RIMS) has been conceived and reduced to practice in trace metal and isotope applications peculiar to its sensitivity and selectivity advantages. The purposes of this paper are to discuss the principles and instrumentation used for TIMS and RIMS, summarize the current status of their development, and illustrate similarities and contrast differences between the techniques.

The basic thermal ionization phenomenon results in the spontaneous emission of ions from a hot surface onto which has been deposited the element, or a salt containing the element of interest. The Saha-Langmuir equation describes the ionization process:

$$\frac{n^+}{n^0} = A \exp \frac{(W-IP)}{kT}$$

Where n^0 = neutral atoms, n^+ = positive ions, $A = g^+/g^0$ = statistical weight ratio of ionic to atomic species leaving the surface, IP = ionization potential of the element being ionized, W = work function of the surface, k = Boltzmann constant and T = temperature in Kelvin.

In general the ionization efficiency is greatest for those elements with low ionization potentials, and for refractory metal substrate surfaces with high work functions. In the early history of the development of this technique, the alkali and alkaline earth elements were among the relatively few of the periodic table that were deemed amenable to this ionization process. Subsequently it became apparent that if the ionization potential of the element were sufficiently high, its electron affinity would permit the formation of negative ions. This observation led to the ability to determine the halides using negative ions. In the interim between the conception of TIMS and the 1960's, the precision and accuracy of isotope ratio measurements was improved from a few percent to a few tenths of a percent. The ensuing decade into the 1970's witnessed the improvement of isotope ratio precisions to a part in ten thousand, and accuracies approaching this level. Current commercially available TIMS instrumentation is capable of isotope ratio precisions in the parts per million range.

In parallel with these improvements, and driven principally by application needs in the geological community and nuclear industry, ingenious improvements have occurred that extend thermal ionization to many other elements of the periodic table that were previously considered intractable. The advent of ionization enhancement agents, such as the silica gel/phosphoric acid process (1) allowed the analysis of submicrogram quantities of lead (and other high ionization potential elements) and provided a powerful tool for environmental, biological and geological investigations through the

measurement of lead isotope ratios. The negative ion analog of thermal ionization advanced analogously, using lanthanum hexaboride coated surfaces (2) to reduce surface work functions and permit extremely efficient ionization of halides and other non-metals previously immune to ionization. A collective result of these advances has been to extend the ionization capability, at varying sensitivities, to more than two-thirds of the elements in the periodic table. More recent developments in the analysis of small actinide samples suggest that time efficiencies may be greatly improved through total integration of the isotopic data (3).

Although chronologically somewhat later in conception and practice, energetic primary ion bombardment beams were used to sputter materials and form secondary ions directly. During the thirty or so years since its inception, secondary ion mass spectrometry (SIMS) has been refined analogously to its thermal ionization predecessor, and is widely used today for the spatial characterization of materials. The fast atom beam (FAB) primary ion source, although developed initially for the direct analysis of liquids, is also being used to determine stable isotope ratios in biomedicine (4).

Thermal ionization and ion sputtering utilize the ions formed directly in the ionization phenomenon. For most elements and/or their attendant matrices, the analyte ions formed directly represent the minority of species produced in the phenomena, whereas the neutral species (including a large proportion of atoms) predominate, often by as much as several orders of magnitude. If it were possible to access this neutral atom population, it might be possible to exploit these species for more sensitive analyses, and/or to extract new information regarding the origin and character of the species. Laser resonance ionization spectroscopy (RIS) (5), combined with mass spectrometry (RIMS), provides a unique opportunity to access the neutral species formed in conventional ionization processes.

Basic advantages of the RIMS technology are: sensitivity, in that each atom that crosses the active volume of the laser can be ionized with unit efficiency; selectivity, such that the tunable laser can ionize specific elements and isotopes in the presence of billions of disparate atoms; generality, in the ability to ionize every element in the periodic table, except helium and neon (6). Since the (RIS) ionization process utilizes neutral atoms and is independent of the directly formed ions in the atomization phenomenon, the atomization and laser ionization steps may be temporally and spatially segregated. This segregation permits the optimization of the parameters associated with the ionization efficiency, such as geometric expansion of the atom plume with time; overall system efficiencies of eight to twenty percent (i.e., of 100 atoms sputtered from a surface, eight to twenty are registered at the detector of the mass spectrometer) have been achieved. Another benefit of the temporal segregation is that the ions formed directly in the atomization phenomenon may be suppressed or extracted to prevent their interference in the mass spectrum.

Biomedical applications are currently underway using RIMS, in

medically diverse areas such as neonatology, neurology, diabetes, and hematology. A method to determine copper in microliter serum samples has been developed (7) and methods are underway for ultra-trace iron, zinc, chromium, aluminum, molybdenum and vanadium in extremely small samples. Femtogram sensitivities have been demonstrated for stable chromium isotope tracers, and picogram levels of chromium have been resolved in microliter blood samples for the purpose of determining red blood cell volume, mass and survival. Extremely simple sample preparations are required.

A detailed comparison of relative advantages among RIMS, TIMS and SIMS/FAB is beyond the scope here; however, selected comparison may be made among a few key factors. Sensitivity: Clearly TIMS and SIMS can achieve overall ionization and system efficiencies of up to a few percent for selected elements. However, a substantial fraction of the elements, including some noble and transition metals, such as rhenium, osmium and chromium, may be analyzed more efficiently with RIMS, even with the limited duty cycle of the pulsed laser system. Selectivity: In principle, and in incipient practice, this is a major advantage of RIMS derived from the selectivity of the tunable laser. Whereas TIMS and SIMS generally require complex sample preparation and purification procedures for elemental/isotopic analysis, a one or two-step process has been sufficient for most RIMS applications. Some TIMS selectivity can be achieved through the use of negative (molecular) ions and thermally selective atomization, but this is not generally applicable. In conventional mass spectrometry, greater general selectivity has been achievable through increased engineering of the ion optics to provide higher resolution, but with attendant loss in sensitivity. In comparison, the 'engineering' with RIMS occurs with the laser selectivity, permitting simpler ion optics and no loss in sensitivity. Accuracy and Precision: TIMS is clearly the leader, providing isotope ratio precisions in the ppm range, and accuracies approaching the parts per hundred thousand range. Analogous RIMS precisions less than one percent and accuracies within two percent have been achieved, and further improvements may be expected. In the current state of development, RIMS precisions and accuracies are analytically useful and competitive for those elements for which there is superior sensitivity.

PRODUCTION OF IONS FROM CHARGED LIQUID DROPLETS IN ELECTROSPRAY, THERMOSPRAY, AND RELATED TECHNIQUES

Marvin L. Vestal
Vestec Corporation, 9299 Kirby Drive, Houston, TX 77054

In recent years spray techniques have become increasingly popular as a means of ionizing high molecular weight, nonvolatile ionic compounds. The spectacular results obtained by electrospray during the past two years (1-3) on large peptides, small proteins, and oligonucleotides have further whetted the interest of the biological community. While there is great interest in these techniques, there is also considerable confusion about the details of the apparatus, the mechanisms involved, the distinctions between various approaches, and the relative merits and capabilities of each. The ambitious goal of this presentation is to at least partially clarify some of these issues.

For purposes of this discussion, and will apologies to techniques which don't quite fit in one of these categories, we may classify the techniques according to the method used for producing the spray. These then become electrospray, thermospray, and aerospray (as suggested at Sanibel Island by John Fenn) to include those techniques which employ gas flow nebulization. In all of these techniques we can separate out five more or less distinct steps in the overall process evolving from a liquid flow to ions in the low pressure gas required by the mass spectrometer. These are the following:

1. Nebulization
2. Droplet Charging
3. Vaporization
4. Ionization
5. Ion transport

1. Nebulization

In electrospray the liquid emerging from a sharpened, small bore hypodermic needle is nebulized by direct application of a high electric field to the surface of the liquid. This produces very fine droplets apparently charged to their Rayleigh limit, and works best at very low flow rates on the order of a few microliters per minute. In aerospray devices, such as that pioneered by Iribarne and Thomson (4) and further developed and applied by Covey and Henion the liquid is nebulized by a high velocity jet of gas directed either transverse to or coaxial with the liquid nozzle. In thermospray the high velocity gas jet is generated in situ by vaporization of a portion of the liquid, which provides very efficient nebulization into relatively small droplets and provides a convenient source of heat for vaporizing large liquid flows. Thermospray generally works best at the higher end of the flow rate regime extending to several mL/min, while aerospray seems to perform best at intermediate flows.

2. Droplet Charging

In electrospray the droplets are charged directly in the nebulization process. This results in the smallest and most highly charged droplets of any of the spray techniques. In aerospray charging is by application of a high electric field to the aerosol. The detailed mechanism of this "induction" charging is not entirely clear (at least to me) but probably results from removal of ions of opposite charge produced in the spray and from polarization and disruption of initially neutral droplets. In thermospray the major charging mechanism is the statistical charging resulting from violent disruption of the liquid containing ions in solution. The latter technique produces essentially equal populations of positive and negatively charge droplets, while the former two produce droplets of the same sign as the applied voltage.

3. Vaporization

In all of these techniques production of molecular ions from the charged droplets requires nearly complete vaporization of the solvent. In the first two techniques the heat of vaporization is supplied by a relatively high flow (ca. several L/min) of heated gas at atmospheric pressure, while in thermospray the heat is supplied to the liquid in the capillary while producing the spray and downstream by heating the vapor at reduced pressure. As has been noted by Henion (6) thermospray can be done at atmospheric pressure, but the performance is poor, presumably because loss of ions by recombination is more important at higher pressures.

4. Ionization

Two basic mechanisms have been proposed for the production of molecular ions from highly charged liquid droplets. These are basically the ion evaporation model proposed by Iribarne and Thomson (7) and the Rayleigh disintegration model discussed by Roelgen and coworkers. (8) Considerable controversy remains concerning the relative importance of these two models, partly because it has proven rather difficult to design experiments that will unambiguously discriminate between them. In the ion evaporation model partially solvated molecular ions are evaporated in competition with evaporation of neutrals as a result of lowering the barrier to ion evaporation resulting from the high electrical field at the surface of a highly charged droplets. For large droplets their stability is clearly set by the ability of surface tension to resist the repulsion of the excess charge. This Rayleigh disruption may either lead to subdivision into two more or less equal droplets or because of local perturbations may expel its excess charge as a jet of small charged droplets. When the Rayleigh disruption has proceeded sufficiently, as it must as vaporization continues, eventually we may end up with only one sample molecule in a charged micro droplet. Further evaporation of solvent gently releases a molecular ion into the gas phase. It may not be possible, or necessary, to distinguish between these mechanisms, since both work best if we produce the maximum number of the smallest size droplets charged to their Rayleigh limits, and then cause the droplets to completely evaporate their solvent molecules.

5. Ion Transport

The most difficult part of the process appears to be getting the molecular ions removed from their birthplace and transported to the vacuum of the mass spectrometer. For compounds significantly more polar than the solvent, all of these spray ionization techniques appear capable of very high ionization efficiencies, probably approaching 100%, but efficient extraction from a high pressure environment in the presence of large quantities of condensable vapor is nontrivial. In both electrospray and aerospray, this is accomplished by sweeping dry gas in the opposite direction to ion transport to sweep away the vapor while an electrical field is applied to cause the ions to drift in the desired direction. In thermospray heat is applied to prevent condensation, and the sampling is done from a lower pressure. In all cases the major loss of sensitivity is due to the very low efficiency with which ion sampling is done.

Summary

All of the techniques discussed have provided useful results, and all have their limitations. To date thermospray is the most widely applied primarily because of its ability to handle normal analytical LC flows and to provide sensitive detection of a wide range of compounds under a variety of LC conditions. Electrospray has provided the most spectacular results on high molecular weight compounds, presumably because it provides the most efficient method for producing the highest specific charge, but applications have been limited by the low flow rates required. Variations of the aerospray approach show considerable promise because of their ability to bridge the gap between electrospray and thermospray. The recent development of capillary electrophoresis techniques should provide a boost for electrospray because of the obvious compatibility of the two techniques.

DESORPTION TECHNIQUES: HOW THEY ARE DIFFERENT

Robert J. Cotter

Department of Pharmacology and Molecular Sciences
The Johns Hopkins University
Baltimore, MD 21205

The so-called "desorption" techniques are many and varied. The different methods employ primary particle energies from the 5 KeV to 100 MeV range or photon densities of greater than 1 MW/cm^2 , and a complex array of matrices including glycerol/thioglycerol, salts, nitrocellulose surfaces, glutathione solutions, finely divided platinum powder and the UV-absorber: nicotinic acid (Figure 1). What they have in common is that they are all effective in producing "soft" ionization of large and complex molecules directly from the condensed phase, and have thus been invaluable for the elucidation of the structures of biomolecules. They are different from electron impact (EI) which uses 70 eV electrons to ionize molecules already in the gas phase and results in extensive fragmentation, or chemical ionization (CI) which is soft, but requires that the samples be volatile.

These high energy projectiles accomplish this remarkable feat of soft ionization because the energy is absorbed and isomerized by the substrate holding the sample before it reaches the molecules of interest (Figure 2). It is this part of the process that has received the

most attention from physicists and theoreticians attempting to shed some light on the "mechanisms." "Thermal spikes," "collision cascades" and "popcorn" (Figure 3) models have all been proposed. As the molecular particles leave the surface of the substrate, it is not clear whether they leave with a charge ("preformed" ions) or acquire protons by collision with "reagent" ions present in the dense plasma. What is clear, however, is that the spectra from all of the techniques resemble CI spectra, i.e. they consist of stable even-electron ions which are internally quite "cool." This low internal energy may result from the fact that internal modes are not highly excited by the desorption process ("popcorn" model) or from a cooling process after desorption due to "solvent shedding."

ENERGY ABSORPTION, ISOMERIZATION AND THE FORMATION OF SECONDARY IONS: THE MECHANISMS

The different desorption techniques give remarkable similar spectra, which can be interpreted with almost the same rigor that EI spectra can be interpreted. While it is not clear (in the complex multi-body collisional process of ion formation) where the proton is attached, heteroatoms (those which contain non-bonding electrons) are as good a place to start as in the interpretation of EI spectra. Thus, a proton attached to the N-atoms in each of the amide bonds of a peptide or the O-atoms in each glycosidic bond of a polysaccharide can be used to explain fragmentation of the adjacent bonds. The interpretation differs from EI, however, in that H-transfers are assumed where appropriate to the formation of an even-electron ion. Thus, the Y' N-terminal sequence ions from a peptide contain two additional protons: one resulting from proton attachment to the amide nitrogen and the other a H-transfer accompanying fragmentation. This close attention to protons is crucial when one considers that glutamic acid and glutamine, aspartic acid and asparagine, and glucose and glucosamine all differ by one mass unit.

But, most interesting is how desorption spectra differ. The attachment of alkali ions to form molecular ion species (and some of the fragments) is more prevalent in IR laser desorption (see Figure 1) than in fast atom bombardment, although spectra from both methods follow the same even-electron rules. The protonated oligosaccharides produced by fast atom bombardment tend to produce little fragmentation, but cleavage of the glycosidic bonds can be

improved by permethylation or peracetylation of the sample. On the other hand, the fragmentation of MK^+ ions produced by IR laser desorption is extensive, but results almost exclusively in two-bond ring cleavages (Figure 4). Derivatization, in this case, actually reduces fragmentation.

Hydrophobicity plays an important role in desorption techniques. In a mixture of peptides, the more hydrophobic residues reside on the glycerol surface in fast atom bombardment, and "suppress" the ion signal from the hydrophilic residues. Hydrophobicity plays an equally important role in plasma desorption mass spectrometry, but for different reasons. Figure 5 shows the PDMS spectrum (PD-MAP) of the tryptic digest of recombinant human growth hormone (rHGH) obtained from Genentech. The sample had been deposited on a nitrocellulose surface, and when washed produced the spectrum shown in Figure 6. In this case, the hydrophilic peptides were removed by washing and allowed observation of the hydrophobic residues (many of these at higher mass).

INTERACTIONS OF SOLIDS, LIQUIDS, AND VAPORS IN ICP-MS: POTENTIAL FOR ADVANCES

Guangxuan Zhu*, Changkang Pan and Richard F. Browner, School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

The advent of inductively coupled plasma mass spectrometry (ICP-MS) has provided a great advance in the capability to determine elements at levels typically two orders of magnitude below what is possible by inductively coupled plasma optical spectrometry (ICPAES). This has consequently opened up many avenues of opportunity for ICP-MS to explore approaches that were effectively closed to ICPAES. Examples include the use of coupled techniques, such as liquid chromatography ICP-MS (LC/ICP-MS) and flow injection ICP-MS (FI/ICP-MS), where the absolute amount of analyte passing to the detector in a transient mode is extremely low. However, even in these situations, there is a further need to improve system performance.

Some important areas in which ICP-MS might be usefully improved are: (1) lower detection limits (2) reduced isobaric interferences (3) improved short and long term precision. There are clearly many ways in which these goals might be pursued, but we have attempted to determine the manner in which the sample introduction process may influence these parameters. Specifically, we have carried out a systematic series of studies in which the primary aerosol is heated in one chamber, then the resultant partially evaporated aerosol is cooled in a subsequent chamber. The manner in which the evaporation processes take place is shown in Figure 1.

Figure 1. Model for aerosol evaporation: aerosol and vapor transport.

While the concept of the heater/condenser experiment is certainly not new, the manner in which it has been carried out has led to a number of significant advances both in our understanding of basic processes taking place in the interface, and in important aspects of performance, such as improved detection limits. The basic system is shown in Figure 2.

A number of basic studies with aerosol evaporation processes have been carried out, paying particular attention to: (1) the influence of the evaporation process on the aerosol drop size (2) the analyte mass transport to the plasma (3) the solvent aerosol mass transport to the plasma and (4) the solvent vapor mass transport to the plasma. It has been demonstrated that as the heated evaporation chamber temperature is raised, the mean drop size decreases non-uniformly as the temperature is raised. At higher chamber temperatures, the solvent is largely evaporated, which allows a much higher percentage of the analyte, now in the form of smaller, more concentrated drops, to reach the plasma. The mass transport of solvent aerosol remains constant at all desolvation chamber and condenser temperatures, and the solvent vapor transport is determined only by the condenser temperature.

Figure 2. Schematic of desolvation system for ICP/MS.

The net result of controlling the evaporation chamber and the condenser at optimum temperatures is to cause an increase in analyte mass transport passing to the plasma of approximately one order of magnitude. With a certain amount of element-to-element variation, this increase in analyte mass transport is reflected in a corresponding increase in signal, and decrease in detection limits for the elements tested. This behavior is contrasted with that experienced in ICPAES, where increases in background level in the plasma largely counteracted the influence of analyte mass transport increase. In the case of ICPAES, therefore, much smaller signal-to-noise ratio enhancements were observed for the same sample introduction setup as that used for ICP-MS.

PLASMA MASS SPECTROMETRY FOR CHROMATOGRAPHIC DETECTION

by

Joseph Caruso, Douglas Heitkemper, Hamzar Suyani and John Creed

Department of Chemistry
University of Cincinnati
Cincinnati, OH 45221

Inductively coupled plasma source mass spectrometry (ICP-MS) affords high sensitivity and low levels of detection for elemental analysis. When coupled with chromatographic methods for separation, it provides unparalleled low level detection and speciation for elemental species of toxicological or environmental concern. It is well known, that various elemental forms have markedly different toxicities as demonstrated, for example by elemental mercury, when compared with methyl mercury compounds. This discussion illustrates that sub-ng to pg detection levels are attainable for various arsenic and tin species after separation with high performance liquid chromatography (HPLC). Other analytical figures of merit such as linear dynamic range and precision are also discussed.

The advantages of HPLC with ICP-MS detection are several: low detection levels, real time chromatograms, multielement or isotope capability, ability to separate interferences from peaks of interest and the potential for measuring isotope ratios on eluting peaks. The interface requirements of HPLC-ICP-MS are relatively simple requiring flows compatible with ICP nebulization rates and minimization of both dead volume and transport of organic solvent vapor to the plasma.

Since urine is the major pathway for elimination of arsenic from the body, it is an important body fluid to monitor for the presence of arsenic. Braman and Roebuck have reported natural levels of 25 ppb or less for four arsenic species of major concern; arsenite (containing As^{+3}), arsenate (containing As^{+5}), monomethylarsonate (MMA) and dimethylarsinate (DMA)¹. In our studies anion exchange HPLC was utilized for separation by employing an amino-bonded phase column with a phosphate/acetate buffer in 30% methanol². Excellent signal to background and good separation are obtained with as little as 2 ng of the arsenic moieties spiked into urine. Detection levels range from 20 to 96 pg for the various As species cited above. In Cl^- containing samples ArCl^+ is formed in the plasma. This has the potential to interfere with any arsenic determination since it occurs at m/z of 75 along with the monoisotopic arsenic. However, in this study by using peak height as the signal, sufficient separation was available so that the potential interference with the arsenite peak was not serious. Comparisons with Fisher Uricheam analyzed standards and NIST certified SRMs showed a good correlation. Linear dynamic ranges (LDRs) were demonstrated at over 3 orders of magnitude. This low level detection capability allowed minimal sample handling. For actual urine samples, only filtering through a 0.2 micrometer filter was necessary prior to HPLC injection. Further detection enhancements at the low pg levels can be achieved by post-column generation of arsine from the eluting species followed by transport to the plasma.

To further assess the utility of HPLC-ICP-MS, studies of alkyltin compounds are discussed. The initial study involved developing separation and detection schemes for trimethyltin chloride (TMT-Cl), tributyltin chloride, and triphenyltin acetate. Both ion

exchange and ion pair HPLC were utilized. Strong cation exchange chromatography was employed with 0.1 M ammonium acetate in 85% methanol as mobile phase³. The ion pair chromatography was done using a C₁₈ column and sodium pentane sulfonate as the ion pairing reagent dissolved in 80% methanol at pH 3. Because of the high amount of organic solvent, background levels were appreciably elevated yielding as high as 11,000 cps, in contrast to the approximately 100 cps attained with equivalent salt concentrations in aqueous solutions. Nevertheless, detection levels ranging from 0.4 to 1 ng were obtained in these experiments, a factor of 1000 lower than those attainable with the same chromatography utilizing ICP optical emission detection³. Precisions on the order of 8% RSD were obtained with both separation types, while LDRs of 3 orders of magnitude were better for the ion exchange chromatography due to the better separation.

With the hope of minimizing the detrimental effects from the organic solvent, micellar liquid chromatography was employed⁴. Sodium dodecyl sulfate was dissolved in purified water at concentrations up to 0.1 M (~3% salt). Below this concentration the separations were not as efficient and above it resulted in clogging problems in the torch injector and the mass spectrometer sampler interface. Only those alkyltin salts of propyl- molecular weight or lower were suitable because of the capacity factor. However, for TMT-CI a detection level of 27 pg was obtained, a factor of 10 lower than the initial study³. Enhanced signal/background was clearly noted in these experiments because the organic solvent was eliminated. Precisions were improved to less than 2% RSD and the LDRs were taken over 3 orders of magnitude.

These studies show that HPLC-ICP-MS can provide detection at the sub-ng to pg levels for selected elemental species of environmental or toxicological concern.

ATTEMPTING TO REDUCE MOLECULAR ION INTERFERENCES IN INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY (ICP-MS)

D. J. Douglas, J. E. Fulford and K. W. Halligan

SCIEX®

55 Glen Cameron Road, Thornhill, Ontario, L3T 1P2

In the six years since the introduction of commercial ICP-MS systems there has been little reduction in the levels of interfering molecular ions (relative to atomic (analyte) ions). A variety of techniques such as changes in the differentially pumped interface, changes in plasma chemistry, desolvation and direct solid sampling have been evaluated and have proved only moderately successful in reducing interferences. The origin of the molecular ions is not always clear but in our view is likely the ICP itself and only to a lesser extent ion molecule chemistry in the differentially pumped interface since the number of potentially reactive collisions in the free-jet expansion is calculated to be small (1). The calculation assumes an ideal skimmed beam, free of shock wave interferences, background gas penetration, and scattering losses which occur to varying degree with any real beam source and which could in principle produce substantially higher levels of molecular ions than estimated by the ideal beam theory. Thus in a series of experiments reported here the levels of some molecular ions relative to analyte ions (of similar mass) were measured for different sampler skimmer separations (x_s). In a second series of experiments the use of triple quadrupole mass spectrometry to remove molecular ion interferences was explored with some preliminary results reported below.

The molecular ions studied and the solution concentrations used are shown in Table 1. The aerosol flowrate (at 1200w power, 15 mm sampling depth) was chosen by measuring the analyte signal vs. aerosol flowrate and then measuring the molecular ion ratio at an aerosol flowrate which gave an analyte signal one fifth of the peak response. This procedure approximates the operating conditions normally used to minimize oxide interferences and matrix effects, and was also found to remove some (small) variations in the level of molecular ions at a fixed flowrate with different sampler skimmer combinations.

The measured levels of interfering ions for four sampler skimmer separations are shown in Table 2. It is seen that (i) for all the sampler-skimmer separations there is no substantial reduction in the molecular ions (ii) at $x_s = 8.5$ and 10 mm there is a significant increase in the ratios ArO^+/Co^+ , ClO^+/Cr^+ , and $NaAr^+/Co^+$. The observations are consistent with the expected gas dynamics of the interface. The calculated Mach disc position (x_m) of the free-jet is 9.0 mm from the sampler. For skimmer positions near or downstream of the Mach disc ($x_s = 8.5, 10$ mm) a skimmed beam is not formed and a shock is formed in front of the skimmer; the gas stagnates and then re-expands through the skimmer with a greater chance for ion molecule chemistry to produce molecular ions. Thus the observations of table 2 are consistent with the hypothesis that ion molecule chemistry does not occur to a major extent in the expansion, particularly if the free-jet is skimmed properly ($x_s < x_m$). More practically, substantial reductions in molecular ions were not achieved from these interface changes.

A consideration of the kinetics of triple quadrupole mass spectrometry shows that if the dissociation cross sections for the molecular ions are large and if the scattering loss cross sections for atomic ions are small then substantial reductions in the ratio of molecular to atomic ions are possible by dissociating the molecular ions in the collision cell of a triple quadrupole MS system (ICP-MS-MS). Thus the total loss cross sections (i.e. the sum of dissociation, scattering, reaction etc.) for some atomic and molecular ions were measured here (at 50 eV LAB energy) with the results shown in Table 3. It is seen that (i) the loss cross sections are similar for atomic and molecular ions and (ii) for the atomic ions the cross sections are significantly larger than those expected purely from scattering losses (ca. $2\text{\AA}^2$) (2). It appears that (i) the dissociation cross sections for the molecular ions studied are small ($<5\text{\AA}^2$) and (ii) all species can be lost from the ion beam due to charge transfer to the argon target used. Support for this second postulate comes from (i) the large loss cross section for N_2^+ (which is near resonant with argon for charge transfer) (ii) the observation of Ar^+ as the major reaction product from ClO^+ , Ar collisions with a threshold at that expected for charge transfer (iii) the observation of Ar^+ from Cd^+ , Ar collisions with a measured cross section similar to the loss cross section of Table III.

Finally the use of ion molecule chemistry to significantly reduce molecular ion interferences was investigated. Cerium and Terbium were run to produce Ce^+ , CeO^+ and Tb^+ shown on a logarithmic scale in the spectrum of fig 1a. Oxygen was then used as a reactive gas in the collision cell and a constant addition linked scan carried out with the third quadrupole 16 amu higher than the first. The rare earth ions react with near gas kinetic cross sections to produce MO^+ in the collision cell which is transmitted by the third quad; the oxide ions react to a much lesser extent and so are effectively removed from the spectrum as shown in fig. 1b. Ion molecule chemistry can thus be used, at least to some extent to substantially remove molecular ions from ICP-MS spectra. We also note that ion molecule chemistry could in principle be used to separate atomic isobaric interferences e.g. $^{58}Fe^+$, $^{58}Ni^+$ since the chemistry of these ions is expected to differ.

TIME RESOLVED STUDIES IN GLOW DISCHARGE MASS SPECTROMETRY

W. W. Harrison and J. A. Klingler
Department of Chemistry
University of Florida
Gainesville, FL 32611

Glow discharge mass spectrometry (GDMS) normally employs a continuous dc argon discharge for sputter atomization and ionization. Pulsed gas discharges have been shown to exhibit certain advantages for enhanced atomic emission, suggesting the possible concurrent improvement for atomic mass spectrometry. For a common average discharge current, decreasing the duty cycle causes higher pulse currents and voltages. This produces greater sputter yield because of the higher energy of the incoming argon ions. Our studies revealed also that advantageous plasma processes occur, encouraging time resolved data collection.

EXPERIMENTAL

A quadrupole-based glow discharge mass spectrometer was used to collect all data. The power supply for the discharge operated in the dc or pulsed mode, when driven by an external pulse generator. A data gate was moved along the pulse envelope by appropriate delays and the resulting spectra compared at selected intervals. All data were collected by pulse counting and displayed on a multichannel analyzer before an eventual hard copy product.

RESULTS AND DISCUSSION

Initial experiments showed that enhanced sputter ablation was observed in the pulse mode compared to dc, as expected. Surprising, however, was the ion pulse shapes that resulted, as shown in Figure 1. The ion profile for the background gasspecies (e.g., OH, CO) was significantly different than that for the sputtered species. A large "afterpeak" resulted in an increase in the analyte signal as shown. By placing the data gate over the afterpeak, a mass spectrum was obtained that showed a high predominance of the analytical sample ions, as indicated in Figure 2. In this way, the often interfering background gas ions are discriminated against.

Figure 1. Typical ion profiles from the pulsed discharge.

Figure 2. Comparison of mass spectra taken from the plateau vs. the afterpeak region.

Time resolution studies taken throughout the pulse envelope showed the difference in ion signals. Particular differences were observed at the induction period and afterpulse regions. The spectra taken on the plateau were similar to dc spectra, as the discharge reached an equilibrium within 1-2 msec. Comparison of afterpeak vs. plateau also showed that dimers form less readily in the former. The cause of the afterpeak is suspected to be the creation of additional argon metastables as the discharge relaxes. This possibility is supported by results from the introduction of methane, a metastable quencher, which causes a sharp reduction of the afterpeak.

**NEW DEVELOPMENTS IN SOURCES FOR
PLASMA-SOURCE MASS SPECTROMETRY**
G.M. Hieftje, D.M. Chambers, B.S. Ross, G.H. Vickers, Q. Jin
Department of Chemistry
Indiana University
Bloomington, Indiana 47405

In plasma-source mass spectrometry, appropriate choice of the ion source affects not only sensitivity, but also precision, stability, and accuracy. Currently, the most widely used source for this technique is the inductively coupled plasma (ICP). However, the source commonly employed in ICP-MS has been adopted virtually unchanged from its counterpart long employed in emission spectrometry. There is no reason to believe that changes in operating frequency, plasma-torch configuration, discharge dimensions, or gas composition would not result in a further improvement in ICP-MS characteristics. Indeed, many workers have already noted substantial interelement interferences in ICP-MS and have attributed them alternatively to events that occur in the plasma, to those that arise in the mass spectrometer or ion optic assembly, or to those which arise during the expansion process between the atmospheric-pressure plasma and the lower-pressure ion-optic zones.

An even greater range of alternatives arises if completely different plasma sources are considered for use with mass spectrometry. In fact, one of the most useful sources to date has proven to be the glow-discharge lamp, a device substantially different from the atmospheric-pressure ICP. Another interesting source, which combines many of the attributes of the GDL and ICP, is the microwave-induced plasma (MIP). An MIP is ordinarily sustained at microwave diathermy frequencies (2.45 GHz) and can be operated at either atmospheric or reduced pressure. At atmospheric pressure, a moderate-power MIP exhibits many of the characteristics of the ICP and, indeed, would be expected to yield analytical characteristics that are similar. MIP discharges have the added advantage of operating at lower gas flows and powers than are customarily employed with an ICP. Furthermore, commonly available microwave support structures such as resonant cavities and wave-launching devices are capable of sustaining viable discharges in helium. This capability is especially important when coupled to mass-spectrometric detection because of the high ionization and metastable energies of helium. For example, it has already been shown that a helium plasma is capable of ionizing fluorine efficiently, something which is difficult in an argon-operated plasma. Fluorine is not efficiently ionized in an argon discharge since its ionization energy lies above that of argon.

At reduced pressures (typically 1-10 Torr), an MIP offers some even stronger attributes for coupling with a mass spectrometer. In the first place, the interfacing of a reduced-pressure discharge to a mass spectrometer is inherently more straightforward. Also, at reduced pressure the MIP should generate an even simpler background spectrum. Finally, a reduced-pressure MIP becomes an even more efficient ionization source; electron temperatures in such a plasma have been found to reach as high as 37,000K.

In this presentation, these various alternatives will be explored and compared. It will be shown that there is little operational or performance distinction between inductively coupled plasmas operated at 27.12 or 40.68 MHz. Although the higher-frequency discharge produces somewhat lower ratios of oxide ions to atomic ions and slightly higher ratios of doubly charged to singly charged ions, it yields detection limits that are comparable to or just slightly worse than those found with the 27-MHz plasma. Also, unless appropriate care is taken, a sampling-orifice-linked discharge often distorts results obtained with the higher-frequency plasma.

Conventional ICPs are sustained in a torch having an inside diameter of approximately 18 mm. We have explored the use of smaller torches having inner diameters of 13 mm and 9 mm, respectively. When operating conditions (input power, gas-flow rates, sampling position within the plasma, and sample-uptake rate) are optimized, the smaller plasmas are found to produce acceptable

performance, even though they can be operated at noticeably lower radio-frequency power and gas-flow rates. The 13-mm torch appears to be superior, however, because its larger dimensions makes positioning of the plasma with respect to the mass-spectrometry sampling orifice less critical. With both smaller plasmas, doubly charged to singly charged ion ratios and oxide-ion to atomic-ion ratios are lower than are found with a conventional ICP. However, detection limits range from being slightly better to being a factor of eight worse than are found with the usual torch.

Our mass-spectrometric examination of a helium-supported MIP has produced some surprising results. Although analytical performance levels of the MIP/MS combination were initially encouraging, especially for elements having high ionization energies, we were intrigued by unusually large interferences caused by easily ionized elements and by an extremely large mass-bias effect. This latter effect, which reflects differing sensitivities for atomic ions of differing mass, could be explained quite readily. Helium, being a far lighter gas than argon, produces a supersonic expansion of much greater velocity. As a result, analyte (sample) ions which travel with the expanding helium bath gas achieve a far greater velocity than they would in an expanding argon stream. Because analyte ions were assumed to reach the bath-gas velocity, their kinetic energies and, accordingly, their kinetic-energy differences would be far greater in a helium expansion than in one comprised of argon. The observed mass bias was surmised to be a result of this greater kinetic-energy spread.

To examine our hypothesis more carefully, we elected first to study in detail an argon expansion, since it had been examined also by other workers. In these initial studies, emission, fluorescence, and electrical-probe measurements were performed, with the optical observations occurring in both the atmospheric-pressure plasma and in the reduced-pressure expansion (interface) zone. Surprisingly, we found that even in the relatively high-pressure (nominally one torr) region in the interface, charge separation seemed to be virtually complete. By the time the expanding plasma plume reaches the second (skimmer) orifice, positive-ion concentrations exceed those of electrons by factors of at least 50. Furthermore, concentrations of selected sample ions in the expanding stream were affected noticeably by concomitant ions. In particular, the greater the mass of the concomitant ion, the lower was the observed concentration of the selected analyte ion. We believe these findings suggest one possible source of the mass-dependent interference that many workers have already observed in ICP-MS.

Carrying these studies further, we have measured ion kinetic energies at several locations in the expanding plasma plume by converting our mass spectrometer into a retarding-plate analyzer. Kinetic-energy measurements taken in the second stage of our vacuum system (held at approximately 10^{-3} torr) show little difference in kinetic energies of analyte ions expanding in an argon stream. In fact, the kinetic energy attained by most ions approximates that expected for the argon bath gas at the plasma temperature. We believe this finding results from the dominant influence of the bath-gas ions near the retarding plate. In contrast, when kinetic-energy measurements are made in the lowest-pressure region of our instrument (nominally 10^{-6} torr), mass-proportional kinetic-energy differences are observed among analyte ions. These latter investigations will be described in greater detail in a companion poster presentation from our research group.

ION KINETIC ENERGIES IN THE LOW-PRESSURE ZONES OF AN INDUCTIVELY COUPLED PLASMA MASS SPECTROMETER

D. M. Chambers and G. M. Hieftje

Department of Chemistry, Indiana University, Bloomington, IN 47405

Most inductively coupled plasma mass spectrometers (ICP-MS) consist of two or three differentially pumped stages. In these systems the analyte-containing plasma is sampled at atmospheric pressure and a portion of this sampled plasma expands into subsequent mass-spectrometer stages. In available ICP-MS systems the first stage has been designed to optimize the skimming of the supersonic free-jet expansion described by gas-dynamics theory. However, many of the equations that specify the geometry of the supersonic free-jet expansion assume a perfect, homogeneous, neutral gas. A departure from these ideal conditions that occurs in ICP-MS instruments can be attributed to the presence of ionized species, the addition of an analyte-containing aerosol, the entrainment of air, and/or a non-homogeneity in plasma-source temperature. Such departures complicate trajectory modeling of neutral bath gas and ionic species in the ICP-MS interface.

The trajectories of neutral species, though complicated, can be described by modifications to ideal gas-dynamic theory that take into account deviations from ideal-gas behavior. One such deviation, observed in our experiments, is that ion trajectories are influenced not only by the gas dynamics of collisions with neutrals, but also by electrostatic interactions between ions with large collisional cross-sections. These large cross-sections arise from low gas-kinetic temperatures that species attain in the first expansion stage. One of the approaches chosen to evaluate these forces has been to examine ion movement in the mass-spectrometer interface.

Ion kinetic energies have been measured in both the second and third stages of an ICP-MS that has been converted to a retarding-plate analyzer. These studies have been coupled with Langmuir probe analysis (1), used to characterize the constituents of the expanding plasma, and have led to the identification of an on-axis positive space-charge region (sheath-like in nature) that extends from the skimmer cone into the second stage approximately 10^{-3} torr of the mass-spectrometer interface. Ion kinetic-energy measurements in this second stage reaffirm the existence of this "sheath" formation. Mean ion kinetic energies measured in the second stage for light and heavy ions are similar (see Figure 1). This phenomenon is believed to be due to a large bath-gas-ion population and substantial ion collisional cross-sections. In the second stage, pressures are sufficient to allow ion-ion interaction, thus reducing the mobility of the analyte ions, which are being "swept" along by the bath-gas ions. The focusing of analyte ions is believed to be achieved indirectly through manipulation of the bath-gas ions. In the third stage, ion kinetic energies cover a range of approximately 5 eV from lithium (7 amu) to uranium (238) (Figure 2). This observed ion kinetic-energy spread is attributed to a low third-stage pressure (normally 10^{-6} torr). In the third stage, analyte ions are less influenced by ion-ion interactions, and are thus able to exhibit mass-dependent kinetic energies. In the ICP-MS third stage individual ions are expected to be focused on the basis of their own kinetic energies.

The use of ideal-gas-dynamic theory alone is not sufficient to model the sampling process employed in an ICP-MS system. Such theories do not take into account ion-ion interaction. The

present experiments have allowed us to identify some of the forces that determine ion trajectories in the mass-spectrometer interface and are being used to redesign both the ICP-MS first-stage interface and ion-optic system.

Figure 1. Mean ion kinetic energies for second-stage retarding. Optimum skimming conditions were used (e.g. first-stage pressure and desolvator condenser temperature).

Figure 2. Mean ion kinetic energies for third-stage retarding. Optimum skimming conditions were used (e.g. first-stage pressure and desolvator condenser temperature). A 0.5 mm orifice separated the second and third stage.

SAMPLE AEROSOL, PLASMA GAS COMPOSITION AND SAMPLER-SKIMMER GEOMETRY EFFECTS
IN INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY (ICP-MS)

Gary Horlick
Department of Chemistry
University of Alberta
Edmonton, Alberta, Canada
T6G 2G2

The inductively coupled plasma (ICP) ion source used for elemental analysis by mass spectrometry (MS) was adapted directly from the inductively coupled plasma used for elemental analysis by optical atomic emission spectrometry. This plasma is a high temperature Ar plasma maintained with a kilowatt RF supply running at 25 or 40 MHz and samples are normally introduced as aqueous aerosols. However, it is becoming increasingly clear that Ar alone may not be the best plasma support gas for ICP-MS.

The analytical performance of ICP-MS can be enhanced by the utilization of mixed gas plasmas. A mixed gas plasma is one in which part of the Ar of one or more of the three torch flows (outer, intermediate, central) is replaced by another gas such as N_2 , O_2 or air. With the addition of 5% N_2 to the outer gas flow, signal levels for many analytes (M^+) can be modestly enhanced (factors of 2 to 4). The most significant enhancements occur for those elements that have high first ionization potentials and for those elements that are strong oxide (MO) formers. On the other hand oxide signal levels (MO^+) are significantly reduced (an order of magnitude) by the addition of N_2 to either the outer or the central gas flow and a mixed gas plasma can also reduce the level of some background and matrix related species. These include ArO^+ , $ArOH^+$, Ar_2^+ , ClO^+ , and $ArCl^+$. Finally, some background species are increased by utilization of a N_2 mixed gas plasma. These include N^+ , N_2^+ , NO^+ , and ArN^+ along with a general increase in the overall background level.

Most samples are introduced into the inductively coupled plasma as aqueous aerosols. However, in ICP-MS, the introduction of samples as aqueous aerosols introduces more complexity to mass spectrometry measurements than it does to optical emission measurements. It is now recognized that a general reduction of the solvent load is beneficial in ICP-MS. The effect of various levels of aqueous solvent load reduction on analyte, analyte oxide and background species will be illustrated. These include use of a simple in line condenser, desolvation with a heating chamber and a condenser, and the combination of an in line condenser and a N_2 mixed gas plasma. Finally the background spectral characteristics of a completely dry plasma will be illustrated. In general, as the level of solvent (H_2O) removal is increased oxygen and hydrogen containing species are removed from the plasma. This can be a significant aid to a number of analyses and in fact, the introduction of samples as dry aerosols may become the preferred mode of sample introduction in ICP-MS.

The separation and the orifice sizes of the sampler and the skimmer cones also have a major effect on analyte species distribution and background signal levels in ICP-MS. Sampler-skimmer geometry experiments can be informative particularly for species that may have different formation mechanisms and zones in ICP-MS. For example, species can be formed in the central channel of the plasma, in the outer edges of the plasma (i.e., involving air entrainment), in a boundary layer around the sampler orifice, in the expansion jet or at the Mack disk. The effect of sampler-skimmer spacing on the signals of ArN^+ , $ArOH^+$, Ar_2^+ , ArO^+ , Ar_2H^+ , and several analytes (M^+) and analyte oxides (MO^+) will be illustrated. By increasing the sampler-skimmer distance 0.23 cm over that set by the instrument manufacturer (SCIEX ELAN Model 250), the relative amount of analyte oxide can be reduced but at the expense of analyte signal sensitivity. However, studies with a N_2 mixed gas plasma indicates that the increased sampler-skimmer separation (0.23 cm) may be more optimal. Some signal levels are improved and in particular the background "continuum" level introduced by the N_2 plasma is almost reduced to a normal level with the increased sampler-skimmer separation.

Finally the effect of sampler and skimmer orifice diameter on analyte (M^+) and analyte oxide (MO^+) signals will be shown. In particular, the sampler orifice diameter has a major effect on relative oxide levels. This will be illustrated for orifice sizes ranging from 0.51 mm to 0.94 mm and for analytes including La, Ho, Lu, and Yb. A curious observation will be presented that indicates that the summation of the M^+ and MO^+ signals of an oxide forming element resembles in overall response characteristics (measured as a function of nebulizer gas flow rate) the signal of a non-oxide forming element. This tends to indicate that most, if not all analyte oxides in ICP-MS are formed "downstream" of the ICP.

In conclusion, while at first glance plasma gas composition, sample aerosol processing, solvent load reduction, sampler-skimmer separation, and sampler orifice diameter may seem like disparate system parameters, they are all inextricably related to and impact on analyte and analyte oxide levels in ICP-MS. In a synergic manner, increased knowledge of the effects of these system parameters on signal characteristics should lead to improved performance in ICP-MS.

MASS RANGE EXTENSION IN QUADRUPOLE ION TRAPS

P.H. Hemberger[#], J.D. Moss[#], R.E. Kaiser^{*}, J.N. Louris^{*}, J.W. Amy^{*}, R.G. Cooks^{*}, J.E.P. Syka⁺, and G.C. Stafford⁺.

[#]Los Alamos National Laboratory, Los Alamos, NM 87545

^{*}Purdue University, West Lafayette, IN 47907

⁺Finnigan MAT, San Jose, CA 95134

Quadrupole ion trap methodologies have recently been extended to biomolecules and inorganic materials by coupling desorption ionization techniques to the quadrupole ion trap.¹ However, to fully exploit the capabilities of the ion trap for the analysis of biomolecules, the mass range of the ion trap must be extended. This work describes mass range extension from 650 Da (the mass limit of the commercial ion trap sold by Finnigan MAT) to 45,000 Da.

In the usual ion trap configuration, the maximum detectable mass-to-charge ratio, $(m/z)_{\max}$, is given by:

$$(m/z)_{\max} = 8V_{\max} / [q_{\text{eject}}(r_0^2 + 2z_0^2) \Omega^2] \quad (1)$$

where V is the RF peak voltage; r_0 and $2z_0$ describe the radius of the ring electrode and distance between end-cap electrodes, respectively; and Ω is the angular frequency of the RF drive voltage. The parameter q_{eject} is the point on the Mathieu stability diagram at which ion ejection occurs ($q_{\text{eject}}=0.908$ in conventional operation of the Finnigan ion trap). Hence, the mass range can be extended in four ways: (i) increasing the voltage of the applied RF, (ii) changing the trap dimensions, (iii) decreasing the frequency of the applied RF, or (iv) forcing instability at a different value of q_{eject} on the Mathieu diagram. Todd et al. have reported mass range extension to m/z 1466 through the use of a "reverse" scan, which uses both RF and DC fields and ion ejection at $q_{\text{eject}}=0.27$ along the $\beta_z=0$ line.²

We demonstrate mass range extension through (1) reduction of electrode size (16x extension)³, (2) reduction of the applied RF frequency (1.7x extension), and (3) resonance ejection at lower q_{eject} (45x extension)³. In this work, an Antek cesium ion gun was coupled to a Finnigan ion trap mass spectrometer (Figure 1). To document and evaluate mass range extension, cesium iodide clusters were injected into the ion trap for mass analysis. Figure 2 is a mass spectrum of cesium iodide clusters to 10,000 Da obtained with an electrode assembly of $r_0=0.25$ cm (1/4 radius of the commercial ion trap). Figure 3 is a mass spectrum of cesium iodide clusters to 45,000 Da obtained by reducing the frequency of the applied RF (from 1.1 MHz to 0.92 MHz) and by resonance ejection of stored ions at the $\beta_z=0.01$ line (corresponding to a value of $q_{\text{eject}}=0.014$). A supplementary ac voltage of 10 V pk-pk was applied to the end-cap electrodes during the mass scan. At a main drive frequency of 920 kHz and $\beta_z=0.01$, the frequency of the supplementary voltage is 4.6 kHz. The mass spectrum of $(\text{CsI})_n\text{Cs}^+$ to 16,000 Da obtained by resonance ejection at $\beta=0.04$ and the mass spectrum obtained using a 2.5 mm radius electrode assembly are in excellent agreement (Figure 4). Cs^+ desorption can also be used to inject biomolecules into a 'mass-extended' ion trap. Figure 5 shows the mass spectra of an injected peptide, Angiotensin I. The mass spectrum was acquired by ejection of ions at $q_z=0.42$ ($\beta_z=0.308$, axial modulation frequency=169.9 kHz).

Ion Injection into Ion Traps

Richard A. Yost and Randall E. Pedder
Department of Chemistry, University of Florida
Gainesville, FL 32611

The last few years have seen a dramatic increase in interest in ion trap mass spectrometers, including RF (quadrupole) and magnetic (ion cyclotron resonance) traps (see figure below), for both fundamental and analytical studies. This remarkable growth in interest has stemmed in part from the unique features provided by ion traps, in which sample ionization, mass analysis, and even detection can be performed sequentially in a single region in space. These features include the ability to perform a variety of gas-phase ionization techniques (e.g., EI and CI) and two or more stages of mass spectrometry (i.e., MS/MS/...) without physical modification of the ion trap.

Ion Traps – 2 Major Approaches

Unfortunately, performing sample introduction and ionization in the same spatial region as mass analysis seriously limits the types of samples and ionization techniques that are practical with ion traps. The obvious solution to this dilemma is to perform sample introduction and ionization in a separate ion source, external to the ion trap, and then to inject these ions into the trap for mass analysis. This approach offers a number of advantages, as summarized below:

Why Ion Injection into Ion Traps ?

-
- Remove restriction of low-pressure gas-phase ionization
 - Isolate sample matrix from ion trapping region (reduce problems with ion-molecule reactions)
 - Control number and mass range of ions in trap (minimize problems with space charging)
 - Select polarity of ions in trap (prevent losses due to ion-ion recombination)
 - Improve ion source accessibility (magnetic trap)
-

Ion Injection into Ion Traps (cont'd) - Richard A. Yost and Randall E. Pedder

The range of sample introduction and ionization methods which are available with internal and external ionization are summarized in the table below. Clearly, the major impetus behind the development of ion injection is the desire to employ modern desorption ionization methods (for condensed-phase samples) with ion traps. In addition, the high sensitivity of electron-capture negative ion CI cannot be achieved with ionization within the ion trap, since electrons will not be thermalized for efficient resonant electron capture.

Sample Introduction and Ionization with Ion Traps

	<u>Internal</u>	<u>External</u>
<u>Gas-phase:</u>		
EI	<u>X</u>	<u>X</u>
PCI/NCI (low-pressure)	<u>X</u>	—
PCI/NCI (high-pressure)	—	<u>X</u>
ECNCI	—	<u>X</u>
<u>Condensed-phase:</u>		
LD	<u>X</u>	<u>X</u>
FAB/LSIMS	—	<u>X</u>
Thermospray LC/MS	—	<u>X</u>

It is important to realize that there are two major challenges to meet in developing a practical ion injection system for an ion trap mass spectrometer, as summarized in the table below. The next two tables review the progress in achieving these goals for both RF and magnetic ion traps. Elsewhere in this volume are extended abstracts which describe a number of further advances in ion injection into ion traps, as listed in the final table.

Challenges - Ion Injection into Ion Traps

1. Injecting (getting ions into the trap)
 - Magnetic mirror effect (ICR)
 - RF phase-dependence (quadrupole ion trap)
2. Trapping (keeping them there)
 - Remove ion kinetic energy by collisions or electrodynamic cooling

Two-dimensional FT/ICR

M. Bensimon, T. Gäumann*, J. Rapin, F. Verdun, M.-E. Walser & Zao Guohong
Institute of Physical Chemistry, Federal School of Technology, Lausanne, Switzerland

FT/ICR, compared to classical mass spectrometry, is a method where the different sectors of the latter are replaced by pulse sequences. The "normal" pulse sequence is shown in Fig 1: The minimum time between ionization and detection is a few milliseconds, long enough for all metastable decays to have died away. This minimum time between ionization and excitation can be extended to several seconds and allows different experiments to be performed. This time can be used to introduce additional pulses or pulse sequences in order to get supplementary information that can be represented in additional dimensions. They can be tentatively classified into three categories:

- a.) **nonspecific pulses** such as a pressure increase, a photofragmentation etc. The reaction time is in this case used as an additional dimension to the mass spectrum.
- b.) **semispecific pulses.** The fact that ions of different m/z -values have different resonance frequencies is used e.g. to perform a programmed ejection.
- c.) **specific pulses.** Ions of a given m/z -value do not only have the same resonance frequency, but they are after an excitation in a coherent motion, i.e. they are also characterized by having the same phase. Examples will demonstrate the different possibilities.

ad a. In FT/ICR it is easy to get the very high resolution that is essential for separating isotope doublets such as $CD_3^{13}CH_5$. However it is necessary to have long transients; this corresponds to pressures in the 10^{-9} Torr range. For the study of ion-molecule reactions the low collision frequency in this pressure range requires very long reaction times. This is particularly cumbersome when working with labeled compounds, because these measurements necessitate a dynamic range that can only be obtained by averaging several thousand spectra. Thus pressure pulsing is a big time saver. The time between ionization and detection can also be used to photofragment an ion. This is demonstrated for toluene cation. Its reactions were subject of many publications. The problem is that the cation has activation barriers for isomerization to other structures (e.g. cycloheptatriene etc.) that are below the appearance energy of the first fragmentation, $C_7H_7^+$. This ion can also have different structures (e.g. benzyl, tropylium). The further fragmentation to $C_5H_5^+$ by a loss of acetylene seems to be a random process that asks for an equilibration of all C and H atoms before fragmentation. The problem is the determination of the ratio of the different isomers $C_7H_7^+$. The pulse sequence is shown in Fig. 3. All fragment ions formed by electron ionization are ejected by a specific ejection pulse. An infrared laser pulse of $10\ \mu m$ wavelength is used to fragment $C_7H_7^+$ with the lowest possible fragmentation energy. The time dependence of the irradiation time allows to estimate the minimum energy needed for fragmentation and its rate constant. The resulting $C_5H_5^+$ is probed by the pulse of an Ar-laser: only one structure (presumably benzyl ion) is decomposed to the $C_5H_5^+$. The results as a function of the irradiation time of the IR-laser are shown in Fig. 2

ad b. The type of measurements described above have the disadvantage that a single ion must be isolated before the start of the reaction sequence. The use of frequency pulses of large amplitudes allow the ejection of selected ions. The problem is to obtain a good separation of two ions having a small mass separation. The notch ejection is a convenient method to eject all ions except one mass [1]. It is also easy to program. By using techniques such as the S-matrix of the Hadamard transform one is able to lower the number of measurements considerably by measuring the reactions of several selected ions at the same time. However the existing software does not tolerate a complex ejection program, as it is needed by such a method in order to improve the signal-to-noise-ratio. The application of this technique in mass spectrometry has first been proposed by McLafferty et al. [2]. A new sweep technique (SWIFT), where the ejection is programmed in the frequency domain, some amplitude smoothing phase shift is applied and the resulting complex spectrum transformed in the frequency domain facilitates considerably the programming [3]. The resulting signal is used to obtain the tailored ejection.

ad c. Beside the evident advantage of improving the signal-to-noise ratio, the Hadamard technique suffers from the disadvantage that a complex ejection program is necessary and that only a prescribed number of predefined m/z values can be used. Whereas the former disadvantage could be avoided by a suitable software, the number of precursor ions that has to be known in advance is inherent to the method. Phase-sensitive

pulsing as it is used in the 2D-method can circumvent this problem [4]. The principle of the method is the following: In a first pulse the ions in the mass range of interest are excited as usual, bringing the ions in a coherent motion. After a delay that varies between 0.1 μ s and 1 ms the pulse is repeated. If the excited ions are in phase with their resonant frequency in the second pulse, they will be further excited and thus ejected. On the other hand, if the ions are in antiphase, they are deexcited back to thermal rotational energy. By increasing the selected increments Δ and taking additional scans, the concentration of the ions with thermal rotational energy varies as a function of Δ . This concentration will be modulated on successive scans with a frequency that depends on their m/z value. During a reaction or a photofragmentation this modulation frequency is transferred to the product. At the end of the experiment the scans are subjected to a two-dimensional Fourier transform: the first dimension is characteristic for the m/z value of the precursor ion, the second dimension gives the resonance frequency of the product ion. The procedure is shown in Fig. 3 at the left are shown three transients with different Δ values. The results after a first transform in t_2 is shown in the waterfall presentation of the middle: from left to right is the normal mass spectrum, from the front to the behind (still as a function of t_1). The difference in the modulation frequencies between $m/z = 15$ and 16 is clearly visible. An improved picture is shown at right, where also the second transform (in t_2) is executed. $m/z = 17$ has no frequency of its own, but only the frequency of its precursor ($m/z = 16$) is seen (the higher frequency is a harmonic). In Fig 4 a waterfall representation of the ion-molecule reactions in CHD_3 is shown. There are evidently a few more reactions present beside the classical proton- and hydride-transfer reactions. The FT transform is a method that works better with many data points. This is of no problem in a unidimensional case. However in the two-dimensional transform, the number of points to be stored might exceed the available memory. Parametric methods such as autoregression or maximum entropy methods [5] need only a few data points, but a high signal-to-noise ratio. An example of a modulation transient is presented in Fig. 5. The signal-to-noise ratio is such that both methods should give comparable resolution. Note that in the autoregression method the intensity is proportional to the peak surface, not the height. In both cases unit resolution is achieved with only 50 data points.

NEW METHODS OF ION EXCITATION AND ISOLATION IN FTMS

Robert B. Cody
Nicolet Analytical Instruments
6416 Schroeder Rd., Madison, Wisconsin 53711

To evaluate methods of ion isolation and ion excitation for Fourier transform mass spectrometry (FTMS), the effect of the excitation method must be determined for the ions that are to be excited and also for ions that are to remain unexcited. The reproducibility of the method must also be considered. Here we evaluate the stored-waveform inverse Fourier transform (SWIFT) excitation method [1] with respect to ease of use, selectivity (resolution), the effect on ions undergoing excitation (or ejection), and the effect on ions undergoing isolation.

In the SWIFT method, the operator defines the excitation in terms of the ion kinetic energies (ion orbital radii) and resolving power to be achieved over the specified mass ranges. The result of this spectral definition process is referred to as the "requested excitation spectrum". Inverse Fourier transform methods [2] are used to calculate the SWIFT excitation waveform that will produce result defined by the requested excitation spectrum. The principal advantage of SWIFT excitation over other excitation methods is that the operator needs only to specify the desired results -- no guesswork or tuning is involved. In theory, a SWIFT waveform can be calculated for any requested excitation spectrum.

We have found that at high magnetic field strengths the ejection of ions over a wide mass range occurs by z-axis (trapping) ejection rather than by ejection in the x,y-plane (the plane perpendicular to the direction of the magnetic field). The extent of z-axis ejection is proportional to the cube root of the mass of the ions to be ejected and increases with the frequency (mass) range over which ions are to be ejected. These factors can be used to design highly efficient SWIFT waveforms. By using SWIFT, we have isolated trace components in a complex mixture in the presence of interferences that have the same nominal mass [3], and we have obtained daughter ion spectra for parent ions that require a resolving power of 10,000 to separate [4].

The SWIFT waveform can be designed to leave an isolated ionic species with any desired kinetic energy. This was verified experimentally by measuring the signal intensity for an ionic species immediately following isolation of that species with a SWIFT waveform. The SWIFT waveform was designed to leave the isolated ionic species with a kinetic energy of 0.18 eV. The signal intensity for the isolated ionic species was 4.1% relative to the signal intensity for the same ionic species excited to a 0.5 cm orbital radius. This corresponds to a kinetic energy of 0.18 eV, which is in excellent agreement with the predicted value.

Kerley and Russell have described an ion isolation method (referred to as "ion partitioning") that uses a Fourier transform mass spectrometer with a dual trapped-ion cell [5]. Ions that are trapped in one of the two trapped-ion cells are excited to an orbital radius that is larger than the radius of a hole in the common electrode (the conductance limit) between the two cells. The desired ionic species is then selectively de-excited to a small orbital radius, and it is transferred to the other cell by grounding the conductance limit. This experiment can also be performed by using a SWIFT excitation waveform to selectively excite all ions except the desired species to a larger orbital radius. The SWIFT approach is simpler than the "excitation/de-excitation" approach because only one SWIFT waveform is required to isolate the desired species, and no guesswork or "tuning" is required.

Applications of the SWIFT technique include single-ion or multiple-ion monitoring [3], high-resolution parent ion selection [6] for tandem mass spectrometry (MS/MS), and complex experiments such as Hadamard transform FTMS[3]. We have found that the results of SWIFT ex-

citation are more reproducible than the results of swept-frequency excitation for the detection of high-mass ions. A tentative explanation for this observation is that swept-frequency excitation waveforms may contain a net dc component that can cause the ions to drift off-center and be ejected [7]; SWIFT waveforms are designed with no net dc component.

Selected-reaction monitoring is a highly specific identification method that can be performed with SWIFT techniques. In this MS/MS experiment, a SWIFT waveform is used to simultaneously eject daughter ions and accelerate parent ions to a chosen kinetic energy. If a target gas is introduced into the trapped-ion cell, the accelerated parent ions can undergo collision-induced dissociation (CID) and the resulting fragment ions are detected by SWIFT multiple-ion monitoring. Figure 1 shows an example of SWIFT selected-reaction monitoring for GC/MS/MS detection of n-butylbenzene. Figure 1a shows the total ion current chromatogram for a mixture of ten compounds. Figure 2a shows the total ion current chromatogram for selected reaction monitoring of the CID of the molecular ion of n-butylbenzene (m/z 134) to produce the m/z 91 and m/z 92 fragment ions.

In conclusion, SWIFT excitation is an efficient and selective method for ion excitation and ion isolation in FTMS. The effects of SWIFT excitation are well-defined for ions undergoing excitation as well as for ions undergoing isolation.

A TRIPLE STAGE QUADRUPOLE GLOW DISCHARGE MASS SPECTROMETER:
THE DISSOCIATIVE REMOVAL OF POLYATOMIC INTERFERENCES

W. W. Harrison
Department of Chemistry
University of Florida
Gainesville, FL 32611

F. L. King
Naval Research Laboratory
Washington, DC 20375-5000

Elemental mass spectrometry seeks to reduce all ionic species to the atomic form. Unfortunately, real-world atomic ion sources are imperfect, creating numerous polyatomic ions that potentially (and actually) interfere with atomic analytical ions of the same nominal mass. High resolution instrumentation solves only some of these problems and then at a high cost. We have taken a different approach by drawing on collision induced dissociation effects to break apart undesired polyatomic ions.

INSTRUMENTATION

A commercial triple stage quadrupole mass spectrometer (Figure 1) was used for all experiments. The conventional ion source was replaced by a glow discharge source with a direct insertion probe.

Figure 1. Triple stage quadrupole with glow discharge source.

An important aspect of the spectrometer was the nonlinear ion flight path, as fast neutrals from the glow discharge ion source can cause noise problems in line-of-sight quadrupole systems. The second quadrupole (Q3) was used as the collision cell by introducing millitorr levels of argon to interact with the ion beam.

RESULTS AND DISCUSSION

The original aim of this study was to determine if polyatomic ions could be dissociated to a great degree, thus reducing interference problems. An interesting aspect that arose during the experiments was the ability to perform certain diagnostics on the ion source processes. An example of the CID effect on GDMS spectra is shown in Figure 2, in which the ions from species like Ar^+ , OH^+ , and H_2O^+ are repressed by collisions with argon atoms, leaving a spectrum enriched in analyte ions. Aside from this directly understandable analytical advantage, the triple stage quadrupole permits the acquisition of parent and daughter spectra.

Figure 2. Effect of CID on removal of background peaks in GDMS.

Figure 3 illustrates the effect of scanning Q1, using Q2 for collision, and setting Q3 to pass on m/z 56.

Figure 3. Parent spectrum for 56 amu ions.

Apparent are the species which dissociate to produce Fe^+ , indicating some of the polyatomic ions that form in the discharge. Daughter spectra may also be obtained to show what species result from certain collisions. The TSQ thus offers both practical and fundamental opportunities for analytical studies.

EXPECTED REGULATORY AND GUIDANCE REQUIREMENTS FOR CONTROL OF AIR TOXICS

Gilbert H. Wood
Technical Support Division
Office of Air Quality Planning and Standards
U.S. Environmental Protection Agency
Mail Drop 14
Research Triangle Park, N. C. 27711

The U.S. Environmental Protection Agency (EPA) and many State and local air pollution control agencies are currently developing regulations and/or guidance for control of hundreds of air toxics. Gas chromatography/mass spectrometry will be required to measure emissions for hundreds to thousands of chemicals in the immediate future (now to the next few years). The sampling and analysis protocols will have to consider how to measure relatively low concentrations of numerous chemicals in the same emission stream. The protocols will be necessary for both testing to obtain data to develop emission limits and for compliance testing. Sound regulations depend on sound data and sound data depend on sound methods. Thus, the greatly accelerated standards development schedule will necessitate a greatly accelerated schedule for methods development.

Some people may doubt that hundreds of air toxics regulations will really be promulgated in the next few years, considering the small number of national emission standards for hazardous air pollutants that have been promulgated under Section 112 of the Clean Air Act in the last 19 years. However, this situation will change for two reasons. First, this low output of Federal standards has caused a number of States to forge ahead with their own regulations rather than waiting longer for EPA. Some of these States are developing test methods to support their regulations but many are forging ahead without developing test methods first. They hope that the methods will be developed by the time that enforcement decisions are necessary.

The second reason is that Congress has also noticed that EPA has not promulgated many hazardous air pollutant standards and has indicated via bills such as the House of Representatives Bill Number 4 - also called the Dingell Bill - that EPA must greatly accelerate the development of standards for air toxics. EPA expects that some bill, not necessarily HR4, but some bill, will be passed within a year that will require a large number of Federal standards in a short time.

The States and Congress are acting because they and EPA believe that control of air toxics is important to the safety and the health of all citizens. Air toxics include over 3,000 compounds detected in ambient air. Many of these are known or suspected carcinogens or have serious non-cancer effects such as respiratory disease, birth defects, or neurotoxicity. Also, many contribute to ozone formation, stratospheric ozone depletion, or indirect exposures. Air toxics are emitted directly from both stationary industrial sources and mobile sources and are also indirectly emitted via atmospheric transformation.

Agreement on the control of air toxics is complicated by disagreement on the perception of the nature of the problem versus reality. For example, some people say that no one has the right to pollute and the quantitative estimates of risk are crude and err on the side of underestimation and thus stringent control, including shutdowns, may be warranted. Other people say that pollution is the price we pay for an industrialized society, that society implicitly considers the risks and benefits of industrialization, and quantitative estimates of risk are crude and err on the side of gross overestimation and thus controls should be reasonable and generally not warrant shutdowns. The reality is that the limited available data can be used to argue either perception and reality probably lies somewhere in between. In most cases, control technology or pollution prevention, or other mitigation measures are available that can substantially reduce potential risk but not reduce the risk to zero. At current levels of control, air toxics are estimated to account for 1,600 - 3,000 cancer deaths per year. Estimates of the average urban individual lifetime cancer risk range from 1 in 10,000 to 1 in 1,000. Pollution is responsible for less than 5 percent of the 400,000 annual cancer deaths for all causes. Thus, air toxics represent a "high risk/high priority" problem area.

Regrettably, the portion of the air toxics problem that is currently quantifiable is limited to those chemicals for which there are both emission data and health data. However, the advent of industry self-reporting via the SARA 313 Toxic Release Inventory as part of the Superfund Community Right to Know Legislation should help. The partial report for 1987 identified over 300 toxic chemicals that totalled over 2.4 million pounds of emissions. Also, EPA's "Unfinished Business" Comparative Risk Project of 1987 reaffirmed the air toxics program area as high risk/high priority for both cancer and non-cancer risk. A number of studies of urban risk have estimated excess cancer of 1 to 30 deaths per year per million population and individual lifetime risks of 1 in 10,000 to greater than 1 in 1,000. A non-cancer study showed approximately half of the 197 chemicals studied exceeded the Acceptable Daily Intake (ADI) and 7 percent exceeded the Lowest Observed Effect Level (LOEL). For example, for chloroform, of 171 facilities for which exposure data were obtained, 162 exceeded the ADI, 50 exceeded the ADI x 10, and 4 exceeded the LOEL.

Information like this has elevated EPA's and Congress' concern about the status of the Section 112 program. Too often the current Section 112 program has taken a very long time to decide and redetermine actions within EPA and in court. Now the court is requiring final action on the remand for five benzene source categories by August 31, 1989, and a decision on whether or not to regulate nine additional benzene source categories by August 5, 1989. EPA is recontinguing development of hazardous air pollutant standards for 11 pollutants and over 20 source categories for which development had been suspended pending the benzene decisions. The pollutants include hexavalent chromium, ethylene oxide, asbestos, trichloroethane, perchloroethane, coke oven emissions, methylene chloride, carbon tetrachloride, chloroform, ethylene dichloride, and butadiene. Also, seven other air toxics regulations under other authorities are currently being developed. These pollutants include some of the previous pollutants plus dioxin/furan, hydrogen chloride, pathogens, cytotoxicants, various metals (arsenic, beryllium, cadmium, nickel, mercury, lead), chlorinated benzenes, chlorophenols, formaldehyde, polycyclic aromatic hydrocarbons, and polychlorinated biphenyls. Some of these will be proposed this year and most of these regulations should be proposed within 2 years.

To ensure that EPA does actually follow through on these standards and many more, Congress plans to revise Section 112 of the Clean Air Act. The Dingell Bill includes a list of 185 chemicals which EPA must assess and a schedule for assessments and regulations. After enactment of the revisions, EPA must publish a list of pollutants within 3 months, consider additions and deletions to the list, and publish a source category list within 12 months. Standards for ten source categories would have to be promulgated within 2 years, 25 percent of the source categories within 4 years, 50 percent within 7 years and all categories within 10 years. The standards would be based on Maximum Available Control Technology (MACT) and would require evaluation of the residual risk within 7 years of promulgation. Where the residual risk is significant, additional regulations would require up to 90 percent additional risk reduction. The main thrust of the Dingell Bill is to increase the number of standards promulgated by including mandatory schedules and lessening the difficulty of the initial decisionmaking by delaying the residual risk evaluation until 7 years after promulgation of MACT. Although the residual risk assessment is delayed, the test methods cannot be delayed because selection of MACT will depend on expected emissions and because the regulations will need to include enforceable emission limits.

The development of these methods is a huge task. The number of pollutants and interfering combinations and emission streams is almost overwhelming. Draft budget estimates for developing methods in the normal ways are far above the available resources. EPA doesn't have the answer yet. Innovative approaches will be necessary. Cooperative projects with EPA, States and local agencies, and industry are being considered. Clean Air Act Amendments to require industry to develop test methods are being considered. Surrogate pollutants will be used in some cases to represent broader categories. EPA will consider all reasonable suggestions to achieve the goal. Your suggestions would be greatly appreciated.

ROLE OF MASS SPECTROMETRY IN EXPOSURE ASSESSMENT PROGRAMS

E. O. Pellizzari
Analytical and Chemical Sciences
Research Triangle Institute
Post Office Box 12194
Research Triangle Park, NC 27709

After nearly two decades, the role of mass spectrometry in air pollution research remains as strong as ever in use with problems that have as their central thrust, chemical characterization and quantification. For example, every facet of the risk assessment model (Fig. 1) from source to health effects employs mass spectrometry with an assortment of ancillary attachments (GC, HPLC, FAB, etc.). A major research area encompassing mass spectrometry has been human exposure assessment studies where people's exposure to air pollutants have been determined. Exposure data as gleaned from population studies are important input into dose, metabolism and pharmacokinetic/toxicokinetic studies. With this information toxicological impact profiles and thus health effects of pollutants are established (1).

Mass spectrometry based technology has been used to identify sources of volatile organic chemicals (VOCs), e.g., those derived from building materials, environmental tobacco smoke (ETS), consumer products, attached garages, etc., which have an impact on indoor air quality and thus human exposure. Methodology has been developed which permits the collection and transfer of VOCs from personal, indoor, and outdoor air, and breath samples to GC-MS for qualitative and quantitative analysis (2-4). Examples of this successful application are demonstrated in the Total Exposure and Assessment Methodology (TEAM) studies (4-6).

The original assumptions concerning air pollution were: (a) outdoor air was the major route of human exposure, and (b) automobiles and industrial emissions were the major sources. With the advent of personal monitoring technology and results from direct human exposure monitoring studies, these assumptions have been significantly tempered. The TEAM studies have provided a wealth of actual human exposure data to VOCs and to semivolatile chemicals (e.g. pesticides, polynuclear aromatic hydrocarbons).

The TEAM program is a probability-base study where the participants selected for monitoring represent the entire population of a defined geographical area. This methodology allows inferences to be made to the general population from monitoring data on a smaller subset of individuals concerning exposure to as many as 30 VOCs. TEAM studies have been conducted with more than 700 people over the past nine years in Elizabeth and Bayonne, NJ, Devils Lake, ND, Greensboro, NC, Los Angeles, CA, Pittsburg, CA, and Baltimore, MD (4-7). In many areas follow-up studies have been conducted on the same participants in another or same season of the year. Several important discoveries have been made from these studies:

- (a) indoor air levels for many VOCs are higher than outdoor ambient levels;
 - (b) personal air levels are generally less than indoor air levels but greater than outdoors;
 - (c) significant source of human exposure to hazardous substances occurs from indoor air pollution, since most individuals spend 70 to 90% of their time indoors;
 - (d) energy conservation measures tend to decrease ventilation, which increases pollutant build-up indoors;
 - (e) within a home, room-to-room variations in concentrations are remarkably small, indicating good air mixing;
 - (f) similar exposure levels are observed in later years for the same season for the same individuals; however, different exposure levels may occur in different seasons of the year;
 - (g) breath levels, an indicator of actual exposure, best correlated with personal air levels;
 - (h) in-home and public building source emission rates were highest for those VOCs in consumer products used as room air deodorizers (e.g. p-dichlorobenzene, limonene, α -pinene) and for VOCs associated with ETS (e.g. benzene, styrene), dry-cleaned clothes (e.g. tetrachloroethylene), mobile sources/attached garages (e.g. benzene, xylenes, octane), and
 - (i) VOC exposure levels correlate with activity patterns of people.
- A recently conducted TEAM study examined hypotheses regarding major sources of exposure to several VOCs (5,8). Among these hypotheses were the following:
- (a) exposures to tetrachloroethylene are mainly due to dry-cleaned clothes in the home or wearing them;

- (b) exposures to aromatic VOCs may be partially due to storage of cars, lawn mowers, gasoline, kerosene, etc., in attached garages or other areas in the home; and
(c) hardware stores may be important sources of exposure to many toxic VOCs.

This study was designed to allow testing these hypotheses in 11 homes over a period of 3 or 5 days. Participants performed activities according to a set schedule--for example, all participants picked up freshly dry-cleaned garments on the second day of the monitoring period, and wore a freshly-cleaned garment on a later day. Personal, indoor and outdoor air samples and breath samples were collected for each participant over the 3-day or 5-day monitoring period. Air exchange rates were also measured to allow the calculation of source emission rates. Table 1 gives the peak 12-hr average tetrachloroethylene levels in nine homes before and after introducing the garments into the house. Five-fold to over an order of magnitude increase was observed in tetrachloroethylene levels, depending on the number of garments cleaned and the air-exchange rate in the home. The participant's actual exposure or dose is reflected by the levels measured in breath.

In addition to homes and public buildings, indoor air quality is also of concern in highly confined areas such as in submarines and in space flight. Air quality in nuclear submarines has been evaluated, using similar mass spectrometry based techniques as used in the TEAM studies. Selected VOC levels in one submarine that has been briefly studied is given in Table 2. VOC levels were an order of magnitude higher than those found in homes. The total organic levels (TOL) in each of the samples were also determined and found to be over two hundred times higher than the levels observed in the TEAM studies. Molhave's (9) research suggests TOL levels above 5 mg/m^3 may impair judgement and response/motor coordinating functions in some individuals. In the TEAM studies, ten percent of all air samples had TOL levels above 5 mg/m^3 (10,11).

In summary, our understanding of human exposure to chemicals has been greatly facilitated by the use of mass spectrometry based measurement techniques. Significant research remains to be performed, however, in all facets of the risk model (Fig. 1). For example little information exists concerning complex mixtures containing polar volatile and semi-volatile chemicals along the pathway of the risk model. The application of supercritical fluid and high performance liquid chromatography in combination with MS will receive considerable attention in future exposure assessment programs.

purposes.

Air monitoring by mass spectrometry has typically been performed by doing atmospheric pressure ionization (API). API has been demonstrated to be very sensitive for certain types of compounds but very insensitive to other compound types. Other drawbacks to the use of API that are characteristic of one or the other of the typical API sources, i.e. beta emitter sources and corona discharge sources, are: clustering; the need for large volume pumping; ionization saturation; the need for bottled gases; and frequent source maintenance. An alternative approach that has been used sometimes is to leak air directly into an electron ionization or chemical ionization source. The major drawback to this approach is that the sample pressure is typically reduced by seven orders of magnitude or more with a corresponding reduction in the concentration of the analyte. Thus an analyte present at a part per million in ambient air has a number density of 2×10^{13} molecules/cm³, but this is reduced to 3×10^5 molecules/cm³ if the sample is leaked into a conventional ionization source at a pressure of 1×10^{-4} torr (an analyte pressure of 1×10^{-11} torr).

We have developed a source that is intermediate to these two pressure regimes and that overcomes many of the operational disadvantages of traditional API sources. The source is called an atmospheric sampling glow discharge ionization (ASGDI) source and it has been described in detail previously.¹ This source operates in a pressure range of 0.2-1.0 torr. An important feature of this source is that the ionization is controlled predominantly by kinetics, not thermodynamics as is generally the case with API sources. Thus, the ASGDI source is especially useful for negative ion analysis for compounds which readily undergo electron capture.

The electron capture rate can be up to two orders of magnitude faster than the rate for ion/molecule reactions. Therefore in the ASGDI source, in which kinetic control is dominant, efficient formation of negative ions that may not be the most thermodynamically stable ions can occur. This also means that trace impurities that can change the ion chemistry in thermodynamically controlled ion sources will have little effect on the ASGDI source.

Once ions are formed, a suitable mass spectrometer is needed for the analysis step. Some of the characteristics of the ideal mass spectrometer are: high sensitivity, simplicity, small size, and MS/MS capabilities. The three-dimensional quadrupole ion trap, known as an Ion Trap Mass Spectrometer (ITMS) has these characteristics. We have interfaced the ASGDI to an ITMS for direct air monitoring. A schematic of the system is shown in Figure 1. The system is housed in a six inch per side cube with six inch conflat flanges. Ions are pulsed into the ITMS from the ASGDI source via an einzel lens which has a split middle element which serves to deflect the beam during periods when it is not desired to inject ions into the ITMS. The normal electron gate pulse from the standard ITMS electronics is used for this deflection. For negative ions the normal electron gate voltages are used while for positive ion injection this voltage is floated up by use of a 300 volt battery. Details of the system can be found elsewhere.²

It has been found that several parameters affect the efficiency of ion injection from the ASGDI source into the ITMS and the appearance of the mass spectrum that is obtained. The main parameters are: the nature of the bath gas; the pressure of the bath gas; and the rf level of the ring electrode of the ion trap. Collision-induced dissociation (CID) that occurs during injection, along with the injection efficiency, affect the appearance of the observed mass spectrum. The amount of CID is dependant upon the same parameters as the injection efficiency.

For bath gases, the lighter the bath gas, the more efficient the ion injection. This can probably be attributed to less scattering upon collision of the ion with the bath gas. Injection efficiency shows an increase with bath gas pressure with a maximum that is dependant upon the bath gas. For H₂ and He this maximum is in the range of 1.5 to 3 millitorr. It is observed that CID decreases with increasing bath

gas pressure. A likely explanation for this is that at higher pressures the ion energy is damped more and thus while there are more collisions at higher pressure, the ions have less kinetic energy and thus the energy of each collision is reduced.

The injection efficiency shows a mass dependent maximum versus the rf level of the ring electrode. Thus, while a wide range of masses can be injected at a given rf level, the relative intensities observed in the mass spectrum will depend upon the rf level. As for the amount of CID, this increases with increasing rf level. This can be attributed to the increased kinetic energy that the ions have once they are trapped in the ITMS. Overall, the data suggest that the CID that is observed in the ion injection process occurs mainly after the ions are in the ITMS, not in the ion injection einzel lens.

An example of the performance capabilities of the system is shown in Figure 2. For this experiment the head space over a small amount of trinitrotoluene (TNT) was being sampled. Ions were injected for 0.3 milliseconds which calculates as a maximum sample input of 50×10^{-15} grams. This signal increases linearly with injection time up to the point where the ion trap is filled up with ions (i.e. ca. 10^6 ions). Further improvements in sensitivity can be achieved by filling the ion trap with ions and then ejecting out all the ions except the analyte ion of interest and then repeating the process.

An important feature of the ITMS is its efficiency in doing MS/MS experiments.³ For positive ions an overall MS/MS efficiency of 75-80% is often observed. There is slightly more variation with negative ions since some negative ions will undergo electron detachment more readily than CID. However, for negative ions with electron affinities of a couple of eV the overall MS/MS efficiency is usually similar to that observed for positive ions. Figure 3 shows the MS/MS spectrum of TNT. The top spectrum is the average of 20 scans, taking a total of seven seconds to acquire. The bottom spectrum is a single scan acquired in 0.35 seconds.

A mass spectrometer that is capable of real-time air monitoring also must be highly reliable since most situations that require real-time monitoring dictate continuous operation. The implication is that the atmosphere being monitored can change at anytime from a benign situation to a dangerous one. It is therefore of utmost importance that instrumental downtime be reduced to a minimum even at the expense of ultimate analytical performance.

The monitoring of closed environments requires determining the concentration of both life gases and trace species, the former taking precedence. In the early 1970's the Central Atmosphere Monitoring System, Mark I (CAMS-I), was developed and deployed on board all American nuclear submarines. This application represents the greatest number of mass spectrometers used for real-time monitoring. The CAMS-I is a fixed collector, permanent magnet mass spectrograph; an analogous commercial instrument is sold by Perkin Elmer Applied Sciences as a medical gas analyzer and a chemical process control instrument. CAMS-I has proven to be a highly reliable and accurate instrument. During the 1980's a new generation submarine atmosphere analyzer has been designed, built, and extensively tested.

In light of the proven performance of the CAMS-I, why was it necessary to develop the CAMS-II? At the time the CAMS-I was designed it was not feasible to use computers to control the instrument due to their size, cost, and reliability. Due to the extraordinary progress in microelectronics, computer control of an atmosphere monitor became feasible. Thus the CAMS-II was designed as a computer-controlled magnetic scanning mass spectrometer of Nier-Johnson geometry, Figure 1. The CAMS-II incorporates both a Faraday cup collector for the intense species requiring accurate measurement and an electron multiplier operated in the pulse counting mode for trace species. A comparison of the two CAMS systems is shown in Table I.

Table I. CAMS Design Requirements

Requirement	CAMS-I	CAMS-II
Mass Range	2-135	1-300
Resolution	1:28	1:300
Detection limit	6 ppm	0.1 ppm
Electron Energy	fixed	programmable
Monitored gases	8	unlimited
Programmable	no	yes
Data Recording	no	yes
Video Display	no	yes

Figure 1. Schematic of the CAMS-II Analyzer.

Before being accepted by the Navy the CAMS-II has undergone an extensive testing program. The final stage of the testing consisted of two years of continuous operation on board a submarine. The CAMS-II performed flawlessly during this period. It did not require any adjustments or calibration maintaining its resolution and mass accuracy within specifications. The CAMS-II is factory calibrated and the calibration factors are burned into its read-only memory. Periodically a verification gas is sampled to assure correct operation.

During normal operation the CAMS-II monitors selected ions in order to analyze the following species: hydrogen, water, nitrogen, oxygen, carbon dioxide, Freon 12, Freon 114, Freon 113, aliphatic hydrocarbons, aromatic hydrocarbons, and benzene. The first five species are analyzed using the Faraday cup detector; the last six are analyzed using the multiplier. This analysis requires about 20 seconds. Every seven hours a complete mass scan between mass 2 and 300 is recorded for future analysis if needed. Figure 2 shows this data from both detectors for mass 44; the slit in front of the Faraday cup is 6 times wider than the slit in front of the multiplier and offset from the true focus of the mass spectrometer.

The ability of the CAMS-II to detect trace species depends upon several factors: inherent sensitivity, interfering ions, and sample transport. Currently the sensitivity of the CAMS-II is about 500 ions/sec/ppm for oxygen. Thus

detection of species at concentrations of a few ppb is feasible. In fact ^{134}Xe has been detected by averaging 50 spectra recorded on a submarine. This isotope is present in air at 8 ppb and the dwell time of the instrument as it is scanned is 20 msec/point. Thus each point represents a one second dwell time. Since the background count rate is only a few counts/minute the main noise source is counting statistics.

Interfering ions are always a problem in direct mass spectrometric analysis. One of the reasons a magnetic analyzer mass spectrometer was selected was its high abundance sensitivity. Figure 3 shows a log plot of the mass spectrum in the mass range of 30 to 50 amu. The background intensity in this region is equivalent to the intensity of a peak due to about 2 ppm of a contaminant. Figure 4 shows the background in the region of 75 to 95 amu. The peaks due to krypton are clearly observable; the natural abundance of ^{83}Kr is 130 ppb. Figure 5 shows the same region of the mass spectrum when a test gas containing 2.5 ppm of benzene, 6.5 ppm of toluene, and 200 ppm of Freon-12 is sampled; note the scale change for the ordinate. Both benzene and toluene are readily detectable.

Sample transport is always a problem when analyzing trace species. The CAMS system samples through stainless steel sample lines at ambient temperature. Materials such as toluene and higher aromatics require a long time to reach equilibrium in stainless-steel lines at ambient temperature; since the CAMS samples continuously, this is only a limitation for situations in which the sample composition is changing rapidly.

In conclusion, the CAMS-II has demonstrated that a mass spectrometer can accurately detect and measure atmospheric species from concentrations of a few ppb to one hundred percent in real time. It is highly reliable having operated continuously without recalibration or other adjustments for more than two years.

**A Rapid Immunoaffinity Cleanup GC/MS Method for
Determination of 3-Methyladenine in Urine**

Marlin Friesen, David E.G. Shuker, Liliane Garren and Virginie Prevost

International Agency for Research on Cancer (IARC), 150 Cours Albert Thomas
69372 Lyon Cedex 08, France

INTRODUCTION 3-Methyldeoxyadenosine, a major adduct formed by reaction of DNA with alkylating agents such as N-methyl nitroso compounds (1), is rapidly repaired by base excision to release 3-methyladenine (3-MeAde). As 3-MeAde has been shown to be excreted in a dose dependant manner via urine, without catabolic breakdown, its measurement in urine may provide a useful marker for prior exposure to methylating agents (2).

The previously available Gas Chromatography/Mass Spectrometry (GC/MS) method for urinary 3-MeAde suffered from the disadvantage that it required a lengthy clean-up involving XAD-column chromatography and HPLC (3). The recent development of a polyclonal antiserum to 3-MeAde offered the possibility of ELISA-based quantitation without the need for GC/MS, but the presence of cross-reactive purines in human urine rendered this approach difficult (4). However, a method which has proved successful is the combination of easily used immunoaffinity columns and GC/low resolution MS carried out on a relatively inexpensive benchtop mass spectrometer.

EXPERIMENTAL Immunoaffinity columns were prepared with a rabbit antiserum specific for 3-MeAde in batches of from 5 to 20 columns at a time. Each column, containing 1 ml of antibody-modified Sepharose gel, was shown to retain quantitatively up to 100 ng of [³H]-3-MeAde. Columns are reusable and no detectable carry over was found from one sample to another even after a column had been recycled up to 30 times.

Two ml of urine, spiked with 50 ng d₃-3-MeAde internal standard, applied to the column is sufficient for reliable analysis. Evaporation of a 1M acetic acid column eluate provides a sufficiently clean sample for direct analysis of the t-BDMS derivative by selective ion monitoring of the (M-57)⁺ ions of 3-MeAde (m/z 206) and a d₃-3-MeAde internal standard (m/z 209).

GC/MS was carried out on a Hewlett Packard 5890 GC equipped with a cold on-column injector, coupled to a Hewlett Packard 5970A Mass Selective Detector operated at 70 eV in the electron impact mode. The GC column (Hewlett Packard Ultra-2, 0.2 mm i.d. X 25 m, film thickness: 0.33 µm) was heated from 55°C at injection to 270°C at 40°C/min and then at 10°C/min to 300°C where it was held for 3.5 min. The mass chromatogram (Fig. 1) for a typical human urine sample (~ 7 µg 3-MeAde/24 h) shows the excellent cleanup achieved by the immunoaffinity cleanup step. The limit of detection is less than 0.5 ng/2ml urine.

RESULTS AND DISCUSSION In collaboration with Dr S.H. Lu of the Chinese Academy of Medical Science in Beijing, People's Republic of China, the method has been applied to the analysis of 3-MeAde in the urine of subjects in two geographical regions having differences in the incidence of oesophageal cancer.

Only slight differences were observed between the two groups (Table 1). Work is in progress to determine to what extent 3-MeAde present in the diet would affect such measurements as it is known that, in animals, any 3-MeAde ingested is excreted unchanged in the urine (2).

ACKNOWLEDGEMENTS This work is supported by the U.S. National Cancer Institute (Grant No. 1-U01-CA 48473-01)

Figure 1

Selected ion monitoring traces for the analysis of 3-MeAde (m/z 206) and d₃-3-MeAde internal standard (m/z 209) in human urine. This sample contains 11 ng 3-MeAde/2 ml urine implying about 7 ug 3-MeAde per 24 h.

ISOLATION AND CHARACTERIZATION OF AN UNUSUAL NUCLEOSIDE FROM HUMAN URINE.
G.B. Chheda, S.P. Dutta, H.A. Tworek, A.K. Bhargava, H. Takita, J.G. Antkowiak and H.B. Patrzyc, Depts. of Biophysics, Laboratory Medicine, Thoracic Surgery, Roswell Park Memorial Institute, Buffalo, New York 14263.

For a number of years, our laboratory has been engaged in the isolation and characterization of novel nucleosides excreted in the urines of cancer patients and normal subjects. In continuation of our studies, we wish to report the finding of a first α -nucleoside, 1- α -D-ribofuranosylpyridin-4-one-3-carboxamide (I) (α -4-PCNR) from human urine (Fig. 1). The unknown (I) was isolated from a 24 hr urine collection of a normal subject (190 μ g) by a previously described procedure¹. It was isolated in elevated amounts in the urines of two chronic myelogenous leukemia (CML) patients (400 μ g, 460 μ g).

(I)

The UV spectra of unknown urinary nucleoside (I) exhibited a λ_{max} at 257 nm at pH 1.3, 258 nm at pH 6.0 and 259 nm at pH 11.0 and were similar to the UV spectra of β -4-PCNR, previously isolated and characterized in our laboratory². The CD spectra of (I) exhibited a negative band in aqueous solution at 254 nm. The differences in retention times between unknown I and β -4-PCNR on RP-HPLC and in the chemical shifts attributed to the anomeric protons in the D_2O NMR spectra (6.05 ppm for (I) and 5.71 ppm for β -4-PCNR) further suggested that the unknown may be an α -anomer of the β -4-PCNR.

1- α -D-ribofuranosylpyridin-4-one-3-carboxamide (α -4-PCNR)

Fig. 1

The GC-MS spectra of a trimethylsilyl derivative of (I) (Fig. 2) showed the highest mass ion at M/Z 558 with characteristic fragment ions identified in the tetra (TMS)₄ derivative of β -4-PCNR². These included a $M-15$ ion at 543 from the loss of CH_3 , a $M-28$ ion at 530 attributed to the loss of CO , the unusual $M-45$ ion at 513 indicating a loss of CH_3NO and the ion at M/Z 349 resulting from the sugar portion of I. The ions at M/Z 349, 259, 245, 243, 230, 217 and 169 characteristic of unmodified ribose preclude a substitution on the sugar. These data suggest that the underivatized urinary unknown I has a molecular weight of 270. The EI mass spectra of underivatized (I) has the highest mass ion at M/Z 270 confirming a mol. wt. of 270 and fragment ions consistent with a ribose nucleoside. These include the base ions at M/Z 138 ($b+H$), and 167 ($b+30$). Ions at M/Z 150 and 121 formed by the elimination of 17 amu, most likely represent a loss of NH_3 while a loss of 44 amu from the elimination of $CONH_2$ gives M/Z 93 ($b-COHN$). The ion at M/Z 133 indicates an unmodified ribose. These data suggest that the unknown nucleoside I may be an isomer of β -PCNR. FAB spectra of the natural unknown I in glycerol gave a $M+H$ ion at 271.0931 ($C_{11}H_{15}N_2O_6$) further supporting the molecular weight of 270 ($C_{11}H_{14}N_2O_6$).

The NMR spectrum of (I) in D_2O exhibited the following chemical shifts (δ) and J values (Hz): 8.72 (d, 1, $J_{2,6} = 2.1$ Hz, 2-H), a pair of doublets at 8.02 and 7.98 (d, 1, $J_{6,2} = 2.3$ Hz and $J_{6,5} = 2.3$ Hz, 6-H), 6.75 (d, 1, $J_{5,6} = 7.6$ Hz, 5-H), 6.05 (d, 1, $J_{1,2} = 4.7$ Hz, 1'-H). The synthesis of the α -nucleoside I was achieved by condensation of pyridine-4-one-3-carboxamide with 2,3-isopropylene-1,5-di-O-acetylribofuranose in the presence of TMS triflate and hexamethyldisilazane in refluxing dichloroethane, followed by deblocking³.

By comparison of UV, NMR, mass spectra and CD data and HPLC retention times of the urinary material with those of the authentic α and β anomers, the nucleoside (I) was assigned the structure of 1- α -D-ribofuranosylpyridin-4-one-3-carboxamide.

MASS SPECTRA

Fig. 2

As to the origin, α -4-PCNR is structurally related to nicotinamide adenine dinucleotide (NAD). Isolation of α -NAD⁺ from numerous sources, including animal tissue, have been reported. These reports have led to speculations concerning its *in vivo* origin and its role in metabolic functions⁴. Although the biological occurrence and significance of the α -NAD⁺ is unclear, the possibility of α -NAD⁺ as a source α -4-PCNR remains attractive.

The *in vitro* anomerization of natural β -4-PCNR as a source of α -4-PCNR was excluded by carrying out proper control experiments on β -4-PCNR under the conditions used to isolate and purify natural (I). Detection of both α and β anomers in a riboside fraction of urine, processed by an alternate milder one-step affinity chromatography procedure³, further supported the existence of natural α -4-PCNR in urine. The significance and possible role of this naturally occurring α -4-PCNR as an agonist or antagonist in some metabolic pathways remains to be investigated.

**LASER IONIZATION FOURIER TRANSFORM MASS SPECTROMETRY
FOR THE ISOMERIC DIFFERENTIATION OF ALKYLATED NUCLEOSIDES ***

R.L. Hettich and M.V. Buchanan
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

Alkylation of cellular deoxyribonucleic acid (DNA) is one form of DNA modification induced by carcinogenic agents. For example, alkylating agents such as N-methyl-N-nitrosourea react with DNA to generate methyl adducts of all four nucleic bases (adenine, guanine, cytosine, and thymine), including several isomers of each base. Since isomeric compounds often exhibit remarkably different biological activity, the structural characterization of these DNA adducts requires sensitive and unambiguous identification at the isomeric level. O⁶-methyl guanine and O⁴-methyl thymine are two compounds of specific biological interest which must be identified and differentiated from the other methyl isomers. Laser ionization Fourier transform mass spectrometry (FTMS) is quite useful for the examination of modified nucleic acid constituents, since this technique can provide detailed structural information for picomoles of non-volatile, thermally labile compounds such as modified nucleosides.

Laser ionization of methyl nucleosides generates negative ions which include an (M-H)⁻ ion for the nucleoside as well as an ion corresponding to the free nucleic base (formed by elimination of the sugar ring). The collisional dissociation of these negative ions from the various methylated adducts of thymine, cytosine, and adenine gave fragment ions which could be used in most cases to determine the position of methyl substitution, as summarized in Table 1. For example, O⁴-methyl thymine fragmented by loss of methanol, whereas O²-methyl thymine lost CH₃. Accurate mass measurements of the parent and daughter ions as well as sequential CID experiments (MS³) were used to examine the fragmentation of these ions.

Deuterium labelling has also been used to help elucidate the positions of alkyl substitution for these compounds. The negative ions mentioned above do not undergo deuterium exchange in the gas phase, since these ions are very weak bases due to resonance stabilization. However, these nucleosides will undergo selective deuterium exchange with D₂O in solution. For example, the amino hydrogens of the nucleosides will undergo rapid deuterium exchange whereas the C8 hydrogen of the nucleoside will exchange more slowly. As a result, deuterium exchange can be used to identify the position of methyl substitution in some cases, since the location of the methyl group will determine the number of exchangeable hydrogens which are present on the nucleoside.

These structural studies have been extended to include large DNA adducts as well. Laser ionization of amino polycyclic aromatic hydrocarbon (PAH) adducts of guanine also generated characteristic negative ions. An intense (M-H)⁻ ion at m/z 317 is observed in the negative ion laser desorption spectrum of C8 para-aminobiphenyl guanine. Collisional dissociation of this ion generates several daughter ions, shown in Figure 1, which provide structural information for the adduct. Loss of NH₃ from this ion implies that the N1 and N² positions of the guanine base are unsubstituted. The daughter ion at m/z 168 corresponds to (aminobiphenyl)⁻, and provides the information necessary to identify the adduct. The ion at m/z 193 corresponds to (aminobiphenyl - H + CN)⁻ and indicates that the aminobiphenyl adduct is attached to the guanine at the C8 position. Several C8 amino-PAH guanine adducts have been examined and the fragmentation pathways observed in Figure 1 appear to be present for all of the adducts.

Cyclic nucleotides are a group of compounds which contain a heterocyclic base, a ribofuranose ring and a phosphate group. They differ from other free nucleotides in that the phosphate group is present as a cyclic phosphodiester moiety, and one of the naturally occurring cyclic nucleotides, adenosine 3',5'-cyclic monophosphate (cyclic AMP), has been shown to have a key role in mammalian metabolic regulation, acting as the intracellular mediator of the action of the majority of mammalian short term sudden effect hormones, for example adrenalin and glucagon (1). A second cyclic nucleotide, guanosine 3',5'-cyclic monophosphate (cyclic GMP), has more specific regulatory roles, functioning as part of the signal transduction mechanism which responds to light perception in the mammalian eye and as a mediator of atrial natriuretic protein action (2), while a third, more recently established, cyclic nucleotide, cytidine 3',5'-cyclic monophosphate, has a suggested involvement in the regulation of cellular proliferation (3). These biochemical functions of cyclic nucleotides led to their description as second messengers (the hormone or other agonist is termed the primary messenger) and make them potential pharmacological targets of great significance. Analysis of cyclic nucleotides is extremely difficult due in part to their low cellular concentrations and also due to their molecular instability. While traditional methods of mass spectrometry have not been of any wide applicability in this field because of the instability of volatile cyclic nucleotide derivatives, the advent of fast atom bombardment mass spectrometry and mass-analysed ion kinetic energy spectrum scanning has significantly changed this situation.

Application of FAB/MIKES analysis to cyclic nucleotides has provided a very effective means of distinguishing 3',5'-cyclic nucleotides, the metabolic regulators, from their 2',3'-isomers, breakdown products of nucleic acids, by the presence of a major fragmentation in the 3',5'-isomers producing a prominent peak at an m/z value corresponding to protonated base plus 42 mass units ($[BH_4 + 42]^+$), and the absence of any such prominent peak in the MIKE spectra of the 2',3'-cyclic nucleotides (4). FAB/MIKES analysis of partially purified extracts, from both mammalian and plant tissues, subjected to sequential chromatographic procedures, have provided the first unambiguous evidence of the presence of cyclic CMP in mammals (5) and of cyclic GMP in higher plants (6). Refinement of the purification procedure has now enabled the first demonstration of the natural occurrence of uridine-, inosine- and deoxythymidine-3',5'-cyclic monophosphates (cyclic UMP, cyclic IMP and cyclic dTMP) in mammalian tissues (7) and in higher plants (8), in the latter case including the exciting observation that cyclic CMP was found in higher relative concentrations in the rapidly proliferating tissues, that cyclic UMP was found only in these regions, and that cyclic IMP and cyclic dTMP were found only in tissues dividing slowly (8).

Analysis of cyclic nucleotide-related enzymes by FAB/MIKES has also proved successful. Cyclic CMP has been identified as one of the products resulting from the incubation of dialysed cell-free preparations from rat brain, liver and kidney with cytidine 5'-triphosphate (CTP). In addition to cyclic CMP and unchanged CTP, the products of the reaction were found to include cytidine monophosphate (CMP) and cytidine diphosphate (CDP) together with four novel cytidine compounds identified as cytidine 3',5'-cyclic

pyrophosphate, cytidine 2'-monophosphate-3',5'-cyclic monophosphate, cytidine 2'-O-aspartyl-3',5'-cyclic monophosphate and cytidine 2'-O-glutamyl-3',5'-cyclic monophosphate (9). This evidence provided the first unequivocal proof of the natural occurrence of cytidylate cyclase activity; the four novel cytidine cyclic phosphates identified provide an explanation of the discrepancies in previous reports which led to controversy concerning cytidylate cyclase.

Analysis of the cyclic nucleotide-related enzymes has now been taken a stage further with the quantitation of cyclic nucleotide phosphodiesterase activity (10). Characteristic peaks of the substrate, cyclic AMP, and product, AMP, were identified in positive FAB mass spectra and MIKE scans of the protonated molecular ions. By spiking enzyme incubates with known quantities of cyclic AMP and AMP and measuring peak heights in the MIKE spectra of both spiked and unspiked samples, the concentrations of cyclic AMP and AMP in solution at the end of a series of enzyme incubations have been estimated. From the data obtained the kinetic parameters, K_m and V_{max} , showed very close agreement with those obtained by radioactive assay.

Further application of FAB/MIKES has been made in the examination of derivatives used in studies of the biochemical function of cyclic nucleotides. The technique has provided the only rapid means of confirming the retention of the cyclic phosphodiester group during the synthesis of the 2'-O-succinyl, 2'-O-succinyl-proteinyl- and 2'-O-succinyl-tyrosinyl-methyl-ester-derivatives of cyclic nucleotides essential for the development of radioimmunoassay, the major method of cyclic nucleotide estimation. Similarly the identity of lipophilic cyclic nucleotides, synthesized to enable the cyclic nucleotides to permeate through cellular membranes, has been confirmed by FAB/MIKES analysis, which has been used to determine the position of butyrylation in N⁶,2'-O-dibutyryl adenosine 3',5'-cyclic monophosphate, N⁶,2'-O-dibutyryl guanosine 3',5'-cyclic monophosphate and N⁶,2'-O-dibutyrylcytidine 3',5'-cyclic monophosphate (11).

An Investigation of Ionization Mechanisms During
Liquid Secondary Ion Mass Spectrometry (LSIMS): Evidence for
One-Electron Reduction of Oligonucleotides and Modified Oligomeric Analogs.

J.A. LARAMEE, B.C. Arbogast, M.L. Deinzer,
Department of Agricultural Chemistry and Environmental Health Sciences Center,
Oregon State University, Corvallis, Oregon 97331-6502.

The base sequencing of oligodeoxynucleotides, DNA/adducts, and modified oligonucleoside analogs is the goal of this work. Oligodeoxynucleotides and modified oligonucleoside structures show intense molecular anions in negative ion LSIMS spectra. In addition, cleavages along the backbone allow for bidirectional (3' and 5' ion series) base sequencing of the DNA chain (Grotjahn *et al.*, 1985). This phenomena has been used to sequence oligonucleoside analogs containing non-phosphodiester backbones (Griffin *et al.*, 1988) as well as analogs containing unnatural base or modified sugar residues neither of which can be enzymatically digested via conventional sequencing methods. Negative ion LSIMS uniquely provides the needed data (Figure 1).

A comparison of experimental (Figure 2a) and calculated (Figure 2b) isotopic cluster patterns for the (M-H)⁻ anion of d(pA)₈ shows poor agreement; Bovine insulin oxidized B-chain and β -cyclodextrin give excellent agreement between experiment and theory. This indicated the molecular anion region of d(pA)₈ was recorded without discrimination and that ionic species other than (M-H)⁻ are present - one electron reduction (Williams *et al.*, 1987) is suggested. The molecular anion cluster pattern can be greatly influenced by the electron affinity of the matrix (Figure 3). Spectral deconvolution reveals the presence of several ionic species in the molecular anion cluster including a radical anion and an MH⁻ species. A theoretical molecular anion isotopic cluster can be synthesized which closely matches the experimental results (histogram in Figure 2a).

Oligodeoxynucleotides up through 18-mers have been ionized and their spectra deconvoluted by solution of a set of simultaneous equations. A critical look at LSIMS data is timely. Since one-electron reduction appears to be mass dependent, the average mass of the molecular anion envelope will shift to higher mass leading to a potential mass measurement error. Moreover, careful use of isotope ratios to track biological pathways or determine isotopic enrichment is necessary and consideration must be made of the ions present. Deconvolution of the molecular anion cluster is used to estimate the relative concentrations of ionic species present.

QUANTIFICATION OF EPOXYEICOSATRIENOIC ACIDS BY CAPILLARY
COLUMN CHROMATOGRAPHY/NEGATIVE ION CHEMICAL
IONIZATION MASS SPECTROMETRY

Ian A. Blair, Jorge Capdevila and Kouwa Yamashita

Departments of Pharmacology and Medicine, Vanderbilt University, Nashville TN 37232

The epoxyeicosatrienoic acids (EETs) are cytochrome P-450 metabolites of arachidonic acid (1). The EETs are endogenous constituents of rat liver, kidney and lung and have been detected in urine (2). They possess a diversity of biological activities including the ability to stimulate peptide hormone release from endocrine cells, mobilize microsomal Ca^{2+} from aortic smooth muscle and anterior pituitary cells, inhibit arachidonic acid-stimulated platelet aggregation and inhibit vasopressin stimulated water transport (2). In order to help determine the role of EETs in endogenous biochemical processes it was necessary to develop highly sensitive and specific method for their analysis. It was of particular interest to develop methodology that would allow their quantitative determination to be carried out from stimulated human platelets. Capillary gas chromatography/electron capture negative ion chemical ionization mass spectrometry (GC/NICIMS) assays have been developed for a number of eicosanoids previously (3). This methodology has now been applied to the analysis of the EETs.

Analysis of the pentafluorobenzyl (PFB) ester derivative of 14,15-EET was carried out by GC/NICIMS. The mass spectrum showed an intense ion at m/z 319 (M-PFB), together with fragment ions at m/z 303 (M-PFB-O) and m/z 301 (M-PFB- H_2O). The 5,6-, 8,9- and 11,12-EET-PFB ester derivatives showed identical spectra. The PFB ester derivatives of the four regioisomers could not be separated by capillary column chromatography. During the course of these studies it was noted that artifactual formation of EETs from arachidonic acid could occur by autoxidation. It was found that this undesirable reaction could be minimized by removal of arachidonic acid prior to derivatization and by adding butylated hydroxytoluene (BHT) as an antioxidant.

Previous studies had shown that EETs are esterified into phospholipids (3) and so we required a method that could be used for the quantification of esterified EETs. Methodology has been developed that involves phospholipase A_2 (PLA_2) hydrolysis of extracted phospholipids. Addition of BHT during hydrolysis minimized autoxidation of released arachidonic acid. Hydrolysis was carried out with PLA_2 at 22 °C for 5 min in the presence of 0.1 % BHT. The crude product obtained from PLA_2 hydrolysis was submitted to reversed phase HPLC for further purification. Purified EETs were hydrogenated with $\text{Rh}/\text{Al}_2\text{O}_3$ and then esterified with pentafluorobenzyl bromide (PFB). Hydrogenation of double bond in EET molecule facilitated complete separation of the 5,6-, 8,9-, 11,12- and 14,15-EET PFB esters. GC analysis was carried out on an HP-17 fused silica capillary column (25 m x 0.25 mm I.D.) (Figure 1). The NICI mass spectrum of hydrogenated 14,15-EET-PFB showed an intense M-PFB anion at m/z 325 together with ions derived from fragmentation at the epoxide moiety at m/z 225 and m/z 241 (Figure 2). Similar types of fragment ions were observed with the other three EETs. Oxygen-18 labelled EETs were synthesized for the use of internal standards in quantitative analysis. Good linearity was observed between the peak area ratio of m/z 325 (M-PFB for $^{16}\text{O}_2$ -EET) to m/z 329 (M-PFB for $^{18}\text{O}_2$ -EET) and weight ratio of $^{16}\text{O}_2$ -EET to $^{18}\text{O}_2$ -EET in the range of 1 to 10 ng/mL. The present method was applied to quantification of EET released from cyclooxygenase-inhibited thrombin stimulated human platelets. It was shown that 5.2 ± 2.8 ng/ 10^9 platelets ($n = 4$) of EETs were released. The possibility that this trace amount was formed as a consequence of autoxidation of arachidonic acid released during the phospholipase hydrolysis cannot be excluded.

Because only partial purification of several phosphoinositides was obtained using TLC and silicic column chromatography, and because triethanolamine matrix ions were present in all FAB mass spectra, B/E linked scanning with collisional activation was carried out in order to eliminate matrix ions and other contaminating ions. Although two LPI species co-eluted during chromatographic purification, for example, B/E linked scanning of the respective deprotonated molecular ions provided essentially pure daughter ion spectra which were free from contaminating ions. (See Figures 2 and 3.) B/E linked scanning also facilitated the identification of structurally significant fragment ions. In all of the B/E scans, abundant daughter ions were typically detected which corresponded to palmitate (m/z 255) or linoleate (m/z 279) (Figures 2 and 3.) There was no evidence of any other fatty acids. Other daughter ions included m/z 433, 409, 315, 241, and 153, corresponding to linoleoyllysophosphatidic acid, palmitoyllysophosphatidic acid, glycerophosphoinositol, dehydrated inositol phosphate, and glycerophosphate, respectively.

Figure 2. B/E linked scan of $[M-H]^-$ (m/z 595) of linoleoyl LPI from carrot cells.

Figure 3. B/E linked scan of $[M-H]^-$ (m/z 571) of palmitoyl LPI from carrot cells.

Palmitoyl,linoleoyl-PI was the only phosphatidylinositol detected in carrot cells. In contrast, arachidonoyl, stearoyl-PI, linoleoyl,palmitoyl-PI, and linoleoyl,linoleoyl-PI were detected in animal PI samples used as chromatography reference standards. Jensen and coworkers (3), using FAB MS/MS, detected small amounts of fatty acids other than palmitic and linoleic acid in soybean PI. As for the other phosphatidylinositols detected, LPI and PIP were also shown by mass spectrometry to contain acyl groups corresponding exclusively to linoleic (18:2) and palmitic (16:0) acid. These measurements represent the first physico-chemical evidence of these phosphatidylinositols in plant cells. Investigations are in progress to determine whether PIP₂ and LPIP are present in carrot cells.

ENHANCED DETECTION OF DIAGNOSTIC ACYLCARNITINES
IN PLASMA AND TISSUE UTILIZING FAB COUPLED
WITH TANDEM MASS SPECTROMETRY

David S. Millington, Daniel L. Norwood and Naoki Kodo
Division of Pediatric Genetics and Metabolism
Box 3078 Duke University Medical Center
Durham, North Carolina 27710

It is possible to characterize a range of inborn errors in the metabolism of branched-chain amino acids and fats by the identification of diagnostic acylcarnitines. These metabolites are usually analyzed in biological matrices (e.g. urine, blood and tissue) by fast atom bombardment mass spectrometry (FAB-MS). The high level of chemical interference in such matrices, however, limits the applicability of the method. This paper describes a new method utilizing partial chemical clean-up coupled with FAB- tandem mass spectrometry (FAB-MS/MS) for the analysis of diagnostic acylcarnitines in plasma and tissue samples.

METHODS Acylcarnitines were recovered from plasma and tissue samples according to the procedure outlined in Figure 1. Recoveries of spiked standards were shown to be greater than 86% for both biological matrices. FAB-MS/MS analyses were performed on a VG Tric-3 triple quadrupole mass spectrometer as previously described (1,2). A "precursors of m/z 99" scan was utilized to produce a spectrum of acylcarnitine molecular cations, referred to as an "acylcarnitine profile". A beam of xenon atoms (8Kev) from a saddle-field ion gun was used to achieve sample ionization. The collision gas for CID was argon (0.5 pbar) and the collision energy was 15 eV.

RESULTS The FAB-MS/MS daughter ion spectra of acylcarnitine methyl ester M⁺ ions show a prominent common fragment at m/z 99 (1). This ion is derived from the loss of both the acyl moiety as the corresponding acid, and the quaternary ammonium group as trimethylamine (Figure 2) and represents the "backbone" of the acylcarnitine molecule. The "precursors of m/z 99" scan therefore generates a spectrum of M⁺ ions from acylcarnitines. Figure 3 depicts three FAB-MS/MS acylcarnitine profiles from blood of a normal child (A); a patient with propionic acidemia (B); and a patient with medium-chain acyl-CoA dehydrogenase deficiency (MCAD) (C). In the normal profile, acetyl carnitine (m/z 218) is dominant with lesser amounts of C₃, C₄ and certain other acylcarnitines also present. The abnormal profiles show the expected diagnostic metabolites: propionyl carnitine (m/z 232) for propionic acidemia; hexanoyl carnitine (m/z 274), octanoyl carnitine (m/z 302), and decenoyl carnitine (m/z 328) for MCAD deficiency. The identification of these acylcarnitines was confirmed by infusion of stable isotope-labelled carnitine to an affected patient (Figure 4).

Diagnostic acylcarnitine profiles have also been obtained from tissue samples (2). Detection limits for this method have been estimated to be 0.5 nmol/ml in plasma and 1 nmol/g wet weight in tissue. By coupling with a continuous-flow FAB interface, samples can be processed very rapidly, making the method feasible for large scale neonatal screening.

OBSERVATION OF SEQUENCE SPECIFIC PEPTIDE FRAGMENTATION USING MS/MS/MS SCAN MODES

Kevin L. Schey, Jae C. Schwartz, and R. Graham Cooks
Chemistry Dept., Purdue University, West Lafayette, IN 47907.

Several MS/MS/MS scan modes¹ have been applied to provide sequence specific fragmentation of penta- and octapeptides from pure samples and from mixtures. These experiments have been carried out on hybrid BEQQ and pentaquadrupole instruments with ionization by either fast atom bombardment with Xe atoms or liquid SIMS with Cs⁺ ions.

The reaction intermediate scan², symbolized $\bullet \rightarrow \circ \rightarrow \bullet$, where $\bullet$ represents a fixed mass analyzer and $\circ$ represents a scanning mass analyzer, is the most useful scan for obtaining sequence information because it provides MS/MS/MS spectra of any peptide in a mixture with little or no interference. In the reaction intermediate scan peptide (M+H)⁺ ions are mass selected from the mixture with the first mass analyzer and an N- or C-terminal sequence ion is selected as the final product ion by the final mass analyzer. Intermediate ions between the selected (M+H)⁺ and final product ions are recorded by scanning the middle quadrupole of the pentaquadrupole or by scanning the sector portion of the BEQQ in a B/E linked scan. A, B, and C sequence ions are exclusively observed when an N-terminal containing ion is chosen as the final product ion. A C-terminal containing ion may also be chosen as the final product ion yielding spectra with X, Y, and Z ions exclusively. The N-terminal reaction intermediate scan of peptide I, Tyr-Ala-Gly-Phe-Met-NH₂ (M+H)⁺ m/z 587, obtained on the BEQQ instrument is shown in Figure 1. By selecting the N-terminal tyrosine immonium ion, m/z 136, as the final product ion, only A and B type ions are observed in this spectrum. The C-terminal reaction intermediate spectrum of peptide II, Tyr-Pro-Phe-Pro-Gly (M+H)⁺ m/z 580, obtained on the pentaquadrupole instrument is shown in Figure 2 where the C-terminal containing Y₂⁺ ion was chosen as the final product ion. Only Y type sequence ions are observed and the sequence of the peptide can be readily determined. The detection limit obtained on the newly constructed pentaquadrupole instrument for a leucine enkephalin sample is 4 nmoles. The pentaquadrupole instrument provides more sequence information than the BEQQ instrument due to the ability of the low-energy collisions to generate fragment ions over the entire mass range. In addition, reaction intermediate spectra obtained on the BEQQ instrument contain artifact peaks due to the poor resolution of the linked scans employed.

The selective parent scan, symbolized $\circ ==> \circ \rightarrow \bullet$, where the first part of this scan ($\circ ==> \circ$) represents a neutral loss scan (loss of a CO group in these experiments), produces spectra with exclusively B or X type ions depending on the final product ion chosen. By selecting an N- or C-terminal ion as the final product ion, only B or X ions are observed, respectively. This scan mode provides more specific sequence information than the reaction intermediate scan, but can only be employed on pure peptide samples if interferences are to be avoided. The selective parent spectrum of peptide I obtained on the pentaquadrupole instrument is shown in Figure 3 indicating B type ions only by selecting the N-terminal immonium ion having m/z 136 as the final product ion.

Sequence determination of unknown peptides can be greatly simplified by using the appropriate sequence of MS, MS/MS, and MS/MS/MS experiments.

TANDEM MASS SPECTROMETRY OF MULTIPLY CHARGED PEPTIDES AND PROTEINS

Charles J. Barinaga, Harold R. Udseth, and Richard D. Smith
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory*
Richland, WA 99352

In the past two years electrospray ionization (ESI), originally described by Dole and coworkers¹ and reinvigorated by Fenn and coworkers², has received considerable attention as a soft ionization source for mass spectrometry. The ESI method produces intact, multiply charged, gas phase molecular ions of peptides and proteins from aqueous solution with mass to charge ratios (m/z) that are easily within the range of quadrupole mass spectrometers. In fact we have shown that mass spectra of proteins of molecular weight greater than 100,000 daltons can be obtained on an instrument limited to 2000 m/z ³. Because of the possible additional structural information from collisionally induced dissociation (CID) /tandem mass spectrometry, multiply charged ions are likely candidates for examination by this technique, possibly producing all or significant portions of the amino acid sequence.

Although the multiply charged ions give abundant fragmentation, it is still a question whether meaningful fragmentation can be efficiently produced by CID. It could also be anticipated that the charge state of the parent ion might significantly affect the daughter ion spectra both in ions observed and their intensities. Three peptides, mellitin, glucagon, and the synthetic T₁ tryptic fragment of glucagon, and the protein cytochrome-c, have been investigated to examine these issues.

Mellitin is a 26 amino acid peptide of M_r 2846 daltons with six possible positive charge sites. Within the 1400 m/z range of the instrument four charge states, 3+, 4+, 5+, and 6+, are observed. A significant degree of meaningful fragmentation is seen in each of the four daughter ion spectra. The dominant cleavage types are B and Y modes⁴. By combining the daughter ion information from all four ions molecular ions (including daughter ions with m/z greater than that of the parent due to unsymmetrical mass and charge cleavage), the sequence for 20 of the 26 amino acids can be reconstructed⁵. Because some of the same daughter ions appear in more than one spectra and sometimes in more than one charge state, fragment assignments can be made with a good degree of confidence. Interestingly the region not probed is the amidated C-terminus containing four of the six possible charge sites.

Glucagon is a larger 29 amino acid peptide, M_r 3483 daltons, with four possible positive charge sites producing three observable parent ions, 3+, 4+, and 5+. Although daughter ions were observed for each parent ion, only a few amino acid residues (4 at the N-terminus and 9 at the C-terminus) were rationalized with almost no interior fragmentation. However by applying the same techniques to the four synthetic tryptic fragment peptides of glucagon of which T₁ is shown, the entire amino acid sequence could be rationalized.

Horse heart cytochrome-c is a small protein of 104 amino acids, M_r 12,360 daltons, and 23 possible positive charge sites. The MS spectra yields a multiply charged distribution from 9+ to 21+ peaking in intensity around 15+. Although many peaks, clustered around the m/z of the parent, are seen in the low energy CID MS/MS spectra of cytochrome-c, we have not as yet been able to rationalize their identity due to the large number of possibilities. The pattern of these fragments may, however, be useful in a qualitative, peptide mapping fashion. In fact the CID MS/MS spectra of the 15+ molecular ion of cytochrome-c from several different species shown in Fig. 1 demonstrates the dramatic fragment pattern differences for these ions, even between ions that differ by only three and four amino acids, e.g. horse vs. cow and cow vs. rabbit respectively.

Thus several statements on the CID tandem mass spectrometry of multiply charged molecular ions of peptides and small proteins can be made. They can be efficiently collisionally dissociated into meaningful fragments,

predominantly Y and B type cleavages, providing an information rich spectra which can lead to significant degrees of sequence determination. The redundancy of ions originating from different charge state parent ions enhances confidence in assignment. CID of enzymatic digestion fragments may be required for those molecules that resist CID. Higher charge states yield greater fragmentation, at least using low energy CID, i.e., quadrupole instrumentation. For proteins, although extensive sequence information may not be readily obtainable, CID results appear useful for rapid peptide mapping or "fingerprinting".

We thank the U.S. Department of Energy, Office of Health and Environment Research, for support of this research under Contract DE-AC06-76RLO 1830. *Pacific Northwest Laboratory is operated by Battelle Memorial Institute.

STRUCTURE DETERMINATION OF NOVEL CYCLIC PEPTIDES BY USING TANDEM MASS SPECTROMETRY

R.L. Cerny and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588 G.R. Pettit, Y. Kamono, and C.H. Herald, Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287.

An increasing number of possible anti-cancer agents are being isolated from marine animals and plant life. Many of these compounds are cyclic peptides that contain unusual amino acids, some of which may result from chemical modification by the marine organism of more normal amino acids.

We have developed a methodology which is effective in determining the amino acid sequences of these peptides. The steps are as follows:

- 1) Obtain FAB mass spectrum and verify molecular species
- 2) Determine exact mass of molecular species
- 3) Obtain MS/MS spectrum of $(M + H)^+$ ions
- 4) Compare FAB spectrum and MS/MS spectrum
- 5) Obtain MS/MS spectra of source-produced fragment ions corresponding to significant fragments observed in the MS/MS spectrum of $(M + H)^+$
- 6) Determine exact masses of fragment ions as necessary to verify empirical formulae.

Some of these points appear rather obvious. The significant information available from MS/MS spectra of source-produced fragment ions, however, has often been overlooked. The utility of this approach can be demonstrated with two examples.

A partial FAB spectrum and the MS/MS spectrum of $(M + H)^+$ of the cyclic peptide hymenistatin 1 (isolated from a South Pacific Ocean sponge) are shown in Fig. 1 and 2. Protonation at a basic amide nitrogen results in ring-opening to form a linear acylium ion. Several abundant fragment ions are observed in the MS/MS spectrum; the ions of m/z 780, for example, results from loss of isoleucine from the acylium terminus. From amino acid analysis, the peptide is known to contain three proline residues. Protonation is likely to occur at any one of these three basic sites, resulting in the formation of a mixture of three different, unresolvable acylium ions. The MS/MS spectrum of $(M + H)^+$ is, therefore, a composite of the individual spectra of these three species. Ions of m/z 780, 794, and 796 are observed in both the FAB spectrum and the MS/MS spectrum of $(M + H)^+$. These ions result from losses of isoleucine, proline, and valine, respectively, from the termini of the three different acylium ions. MS/MS spectra of the source-produced fragment ions provide resolution of the different species and allow unequivocal determination of the cyclic peptide sequence. Exact mass measurements are used to verify key empirical formulae.

Fig. 1

Fig. 2

A second example is provided by the structure determination of dolastatin 13, a cyclic peptide isolated from the Indian Sea Hare *Dolabella auricularia*. The first problem encountered is the determination of the molecular species. The FAB spectrum of the peptide obtained using a protonating matrix (see Fig. 3) produces a apparent $(M + H)^+$ of m/z 888. Addition of a Li^+ salt (see insert), however, results in the formation of $(M + Li)^+$ of m/z 912. The ions of m/z 888 result from loss of H_2O from the protonated molecular species. The MS/MS spectrum of $(M + H)^+$ (see Fig. 4) is also dominated by H_2O elimination. Upon magnification of the data, several other significant ions are observed. There is, however, no clear association between them. MS/MS spectra of the source-produced fragment ions of m/z 487, 646, and 789 clearly show that these ions are not related and result from competitive fragmentation processes. The structure cannot be determined by means of the MS/MS spectrum of $(M + H)^+$ alone. A fragmentation scheme obtained by combining MS/MS data of several fragment ions with exact mass measurements is shown in Fig. 5. Several different competing processes occur; some produce equivalent fragment ions via different routes. The determined structure is shown in Fig. 6. The basic structure of the peptide consists of a six-membered amino acid ring with a two amino acid side chain. A unique cyclic hemiacetal (presumably derived from a Phe-Glu dipeptide precursor) is incorporated in the cyclic portion of the molecule. Cyclization occurs through the theonine oxygen. Another novel aspect of the peptide is that the terminus of the side chain is not a normal amino acid but is rather methyl-glyceric acid.

The motivation for this work is best understood from a comparison of Figures 1 and 2, each a CID spectrum of protonated Dynorphin Fragment 1-9 (YGGFLRRIR-OH)⁺, m/z 1137.5. Figure 1 was obtained by using a VG 70-4SE tandem double focussing instrument (EBEB); only a single loading of 0.5 nmol of peptide on the FAB probe was required. Figure 2 resulted from use of a VG ZAB-EQ hybrid tandem instrument (BEQ); multiple sample loadings and scan accumulations were used to obtain this spectrum. The contrast is striking! Test cases used in this work included the Dynorphin Fragments from 1-5 to 1-9 inclusive, and oligomers of phenylalanine up to Phe₈. The latter were studied to study size effects without interference from peptide composition. The EBEB instrument yielded CID spectra of excellent quality under simulated real-world analytical conditions, viz. 0.5-1 nmol of sample consumed; the only exception was Phe₈, for which the precursor beam current of 10⁻¹⁴ A was so low that the quality of the CID spectrum was limited by ion statistics. In comparison the hybrid instrument yielded a good quality spectrum for Phe₈, and a poor spectrum for Phe₇, only after multiple sample loadings with scan accumulation. The EBEB instrument easily produced rich CID spectra for all the Dynorphin Fragment peptides studied here, with only directing effects of composition (basic residues at terminus). The low energy CID spectra were subject to extreme compositional effects, in that highly basic residues (e.g.arginine) stabilised peptides to CID (Fig.2).

The reasons for the low CID efficiency of the hybrid instrument compared with the extremely high efficiencies observed for the same instrument with precursors below 500 Da or so, can be considered in two categories:

- A. Dynamic ion optics of the qQ assembly.
- B. Fundamental aspects of the collisional activation (CA), and subsequent dissociation, of the protonated peptides.

Point A is the subject of current work, but is not a dominant reason here since protonated Gramicidin S (m/z 1141.5) yielded an excellent CID spectrum under conditions identical to those used for Fig.2. It appears that CID of large organic ions at keV energies can access CA mechanisms not available at low energies; this is confirmed by the abundant sidechain cleavages (d,v,w fragments) observed at high energies but not at all below about 300 eV in the hybrid instrument. The most probable candidate is electronic excitation, but this cannot explain the dramatic switch from high to low CID efficiency for low energy CID as the mass is increased above 500-600 Da. It has been proposed that increasing disparity in size between projectile and target demands a switch in the momentum transfer CA mechanism from the "elastic" limit (target interacts with entire projectile) to the "spectator" limit (target atom interacts elastically with a portion of the projectile which subsequently shares the transferred energy/momentum with the spectator portion). (See A.J.Alexander and R.K.Boyd, IJMSIP, in press).

Other qualitative differences include the high abundance of internal cleavage fragments (both N- and C- termini lost) in the low energy case, due probably to the multiple-collision conditions normally employed. Loss of the C-terminus is a low-energy process (appears under unimolecular conditions) but is subject to compositional conditions as yet unknown.

The application of high-resolution separation techniques coupled with mass spectrometry is a powerful approach to solving problems in the area of protein structure and is especially suited to the characterization of biotechnology products obtained from recombinant DNA methods and automated synthesis (1). We have previously shown that microbore LC/CF-FAB mass spectrometry is a very effective tool in this regard (2,3). Since the CF-FAB carrier solution, 5% glycerol 3% acetonitrile in water, is suitable for the analysis of peptides, we have in this study examined the use of CF-FAB to introduce the effluent derived from capillary zone electrophoresis (CZE) to a mass spectrometer. CZE is a high resolution separation method for charged molecules based on their differential rates of migration in an electric field created by applying a high voltage (20-30 KV) across an open tubular fused silica capillary (10-100 μ m ID) filled with a buffer solution (4). Performing electrophoresis in the "capillary dimension" permits efficient cooling of the process so that Joule heating is minimized, reducing sample zone broadening and thereby increasing separation efficiency. Another consequence of performing electrophoresis in silica capillaries is the creation of a phenomenon known as electroosmotic flow. This flow also contributes to the high resolution capability of CZE and permits a unidirectional non-parabolic bulk flow of capillary solution containing all analytes whether they be cations, anions, or neutrals, toward the cathode.

In order to effect a transfer of CZE effluent to the CF-FAB probe an interface device incorporating a unique combination of features that were previously and separately employed by others (5,6) was developed as shown in Figure 1. CZE was performed using an apparatus constructed at Applied Biosystems Inc. similar to that described by Jorgenson (4). The CZE fused silica capillary was 90 cm long. As indicated in Figure 1, the effluent end of the CZE capillary (50 μ m ID) and the pick-up end of the CF-FAB capillary (75 μ m ID) meet in a short segment of Teflon tubing (0.15 mm ID) placed in a plexiglass block consisting of two 90 degree intersecting passageways (1/16 in. ID). The other open passageway permits the introduction of the "flow-through" cathode and CF-FAB matrix. The flow rate differential between that in the CF-FAB capillary (5 μ L/min) and the CZE capillary (0.1 μ L/min) and the enclosure of the capillary juncture in the Teflon sleeve permits efficient transfer of CZE eluate to the mass spectrometer as shown in Figures 2 and 3. Figure 2 shows both the UV detector trace (upper) and the MS total ion chromatogram (lower) derived from a CZE/CF-FAB analysis of a synthetic peptide reaction mixture prior to purification of the desired product (the major peak). Direct comparison of the resolution recorded by the UV and MS detectors is difficult because of the differences in their physical characteristics and operating dynamics. Nevertheless, if one regards the chromatograms as an indication of 'apparent' resolutions as recorded by these detectors, then the profiles indicate that this apparent resolution is quite similar and that no major band broadening has occurred as a consequence of transfer in the interface. A similar result is shown in Figure 3 for the CZE/CF-FAB analysis of a tryptic digest of 40 pmol of recombinant human growth hormone. Again the UV trace and the total ion chromatogram show very similar profiles.

CF-FAB mass spectrometry was performed with a Finnigan MAT 90 high resolution instrument equipped with an ION Tech b11NF saddle field gun using Xe to create energetic atoms. The CF-FAB probe used was the Finnigan-MAT Bioprobe. The mass spectrometer was generally operated at a resolving power of 1500 and an accelerating voltage of 4.7 KV. The magnet was scanned at approximately 10 sec/decade. CsI was used to calibrate the instrument.

We conclude that CZE separations in combination CF-FAB analysis coupled through the interface described here is a powerful, high resolution, and sensitive tool that can be exploited by the protein chemist to assess protein/peptide structure.

SENSITIVITY ENHANCEMENT OF PARTICLE BEAM LC/MS.

Ross C. Willoughby, James D. Buchner, and Edward W. Sheehan;
Extrel Corporation, Pittsburgh, Pa. 15238.

INTRODUCTION: Particle Beam (PB)-LC/MS are transport-enrichment interfaces that allow analytes contained in high flow (1 mL/min) effluent from a liquid chromatograph to be introduced into low pressure ion sources using conventional EI, CI, and FAB ionization. The first PB-LC/MS interface was referred to as the MAGIC-LC/MS¹.

Sensitivity with PB-LC/MS is dependent upon the efficiency of several processes; including, 1) efficiency of solute particle transport, 2) efficiency of solvent removal, 3) and efficiency of solute vaporization.

OBJECTIVES: The following studies are part of a continuing effort to evaluate the operating parameters that are critical to the performance of particle beam interfacing. It is the object of these studies to improve the sensitivity of particle beam sample introduction by optimizing these critical parameters. 1) Study the effects of nozzle/skimmer separation on quantitation, source pressure, and solute transport efficiency. 2) Study the effect of ion source contamination on sensitivity.

EXPERIMENTAL (One):

Condition A-	Mobile phase-none
	Flow rate- 0.00
	Flow rate nebulizer gas- 2 Liter/min
	Gas composition- Air
Condition B-	Mobile phase composition- 50/50 MeOH/H ₂ O
	Flow rate- 0.35 mL/min
	Flow rate nebulizer gas- 1 Liter/min
	Gas composition- Helium

RESULTS: The most sensitive performance has been observed to be at or near the minimum of the air curve. This is slightly outside the separation associated with the minimum pressure curve for condition A. No aerodynamic explanation for these observations is available at this time; however additional studies with flow versus separation may lead toward a physical explanation. In order to attain optimal performance, it may be necessary to change N/S separation depending upon the flow and solvent conditions.

The observed curvature of the analytical plots (Figures 2) are explained by lower momentum associated with the lower concentrations. This curvature was observed at much higher concentration with earlier designs. Possibly minimizing turbulence in the momentum separator will shift the drop-off to lower masses. Another solution to this mass transport problem has been the use of a less volatile matrix in the mobile phase, resulting in particle size being independent of solute concentration.

EXPERIMENTAL (Two): This experiment demonstrates the significant effect of source contamination on both response and background. A clean, well-tuned systems was subjected to repeated injections of phenylthiazine for 150 injections of 10 ng. The signal-to-noise was then measured as a function of increasing source contamination. The replacement of the ion region with a replaceable ion source repeller assembly was performed after 150 injections.

RESULTS: Experiment two measured the response of the mass spectrometer after repeated injections of phenylthiazine (10ng injected). After 150 injections the signal-to-noise was significantly reduced. Replacing the ion source repeller assembly with a clean volume reestablished the initial performance.

PARTICLE BEAM LC/MS BY FAB

Phillip E. Sanders, Ross C. Willoughby, and Samuel Mitrovich
Extrel Corporation
240 Alpha Drive, Pittsburgh, PA 15238

Continuous flow FAB has demonstrated the ability to accomplish real time chromatographic separations coupled with sensitive fast atom bombardment ionization. However, problems such as the necessity for microbore LC systems and the associated low flow rates and clogging problems make continuous flow FAB a relatively difficult technique for routine analysis.

Particle beam introduction of the analyte through ThermoBeam™ (TAB) allows for the use of standard chromatographic systems at high flow rates (e.g. 0.5-2.0 mL/min.) reducing the need for microbore LC systems and their associated problems.

The matrix compound may be added to the system in a number of ways such as: post column addition, addition through the FAB target, or addition through flow injection. This flexibility of matrix addition makes it possible to perform a wide variety of experiments while maintaining a high flow rate of analyte into the mass spectrometer. Matrix addition through the TAB interface is possible utilizing concentrations in the range of 0.01-1.0%.

Higher matrix concentrations are possible through direct introduction through the target and the flow injection technique.

A cesium ion source (ANTEK, Palo Alto, CA) was used to generate the primary ion beam. The energy of the primary ions were 10 kV. Other sources of fast atoms or ions were tried: e.g. saddle field gun, capillaritron gun, but the cesium source produced the best results. The sensitivity of TAB/FAB has been demonstrated to be good, e.g. 5 ng of erythromycin (m.w. 733) yields a sodiated adduct of m/z 756 with a signal to noise ratio well over 10:1.

Flow injection experiments were performed with TAB/FAB on other compounds such as: benzo-[a]-pyrene glucuronide, somatostatin, alpha solanine, and bovine insulin chain B.

DETERMINATION OF ALKYL BENZENE SULFONATES BY CAPILLARY ZONE ELECTROPHORESIS - MASS SPECTROMETRY

M. Vassiliadou, Department of Chemistry, and
T.M. Mills, Department of Biochemical and Biophysical Sciences,
University of Houston, Houston, Texas 77004
and

S.R. Missler, E&P Technology Division,
Texaco Inc, Bellaire, Texas 77401

The objective of this research is to develop capillary electrophoresis - mass spectrometry (CE-MS) for determination of petroleum related compounds. In the present study, CE-MS was applied to the determination of alkylbenzene sulfonates, compounds commonly used as surfactants and detergents in the petroleum industry. The interface design under evaluation was first introduced by Ewing¹ and incorporates coupling of a CE capillary column to a continuous flow fast atom bombardment (fFAB) capillary.

Capillary electrophoresis separation of homologous alkylbenzene sulfonates was first developed off-line. Detection of eluting bands was accomplished by removing the polyimide coating from a section of column, thus forming a quartz window for UV detection. This arrangement enabled determination of CE separation efficiencies without band broadening due to extra column effects. Column diameters of 50 μ m gave the best resolution, while 75 μ m columns plugged less frequently and gave better detection. Figure 1 shows a typical separation achieved for selected alkylbenzene sulfonates.

CE-MS separation of alkylbenzene sulfonates is presented in Figure 2. Separation efficiencies are reduced compared to results shown in Figure 1 for the same compounds. Band broadening is probably due to extra column effects (dead space, diffusion and turbulence) at the coupling, laminar flow and diffusion in the fFAB capillary, differences in the anodic and cathodic buffers, and overloading. However, under-resolved peaks in conventional CE are easily deconvoluted by CE-MS, as demonstrated by the mass electropherograms for C-9 and C-10 alkylbenzene sulfonates.

Figure 3 presents mass spectra corresponding to the respective sulfonates of Figure 2. The organic anion of each sulfonate salt predominates, and is observed well above the background.

CE provides an alternative to ion-pairing HPLC for separation of ionic compounds such as alkylbenzene sulfonates. The combination of CE and MS appears most promising and constitutes a powerful technique in separation and characterization of petroleum related compounds. Future work will include refinement of the CE-MS interface and extension of the method for characterization of other compounds.

Capillary zone electrophoresis (CZE) and capillary liquid chromatography (CLC) have proven to be extremely useful tools for the analysis of nonvolatile and/or thermally labile compounds such as biomolecules. The high separation efficiencies that can be obtained with these microcolumn separation methods facilitate the separation of very complex mixtures, such as biological extracts. While LC remains the most widely used separation method with mass spectrometry, the distinctly superior separation efficiency of CZE over LC is attracting the attention of an increasingly large number of researchers. CZE has demonstrated separation efficiencies in excess of 1,000,000 theoretical plates of separation efficiency in less than 20 minutes (1) and in excess of 100,000 theoretical plates in less than 1 minute (2).

The development of "continuous flow fast atom bombardment" (CF-FAB) interfaces by Caprioli, Fan and Cottrell (3) has provided an MS interface that is particularly well suited for the analysis of biomolecules. Our research groups have therefore been pursuing the coupling of CLC (both open tubular liquid chromatography (OTLC) and packed microcapillary liquid chromatography) and CZE with sector mass spectrometry using CF-FAB. The very low flow rates of the CZE and CLC microcolumns (25 to 50 nL/min) places stringent requirements upon the design of the CF-FAB/MS interface. Therefore, an interface was designed (4) which uses a pair of coaxial fused silica capillary columns to independently deliver the microcolumn effluent and the FAB matrix solution directly to the face of the FAB probe. An evaluation of different FAB matrix solutions has revealed (5) that a solution of glycerol in water (25 % v/v) at a flow rate of approximately 1 μ L/min is optimum for most experiments. This coaxial CF-FAB interface offers the following advantages: independent optimization of the composition and flow rates of the two liquid streams; preclusion of any deleterious effects of the polar, viscous FAB matrix upon the separation process; and minimal band broadening.

The coaxial CF-FAB system has been used to interface both CZE and CLC with a VG ZAB 4F four sector mass spectrometer. The combined systems have been used to analyze several classes of biomolecules, including peptides. They have been successfully used to acquire on-the-fly FAB/MS spectra (Figure 1), and, with CLC, MS detection limits of 500 attomoles have been obtained. High resolution chromatographic separations have been obtained using packed microcapillary columns (50 μ m id packed with 10 μ m C8 and C18 particles) (Figure 2). The capabilities of the ZAB 4F have been exploited to obtain on-the-fly collisionally activated dissociation (CAD) MS/MS spectra of picomole to femtomole levels of biomolecules (Figure 3), which yield abundant structural information. With CZE this interface has proven (6) to be capable of acquiring MS and MS/MS spectra from low femtomole amounts of peptides while maintaining high (hundreds of thousands of plates) electrophoretic separation efficiencies (Figures 4-6).

Richland, WA 99352

Capillary zone electrophoresis (CZE) is attracting extensive attention as a fast, high resolution analytical and micro-preparative separations technique for systems of biological interest. In zone electrophoresis, a column is filled with a single electrolyte having a specific conductivity. The mixture of substances to be separated is applied as a narrow band to the head of a buffer filled column in a band whose width is much less than the length of the column and at a concentration too low to affect the buffer conductivity. An electric field is then applied across the length of the column and the individual substances migrate and separate according to their net electrophoretic velocities. Zone electrophoresis carried out in small diameter (< 100 μ m) fused silica capillaries is a relatively new approach to the high resolution separation of aqueous samples. Very small volume samples (picoliter range) with separation efficiencies on the order of 10^6 theoretical plates for amino acids have been achieved (1). The method can be further enhanced by the dynamic combination of detection sensitivity and selectivity offered by mass spectrometry (MS). The on-line marriage of mass spectrometry to CZE is accomplished by an atmospheric pressure electrospray ionization source interface. Electrospray ionization (ESI) is rapidly growing as an ionization method of choice for nonvolatile biomolecules since the pioneering experiments of Malcolm Dole (2) and later by John Fenn (3). Fenn's group first demonstrated that ESI is a "soft" ionization technique, yielding little or no fragmentation, capable of producing intact multiply charged molecular ions for proteins with molecular weights (MW) exceeding 30 kDa from highly charged liquid droplets at atmospheric pressure through a field-assisted ion desorption process (4). Our research efforts have demonstrated that proteins with MW's greater than 100 kDa can be analyzed using a conventional quadrupole mass spectrometer with an upper m/z limit of only 1700.

Previous CZE-MS experiments have demonstrated the feasibility to analyze amino acids and small peptides. However, the CZE separation of larger protein systems in untreated fused silica capillaries has often resulted in broad, tailing peaks due to Coulombic attraction and adsorption of analyte on active sites to the negatively charged silica wall. Separations performed in buffered systems with the pH above the isoelectric point (pI) of the proteins allows both the proteins and the capillary wall to be negatively charged and mutually repulsive to greatly improve the resolution (5), as demonstrated in Figure 1. Subpicomole CZE-MS separations of myoglobins and smaller peptides can be easily performed in this manner, with over 125,000 theoretical plates obtained. CZE protein separations can also be achieved through the use of very low pH aqueous phosphate buffers, lower than the pI of the analytes (6). Preliminary CZE-MS results have been obtained for a mixture of horse and whale myoglobins and a variety of cytochrome c proteins at pH 2.4.

ANALYSIS OF TRYPTIC DIGESTS BY ON-LINE CAPILLARY ZONE ELECTROPHORESIS
TANDEM MASS SPECTROMETRY, Eric, Huang, and Jack D. Henion, Drug Testing and
Toxicology, Cornell University, 925 Warren Dr., Ithaca, NY 14850 and Thomas
R. Covey, Sciex, Inc., 55 Glencameron Rd., Thornhill, Ontario, Canada.

Recent interest in novel separation techniques suggest new alternatives to HPLC tryptic "mapping". Capillary zone electrophoresis (CZE), for example, promises separation efficiencies in excess of several hundred thousand plates in fairly short analysis times. If this technique is interfaced on-line with a tandem mass spectrometer (CZE/MS/MS) analysis of tryptic digests could provide very high separation power plus molecular weight and possibly sequencing information all within an analysis time of approximately 20 minutes. We have recently applied our CZE/MS/MS system(1) using atmospheric pressure ionization and the ion spray interface(2) to the characterization of tryptic digests of known proteins to evaluate its analytical potential.

The ion spray LC/MS interface(2) was connected directly to the CZE system. The effluent from the CZE column passed through the ion spray LC/MS interface held at 3kV which produced charged droplets directed in the region of the ion sampling orifice of a TAGA 6000E tandem triple quadrupole mass spectrometer. The inlet end of the CZE system was held at 30kV while a buffer of either 10mM or 20mM ammonium acetate diluted with acetonitrile(50:50, v/v) and pH-adjusted with ammonium hydroxide or acetic acid. The separation column was a 100um x 100cm untreated fused-silica capillary while hydrostatic injections were utilized. A variety of proteins were digested with trypsin and prepared for analysis in the conventional manner.

Figure 1 is a total selected ion current profile for a SIM CZE/MS analysis of a tryptic digest of myoglobin. Singly- and doubly charged-ions characteristic of the peptides present were monitored with a buffer pH of 6.9 to obtain this ion current electropherogram. Our experience is that high separation efficiencies are obtainable by CZE/MS of such mixtures, but not without considerable difficulties. One must be careful to avoid overloading the capillary column with too much sample and pH control is critically important. There were many cases where most of the sample components eluted in one narrow region of the electropherogram at a given pH. A small change in the pH would then dramatically effect the separation such that some of the components did not elute or eluted too quickly. Thus, careful attention to the CZE technique and the experimental conditions must be observed.

We have analyzed a variety of different tryptic digests including hemoglobin and myoglobin and find that CZE/MS is a potentially exciting analytical technique especially once the vagaries of the capillary electrophoresis process are better understood. In our experience the ion spray interface for coupling the CZE system to the atmospheric pressure ionization system is analytically rugged and routine to implement.

TOTAL SIM OF TRYPTIC DIGEST MYOGLOBIN
(pH 6.9)

LC/MS DETERMINATION OF LEUCINE-AND METHIONINE ENKEPHALIN IN EQUINE CEREBROSPINAL FLUID(CSF), Jack Henion and Wolfgang Muck, Drug Testing and Toxicology, Cornell University, 925 Warren Dr., Ithaca, NY 14850.

Understanding the various functions of the endogenous "opioid system" (opioid receptors and endorphins/enkephalins as natural ligands) can only be accomplished by highly sophisticated analytical techniques capable of detecting trace quantities of target peptides in biological fluids and tissues. Different approaches have been described which emphasize the key role of mass spectrometry as a vital part for unambiguous identification and confirmation. The often applied analysis of collected HPLC fractions by FD-MS or FAB-MS, however, is tedious and labor intensive.

As preliminary work for investigations related to pain relief phenomena in the horse and the possible abuse of enkephalins at race tracks, a method for the determination of leucine- and enkephalin (LE & ME) in equine cerebrospinal fluid (CSF) has been developed. The analysis scheme is similar to that outlined by Desiderio et al.(1). (D-Ala²)-leucine enkephalin is used as the internal standard (IS). Sample enrichment is based on liquid-solid extraction on C18-material after protein precipitation with acetonitrile. Reversed-phase micro LC (1mm x 100mm, C18 with 3 μ m particles, acetonitrile/trifluoroacetic acid) with mass spectrometric detection via an ion spray LC/MS interface and a commercially available atmospheric pressure ionization (API) triple quadrupole mass spectrometer provided the required selectivity and sensitivity for monitoring pg-levels of the two pentapeptides. The tandem mass spectrometer was run under selected reaction monitoring (SRM) conditions using m/z 120,136,278, and 556(LE) resp. 574(ME) and 120, 136, 292, and 570 for the IS.

Capillary zone electrophoresis(CZE) has received considerable interest due to its potential as a suitable analytical technique for the separation of complex mixtures containing biopolymers. The availability of our recently developed CZE/MS interface(2) allowed us to quickly change to another separation technique (100 μ m x 100cm fused-silica, acetonitrile/20-30 mM ammonium acetate (50/50) using hydrostatic injection) under the same on-line MS conditions and provided comparative studies to get clearer evidence of the capability and feasibility of CZE/MS confronted by this real-world bioanalytical problem.

The results showed that the limited sample volume for CZE(5-15nL) is a practical shortcoming in that the injected sample concentration must be at least in the low ppm range in order to introduce enough sample for detection by the APIMS. In contrast, the micro LC/MS system could accommodate several microliters of sample and can detect low ppb levels in the injected sample. Thus the CZE/MS system is not as well-suited for trace analysis and should be used where sample limitation is not a problem. However, aside from this restriction both approaches are a viable means of analyzing biological samples of the type described herein.

THE ON-LINE COMBINATION OF CAPILLARY ISOTACHOPHORESIS WITH MASS SPECTROMETRY

Harold R. Udseth, Steven M. Fields, Joseph A. Loo and Richard D. Smith
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory*
Richland, WA 99352

Capillary zone electrophoresis (CZE) has been demonstrated to have tremendous potential for high-resolution separations of ionic compounds of biological interest. The small capillary diameter ($<100\text{ }\mu\text{m}$) used in CZE and the need to keep the ionic strength of the sample two orders of magnitude less than that of the buffer place rather stringent limits on the amount of sample that can be injected. Isotachopheresis in a capillary format (CITP) is a complementary scheme that overcomes these limitations (1). The CITP/MS combination has several attractive features. First, there are no fundamental limits on the sample size that can be introduced. Second, CITP can result in the concentration of samples that are injected in dilute solutions. Third, once the separation is developed the sample elutes continuously allowing efficient use of detector time. Fourth, the ideal peak shape in CITP is sharp sided and flat topped. This is an ideal peak shape for mass spectrometric detection. The scan speed of most mass spectrometers is not challenged and MS/MS analysis is facilitated (2,3).

Electrospray ionization (ESI) has been shown to be an effective means of ionizing labile biopolymers from solution. In this work we present the results of an examination of two systems using CITP coupled to mass spectrometry by an ESI interface of our design (2).

Two mass spectrometers were used in these studies. The first was a single stage quadrupole. It was assembled from Extrel components and the vacuum system was designed for an atmospheric pressure inlet. An rf only set of rods precedes the analysis stage to aid in efficient transport of ions. The second was a Sciex 6000E triple quadrupole. The instrument was used with our ESI interface. The electrophoresis was done in a $100\mu\text{m}$ i.d. fused silica capillary column. DB-17 and OV-1 coated columns were used. The effect of treating the inside of the column is to eliminate electroosmosis and reduce peptide or protein binding to the surface. To minimize the total time, once the steady state has been reached the sample was flow migrated from the column by the application of a small pressure head.

An equimolar mixture of the small proteins bradykinin (Mr 1060) and Angiotensin (Mr 1296) was prepared from standards obtained from Sigma. The leading buffer was 0.01M ammonium acetate titrated to pH 4.9 with acetic acid. The sample was prepared at 10^{-4}M each in the leading buffer. The trailing buffer was 0.01M Ala^+ titrated with $\text{Ba}(\text{OH})_2$ to pH 7.1. The column was 2.5 M long with a DB-17 stationary phase. The column was initially filled with the leading electrolyte and then a sample band 64 cm long was loaded by pressurizing the sample reservoir. The column was transferred to the trailing buffer reservoir and the separation was developed at 58 kV off line for 15 minutes. The electrospray was then started. The sheath was methanol and the sample was eluted with voltage applied under a modest pressure head.

The separation reached steady state with two components separated into their own bands. The presence of a valley between the two components indicated the presence of impurities of intermediate mobility. The single ion chromatograms demonstrated the multiple charging which is so characteristic of ESI. Spectral scans taken over the mass range of interest during the elution of each of the major components showed clean spectra. A spectral scan taken in the valley between the bands for two components indicated small amounts of poorly characterized impurities of intermediate mobility.

An enzymatic digest of glucagon was prepared as an example of a less well characterized mixture. Since the enzyme was not of high purity the cleavages are not well characterized. It consisted primarily of trypsin and chymotrypsin. Trypsin is highly specific cleaving only Lys- and Arg-bonds. Chymotrypsin is less specific and is in fact a family of enzymes. Thus although a weak digest of glucagon by trypsin should lead to only four products, the presence of other enzymes considerably complicated the possible product mixture.

The leading buffer was 0.01M ammonium acetate titrated to pH 4.6 with acetic acid. The sample was made up in the leading buffer to a concentration of 10^{-4} M. The trailing electrolyte was 0.01M acetic acid. The column was 0.75 M long with a OV-1 stationary phase. The column was initially filled with the leading electrolyte and then a sample band was loaded hydrostatically. The column was transferred to the terminating electrolyte and the development was started. The ESI was used continuously from the very beginning with a methanol sheath. The voltage was manually ramped to 10 kV over a period of 9 minutes. After 30 minutes the electrolyte reservoir was raised 5 cm to elute the separation from the column. In a separate experiment an on column UV detector operated at 210 and 280 nm was used to monitor the separation under identical conditions.

Single ion plots for the most prominent peaks seen in the spectra show the bands in the beginning and end of the sample are more fully developed while those in the center still exhibit mixed band characteristics. Most, but not all of the ions could be correlated with expected digest fragments. As would be expected the single amino acid residue Arg is present and has the highest mobility amongst the sample components. The next band to elute is also well characterized and correlates with the T1 (2+) fragment. Two mixed bands correlating with the T2⁺ and T4-478 (2+) fragments appear next. The next two bands are again well developed but do not correlate with any expected major digest fragment. The last band to elute is again well characterized and correlates with the T4-1049 (2+) fragment.

The relatively long period of time over which a peak elutes in CITP makes it an attractive candidate for MS/MS analysis. Such an analysis was done on the leading and trailing bands of the sample. They gave structurally informative results that can be used to confirm the tentative identifications.

The combination of CITP with mass spectrometric detection is a promising, but still developing technique. The interface to mass spectrometry does not detract from the separation power of this technique. There is considerable variation in the sensitivity of ESI for the various fragments in a typical digest. Although most of the expected fragments were detected, some of them were not. For those fragments that are detected the sensitivity is generally good. The CITP format is ideal for MS/MS operation. We are confident that the CITP/MS combination will continue to develop in importance.

We thank the U. S. Department of Energy, Office of Health and Environmental Research, for support of this research under Contract DE-AC06-76RLO 1830. *Pacific Northwest Laboratory is operated by Battelle Memorial Institute.

We have reported previously on the identification of domoic acid as the neurotoxin responsible for the outbreak of amnesic shellfish poisoning following the ingestion of cultivated blue mussels harvested from a localized area of Prince Edward Island.¹ Subsequent work has led to the development of routine methodology² for the quantification of this toxin in a variety of marine matrices including seawater, plankton and shellfish tissues by HPLC with either UV diode array detection or fluorescence detection, the latter using a fluorenylmethoxycarbonyl (Fmoc) derivative. The present work describes an evaluation of mass spectrometry-based methods for the confirmation and determination of domoic acid in complex matrices.

Gas chromatography-mass spectrometry

Domoic acid is a polar, non-volatile and thermally labile molecule and therefore requires chemical derivatization to enable its analysis by GC or GC-MS. We have developed a rapid extraction and clean-up procedure for complex marine matrices to facilitate the preparation of an N-trifluoroacetyl-O-tert-butyltrimethylsilyl derivative of the toxin. The mixed reaction approach overcomes the problem of incomplete silylation of the amine functionality observed in earlier work using only the silyl reagent.³ The derivatization is fast and proceeds under the necessary mild conditions required by this labile molecule.

The resulting DA-TFA-TBDMS derivative (Figure 1) is stable and is suitable for GC-MS. The EI mass spectrum shown in Figure 1 is notably clean, with a high proportion of the ion current being carried by the ion $[M-tBu]^+$ at m/z 692. This abundant ion at high mass is well separated from any interfering reagent species and is ideal for single ion recording (SIR). Reaction mixtures were injected directly into a GC-MS system and a typical separation of a contaminated mussel extract is shown in Figure 2. In the SIR mode we were able to detect low nanogram levels of domoic acid.

Liquid chromatography-mass spectrometry

We have adopted two approaches to the coupling of our routine LC methodology (Figure 3) for domoic acid to the mass spectrometer:

Continuous flow fast atom bombardment: initial results using flow injection seemed promising with low picogram sensitivity available in the full scan mode with as little as 1 nanogram required to obtain a recognizable spectrum for identification. Although we were able to obtain a chromatographic separation of the toxin using a packed fused silica capillary column coupled directly to the flow FAB probe (flow rate 3 μ L/min), we were not able to resolve any of the isomers known to be present nor detect any other components of this complex mixture. Problems with maintaining a stable ion current during a gradient were compounded by the loss of column performance due to the glycerol matrix in the mobile phase.

Ion spray mass spectrometry: we have recently reported encouraging results in the use of this technique for the analysis of several marine neurotoxins including domoic acid.⁴ In continuing this work we have been able to achieve excellent results for the gradient LC-MS analysis of mussel and plankton extracts for this toxin. A selected mass chromatogram of the protonated molecular ion m/z 312 is shown in Figure 4. Chromatographic integrity is well-maintained, and we were able to confirm the presence of numerous isomers and derivatives of domoic acid. The clean mass spectra produced (Figure 5) gave invaluable molecular weight information, while the MS/MS capability of the triple quadrupole MS provided useful structural information.

Applications of Packed Column Supercritical Fluid Mass Spectrometry
Using A Thermospray Ion Source

R S I Joseph, M S Lant and P Woolgar
ICI Agrochemicals Jealott's Hill Research Station
Bracknell Berkshire RG12 6EY England

Introduction

Supercritical fluids are recognised as good mobile phases due to their low viscosity, high diffusivity and increased analyte solubility relative to liquids. The coupling of supercritical fluid chromatography (SFC) to a mass spectrometer therefore combines these chromatographic properties with a very specific, selective and sensitive detector.

The purpose of this study was threefold. Firstly to determine if it was possible to connect a supercritical fluid chromatographic system to a mass spectrometer via a Vestec thermospray interface. Secondly to obtain qualitative data to help in the identification of metabolites of agrochemicals and thirdly to endeavour to evaluate the SFCMS system for quantitative analysis.

The compound chosen to evaluate the system was Hexaconazole (1) a triazole fungicide. Putative metabolites of hexaconazole were also analysed (2-4).

Experimental

All experiments were performed on a Finnigan MAT 4600 mass spectrometer using a Vestec thermospray interface. No modifications were made to the interface. The SFC system was home made and comprised of two Gilson HPLC pumps, with a cooling jacket around one of the pump heads. A rheodyne 7037 pressure relief valve was used as a backpressure regulator. The discharge mode of ionisation was used for all experiments.

Results and Discussions

The total ion current chromatogram obtained from the SFCMS analysis of Hexaconazole and three putative metabolites is shown in figure 1. A good separation was achieved resulting in the partial separation of the diastereomers of diol (3) (peaks 3 and 4). The mass spectra obtained from Hexaconazole and diol 3, which is representative of the other diols are shown in figure 2. The spectra are very simple and only protonated molecular ions are observed.

Selected ion monitoring (SIM) data were obtained for hexaconazole (1) using ions m/z 314 and m/z 316. A limit of detection of 2.4 ng injected on column was obtained (Figure 3). The reproducibility of the system was determined by making six replicate injections of hexaconazole (24 ng). A coefficient of variation (cv) of 9% was obtained. The use of an internal standard would help to improve this figure.

A calibration line relating the peak height of m/z 314 with the concentration of hexaconazole was linear in the range 2.4 ng to 60 ng injected on column (figure 4). The regression characteristics were slope, 25 intercept, 497 with a correlation coefficient of r , 0.993.

Conclusion

1. A Vestec thermospray source can be used for coupling a SFC system to a mass spectrometer.
2. Good qualitative data can be obtained with simple CI type spectra producing protonated molecular ions.
3. The system can be used for quantitative analysis with or without an internally standardised method. The use of an internal standard will improve the accuracy and precision of the method.
4. The system is easy to set up and use and this is shown by the fact that the above work was carried out in one week.

Acknowledgement:- The authors would like to thank Mr Graham Kilpatrick from Inter-ion Limited for the kind loan of the Vestec thermospray interface.

**HIGH TEMPERATURE VAPORIZATION EFFECTS
IN PARTICLE-BEAM MASS SPECTROMETRY**

W. Eric Harris and Richard F. Browner School of Chemistry, Georgia Institute of Technology,
Atlanta, GA, 30332-0400}

Particle-beam mass spectrometry (developed from MAGIC-LC/MS) has proven very effective in its ability to generate classical spectra from any compound amenable to the direct insertion probe analysis. This makes the technique valuable for a wide range of compounds ranging from high to intermediate volatility. Recent studies have also demonstrated that compounds of low volatility may also be readily vaporized using fast atom bombardment (FAB). However, while fast atom bombardment has great utility for many compounds, it is functionally more complex than standard EI particle-beam mass spectrometry. Additionally, FAB generated mass spectra are not readily searched using standard library procedures.

As stated above, the limiting factor for many methods is the inability to achieve vaporization of the sample, in such a state that is representative of the original structure. The goal of this study is to better understand the interaction of the particle beam and the heated ion source. All previous efforts have been directed toward the interactions role in detection limits and sample transport, but not on its affect on the vaporization of the sample and the sample integrity.

Once we have transported the sample to the ion source it becomes necessary to vaporize it. The problem being that some compounds do not go easily into the vapor state. This volatility problem exists because of the instability of many molecules at the temperatures required for their evaporation. The energy added to break surface bonds is distributed instead toward the decomposition reaction.

For us to limit the decomposition reaction, we must affect a change in the relative rates of the two competing processes, decomposition and volatilization. Basically, it is considered that heating an unstable, nonvolatile compound can be viewed as causing a kinetic competition between decomposition and volatilization, where decomposition is favored since the activation energy for the breakage of intramolecular bonds in these compounds is less than that required for the breakage of intermolecular bonds.

One way for us to affect a change in the relative rates and enhance the yield of intact molecules over fragments produced by surface decomposition processes, is to increase the rate at which energy is deposited into the sample. If the rate of evaporation of a neutral fragment is determined by an activation energy for decomposition, which is lower than the parent molecule evaporation activation energy, then the arrhenius plots of relative ion abundance vs. $1/T$ must intersect at some value of T . The fragment specie produced with its lower activation energy may be strongly favored at the lower temperatures but if the parent molecule can survive temperatures above the intersection of the respective plots, then it will be more abundant in the gas phase at the higher temperature.

One major detrimental factor in the process is multi-layer adsorption. the affect of multi-layer adsorption is to setup a temperature gradient from the molecules on the surface of the heating source out to the molecules at the surface. This causes an "overheating" past the temperature needed for efficient evaporation of the underlying molecules to achieve evaporation of the surface molecules.

In our study we looked at both the temperature and concentration effects on the loss of water from cholesterol. Often cholesterol is used as a measure of the thermal efficiency of a system. When cholesterol is subjected to thermal energy, the solid sample undergoes the degradative loss of water comparative to the amount of thermal energy it incurs. Therefore the ratio of the M^+ to the $M^+ - 18$ ions is a useful measure of the thermal efficiency of a system.

The results of our experiments are shown in figure one. The major overall trend is less thermal degradation with lower concentrations. This is apparently true due to the lessen affect of multilayer adsorption. For the two greater injection amounts of 1.0 and 0.5 ug, increasing the temperature only increases the amount of thermal degradation opposite the projected trend. We suggest that given the temperature gradient with the multi-layer adsorption, increasing the temperature only increases the

amount of "overheating" and therefore the amount of thermal degradation. As we lower the concentration of the injections, we do not see the apparent trend for the ratio to decrease with temperature. Hopefully, this suggests that we are getting closer to a mono-layer effect and show increase volatility.

We were even able to see the effect of concentration on individual chromatographic peaks. As the first particles reach the ion source, the ion ratios are good, but as amount increases reaching the ion source the ratios decrease, as seen in figure two.

In conclusion, we have seen that particle beam has the ability to enhance spectra if enough energy is imparted to the analyte and the analyte is present in low enough concentration to approach a mono-layer effect. Another benefit not discussed in this poster is that of the increased rate of desorption. If we can lower the activation energy, we also increase the resolution of the system.

TEMP. AND CONC. EFFECTS ON 386/368 ION RATIO

FIGURE 2

IN VITRO ANALYSIS OF ANTIMETABOLITES
IN BLOOD PLASMA BY MAGIC LC/MS

W. Eric Harris and Richard F. Browner School of Chemistry, Georgia Institute of Technology,
Atlanta, GA, 30332-0400}

The major desire in chemotherapy is to achieve a constant drug level in the patient over a long period of time. This level must be controlled above the toxicity level of the cancerous cell and below the toxicity level of the host. Methods of antimetabolite (a major class of chemotherapy drugs) introduction include giving one bolus, whose concentration would degrade with time. Using this method, high concentrations occurring shortly after introduction could be determined and lower concentrations extrapolated. This gave a somewhat reasonable method for determining the concentration of the anticancer agent, but the introduction method gives varying amounts of the agent in the system instead of constant known concentration.

The current method of choice is to administer the agent by continuous infusion. In this manner, dilute solutions are continuously pumped into the patient and a constant cancer agent level is attained. Determining the actual level of this agent is compounded by the differing enzyme activity from patient to patient and day to day which breaks down the agents to inactive byproducts. There is a need to be able to attain low level detection of these antimetabolites in the blood plasma without time consuming extractions.

The goal of this study is to demonstrate the ability of MAGIC LC/MS to provide quantitative detection of these antimetabolites at low levels of concentration. Currently we now use a production model particle beam interface produced by the Hewlett Packard Co. which was developed from the MAGIC LC/MS interface developed at the Georgia Institute of Technology.

Experimental Setup and Procedure:

Instrumentation:

Hewlett Packard 5988 Quadrapole Mass Spectrometer
Hewlett Packard 59880A Particle Beam Interface
Hewlett Packard 1090 Liquid Chromatograph
Hewlett Packard Hypersil ODS 3um column, 60 x 4.6mm

Chemicals obtained from Sigma Chemical Co.

Uracil #U-750
Thymine #T-0376
5-Fluorouracil #F-6627

The elution was isocratic using Methanol at a flow rate of .6 mL/min. The peak eluted just after the void volume of the column but the chromatography is necessary to remove many mass interferences.

Extraction Procedure:

1. Obtain 1 mL of blood plasma.
2. Add 3 mL of phosphate buffer (pH + 6.85).
3. Extract with diethyl ether/isopropanol, (80/20) three times.
4. Pool organic phases and mix well.
5. Concentrate to dryness under nitrogen.
6. Dissolve residue in 100 uL methanol and homogenize (sonicate).

Note-Extreme care must be taken during the extraction process so that no aqueous phase is taken with the organic phase. This would introduce mass interferences damaging the ability to achieve quantitation. The extraction normally gives better than 80% recovery.

Apparently, with the extraction and the chromatographic cleanup, the pyrimidines of interest elute from the column in one narrow band. Coupling this with their excellent adeptness for either chemical ionization using isobutane or electron impact ionization, quantitation is achievable as seen in figure one.

Fluorouracil is the antimetabolite which gives all other methods trouble. The quantities present in patients receiving the chemotherapy drug by continuous infusion range from 10 to 40 ng per mL of blood plasma. Using isobutane as a CI gas, we could detect (3 to 1 ratio) as low as 3 ng in one mL of blood plasma. Part of the sensitivity study is shown in figure two.

Thymine and Uracil are present at levels from 100 to 800 ng/mL of blood plasma and ionize easily giving improved signal over the Fluorouracil and quantitative results.

In conclusion, we have seen that Particle Beam LC/MS has the ability to provide quantitative detection of these antimetabolites at the levels present in chemotherapy patients. The extraction is simple and can easily be run with limited discomfort to the patient due to the small amount of plasma needed (as compared to 5 mL needed for other analysis). As always, the process using the mass spectrometer is fast and accurate allowing the physician to quickly react to any major fluctuations in the antimetabolites concentration, thus obtaining a constant level below the toxicity level of the patient and above that of the cancerous cell. Presently, we are collaborating with the University of Alabama, Birmingham Pharmacology Department to run a series of plasma samples to validate our findings on real world samples.

AEROSOL TRANSPORT STUDIES IN PARTICLE BEAM MASS SPECTROMETRY

Katherine R. Edman, John D. Kirk, and Richard F. Browner
School of Chemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400.

Improvement of detection limits is a constant goal of all types of LC/MS interfacing. In the case of particle beam mass spectrometry (based on MAGIC-LC/MS), the aim is to reduce detection limits from typical values in the low nanogram range to values in the middle to upper picogram range. One way to partially accomplish this is to increase the efficiency of vaporization of the sample in the ion source area of the mass spectrometer. This paper will address the problem of aerosol transport in the interface by describing a series of carefully controlled experiments in which test compounds are injected through the interface and collected in a specially designed chamber, configured to simulate closely the physical environment in the ion source region of the mass spectrometer.

Experiments will be described in which a variety of commonly-used mobile phase solvents (e.g., H₂O, MeOH, CH₃CN) are examined, and operating parameters such as the liquid flow rate are varied. The mass of collected sample is determined by HPLC with UV detection, and by use of suitable test compounds, it will be possible to make absolute comparisons between sample transport parameters for the solvents tested.

The transport efficiency improves as the polarity of the solvent decreases: water, being highly polar, has poor transport efficiency (approximately 2%), whereas hexane, the least polar solvent tested, also yielded the best transport efficiency. Decreasing viscosity of the solvents did not necessarily predict improved transport efficiency, however. Common reversed-phase organic solvents, such as methanol, acetonitrile, and THF had comparable transport efficiencies, usually around 10 to 15%. Without exception, the transport efficiency was better for fast mobile-phase flow rates (0.7 to 1.0 mL/min) than for slower flow rates.

Two similar compounds, benzophenone and 2,2',4,4'-tetrahydroxybenzophenone (THB), were used as the test compounds for these studies. When both analytes were used to test a solvent, the benzophenone transport efficiency is 2-4% less than that of THB. It is suspected that this decrease could be due to the sublimation of benzophenone in the collection chamber. If this proves to be the case, another substituted benzophenone will be used in future studies.

FAST ATOM BOMBARDMENT: BROADENING THE CAPABILITIES OF PARTICLE-BEAM LC/MS

J. D. Kirk and Richard F. Browner School of Chemistry, Georgia Institute of Technology, Atlanta, GA, 30332-0400}

Combining an HPLC with a mass spectrometer has been a problem of major concern to analytical chemists since the introduction of the GC/MS combination. Particle-beam mass spectrometry (derived from MAGIC-LC/MS) has the ability to generate searchable quality electron impact (EI) and chemical ionization (CI) spectra for a wide range of compounds. Generation of such spectra is accomplished only because of the efficient removal of solvent from the analyte before it reaches the mass spectrometer. The analyte leaves the interface in the form of a narrow particle beam which is flash vaporized in the heated ion source region. Compounds which produce high enough vapor pressures may be ionized using EI or CI processes.

A great number of compounds found in HPLC effluents are too involatile to produce high enough vapor pressures for EI and CI processes. These types of compounds require special ionization techniques (*i.e.* laser desorption, and fast atom bombardment (FAB)). This paper addresses the use of FAB as an alternate ionization process for particle-beam LC/MS. Figure 1 shows the experimental set-up. A drop of an appropriate matrix is placed on a probe tip inside the ion source region of the mass spectrometer. The particle beam created from the HPLC effluent by the interface strikes the matrix and is instantaneously ionized by the FAB gun producing standard FAB spectra.

Figure 1

Prior to any chromatography it is necessary to check the compounds of interest to be sure they will generate FAB spectra. This is not unlike standard HPLC with UV detection where one checks to make sure the compounds absorb in the UV. Figure 2 is an ion chromatogram of some azo dyes which were run on the system with no column in place. Spectra were obtained and determined to be of good quality. In a later experiment the dyes will be separated and analyzed using Particle beam LC/FAB-MS.

Figure 2

A mixture of two pharmaceuticals was separated and analyzed using the particle beam system. Figure 3 shows the ion chromatogram of the mixture. Note that the two baselines are due to the fact that the matrix produces a high ion count at m/z 181 which corresponds to the $(M+H)^+$ of aspirin. On the other hand at m/z 328 which corresponds to $(M+H)^+$ of Naloxone, there is very little ion production from the matrix, thus a lower baseline. Chromatographic conditions for the run were 94% methanol, 1% acetic acid, and 5% water, a flow rate of 1 mL/min on a Whatman Partisil C-8 column.

Figure 3

While this first chromatogram is simple and of little practical use, it is exciting in the fact that a new technique has been proven to work and the applications of this technique are unlimited.

LC/API/MS BY PARTICLE BEAM LIQUID CHROMATOGRAPHY

Edward W. Sheehan, H. H. Lo, and Ross C. Willoughby
Extrel Corporation, 240 Alpha Drive, Pittsburgh, Pa. 15238

Introduction. Atmospheric pressure ionization (API) sources for mass spectroscopy have been developed by several groups. The impetus for the development of API-MS can be traced to the biomedical community, whose spokespersons express an apparently limitless need to press ever lower the minimum detectable amount in samples of numerous complex organic materials. More recently, the analysis of trace quantities of compounds in air for air pollution studies; and in gases for the semiconductor industry has caused a resurgence in the interest of API-MS.

The upsurge of LC/MS in the last few years has caused the need for lower detection limits. While most LC/MS techniques have been limited to low nanogram levels there have been some groups that have pushed these levels down to the low picograms levels.

Objectives. It was the purpose of the present studies to explore the state of the art of API/MS and to demonstrate the feasibility of API spectra with four different designs. Design A is commercially available design from Extrel Corp (Ketkar and Siegel). Design A is currently used for monitoring the composition of air and effluents from incinerators. The other three designs (Designs B, C and D) are prototype designs. Design B was designed to study the transport of ions and charged particles through a momentum/ion separator. Design C was an adaption of Designs A and B to resolve the shortcomings of Design A (tailing) and Design B (lack of response). While Design D was an adaption of the electrospray developed by Yamashita and Fenn at Yale University; and ionspray developed by Bruins et al. at Cornell University.

Results. Table I is a summary of our results. Design A yielded the best results but it was hampered by extensive tailing of the peak. The most dramatic results were obtained with Design D. Spectra of multiply charged ions were detected for gramicidin S, mellitin, and substance P. Figure 1 is the full scan profile spectrum of mellitin, similarity reported by Covey et al.

OPTIMIZATION AND EVALUATION OF PARTICLE BEAM HPLC/MS PERFORMANCE FOR THE ANALYSIS OF PESTICIDE COMPOUNDS AND METABOLITES

C. S. Smith, P. C. Knox, and R. D. Voyksner, Analytical and Chemical Sciences,
Research Triangle Institute, Research Triangle Park, NC 27709

Introduction

Nine pesticides and related compounds were chosen for study using a particle beam (PB) HPLC/MS interface in order to explore analysis capabilities with this new and promising instrumental technique. The analytes represented a wide range of chemical classes that have poor gas chromatographic performance properties. These compounds included a phenyl urea, organophosphates and carbamates, a dinitroaniline, sulfur and oxygen heterocyclics, and several sulfones and sulfoxides. Our objectives were to determine optimal PB HPLC/MS instrumental parameters (such as mobile phase pH, composition and flow rate, nebulizer position, helium flow rate, and desolvation and MS source temperatures), to evaluate qualitative and quantitative data collected under optimum conditions, and to compare PB results with those generated with a thermospray HPLC interface.

Experimental

All PB HPLC/MS experiments were performed using a HP Particle Beam interface and HP 5988 MS system with a Waters HPLC system. A Vestec thermospray interface, Finnigan 4500 MS, and Waters HPLC system were used for the thermospray experiments.

The compounds studied were difenoxuron, fenamiphos sulfone, aldicarb, fenamiphos sulfoxide, thiobencarb, aldicarb sulfone, trifluralin, atraton, and plantvax. For the optimization experiments, only four of these compounds were used. All optimization experiments were performed with sample loop injections (no HPLC column). Full scan spectra were then collected with those instrumental parameter settings considered optimal.

Results

Most interface parameters investigated were found to be mobile phase dependent instead of analyte dependent. The best instrument response to all of the test compounds was obtained with methanol as a mobile phase. Other organic solvents investigated were acetonitrile, isopropanol and tetrahydrofuran. Increasing water content in a methanol mobile phase caused a decrease in the detected ion current. The signal intensity decreased approximately 15% over the range when changing buffers from 0.1 M acetic acid to 0.1 M sodium acetate to 0.1 M sodium hydroxide in 50% methanol/water. Methanol was used as the mobile phase for all instrument parameter optimization. An optimum HPLC mobile phase flow rate was determined to be about 0.6 mL/min with methanol.

The optimal nebulizer setting was somewhat compound dependent; however, all the compounds showed two optima in the regions corresponding to a capillary tip position approximately 0.5 mm inside and 0.5 mm outside the nebulizer nozzle tip. The best signal intensity was produced with a helium flow into the nebulizer such that the instrument inlet flow gauge reading was approximately 30 psi. A desolvation chamber temperature setting of about 550 °C produced the best results, but the optimum MS source temperature appeared compound dependent.

Particle beam electron impact-type spectra (see Figure 1) showed logical fragmentation patterns, and molecular ions were detected for all compounds except aldicarb and aldicarb sulfone. The spectra compared well with references from the NBS Mass Spectral Library. When the PB interface was operated under CI conditions (see Figure 2), the spectra showed $[M+H]^+$ and $[M+20]^+$ ions as well as large characteristic fragments similar to those seen with thermospray.

A calibration curve was constructed with twelve (12) injections of aldicarb sulfone at each of five calibration levels ranging from 20 ng and 500 ng. Linear regression analysis of the calibration data showed a r^2 value of 0.994. Triplicate injections at the 20 ng level had a RSD of 7%.

THE APPLICATION OF PARTICLE BEAM HPLC/MS TO THE ANALYSIS OF DERIVATIZED AND
UNDERIVATIZED PROSTAGLANDINS

Alexander B. Schilling , Hewlett Packard Co., Naperville, Illinois.

Prostaglandins are a group of fatty acids that modulate a broad range of physiological functions. As such, they may be involved in a number of pathological conditions. The measurement of the prostaglandins by MS has been primarily accomplished through the use of GC/MS with negative ion chemical ionization (NCI) (1). This technique offers high sensitivity, but requires extensive sample derivatization (esterification, silylation and oximation) prior to analysis. Underivatized prostaglandins have been studied by desorption CI/MS (DCI/MS) (2,3). However, the potential for variations in sample handling make it unsuitable for use in quantitation.

The current study examines the use of the Particle Beam(PB) HPLC/MS as a tool to allow the measurement of prostaglandins via HPLC. Unlike GC, HPLC does not require extensive derivatization to effect separation of involatile compounds. In addition to observing the positive CI (PCI) and NCI MS of the underivatized prostaglandins PGE₂, PGF_{2a}, TXB₂, and TXB₂-o-methyl acetal, a series of corresponding methyl esters and pentafluorobenzyl esters were prepared. These derivatives were purified by normal phase HPLC and examined by PB/HPLC/MS.

Experimental:

All spectra were acquired using a HP 5988A LC/MS system equipped with a PB interface and RTE-A data system scanning from 250-600 amu. A mixture of Methane:Ammonia 99:1 was used as reagent gas for both PCI and NCI at a source pressure of 0.5 torr. HPLC was performed by a HP 1090L equipped with an autoinjector. A hypersil SI (3uM particle, 60x4.6 mm) column was used for all separations with a mobile phase of CH₂Cl₂:MeOH 100:0 to 70:30 in 15 minutes. Methyl esters were prepared by reacting 100ug of a given prostaglandin in 0.5ml of ethereal diazomethane for 5 min and then evaporating. Pentafluorobenzyl esters were prepared by reacting the prostaglandin with 50uL of a 1:3 solution of pentafluorobenzyl bromide in ACN and 50uL of a 1:4 solution of diisopropylethylamine in ACN for 5 minutes at 40 C, followed by evaporation. All residues were dissolved in CH₂Cl₂.

Results and Discussion:

Figure 1 shows the PCI spectrum of PGE₂ in the molecular ion region. The PCI spectra of the prostaglandins were found to resemble those obtained by DCI earlier, suggesting that rapid volatilization was occurring in the ion source. Source temperature was found to influence the observed abundance of NH₄⁺ adduct ions vs elimination ions. Also, total sensitivity to the prostaglandins increased at higher source temperatures. In general, limits of 0.5 to 2 uG and 0.1 to 1uG were observed for the free acids and methyl esters respectively. The use of NCI in scan mode, or PCI with selected ion monitoring (SIM) mode allowed 10x greater sensitivity over PCI in scan mode. Figure 2 shows the results for the NCI MS of PGE₂ pentafluorobenzyl ester in both scan and SIM mode. These derivatives yielded the best sensitivity with better than 10:1 s/n at 1 ng. Because chlorinated solvents are known to compete with solute in the resonance electron capture mechanism of NCI (4), it is expected that greater sensitivity may be obtained via the use of nonchlorinated solvents in either normal or reverse phase.

These results demonstrate the feasibility of using PB/HPLC/MS to reduce the number of derivatization steps (one instead of three), and therefore the time, needed to analyze prostaglandins at physiologically useful levels vs GC/MS. Studies on the application of this technique to urinary metabolites are in progress.

Characterization of Flavors and Aromas by GC/MS and Particle Beam LC/MS.

Thomas C. Marecic, Matt Dilts, Edward Sheehan
Extrel Corp., 240 Alpha Dr., Pittsburgh, PA 15238

INTRODUCTION

The characteristic flavors and aromas of fruits and fruit products are the result of complex mixtures of organic compounds. Because flavor components occur in natural products as complex mixtures, several sample handling techniques have been developed in order to analyze citrus constituents by using mass spectrometry. Components of high volatility (b.p. < 125 °C) and intermediate volatility (b.p. 125-225 °C) have been easily identified by using GC-MS. They are usually separated on conventional GC and volatile enough to be introduced into the source of a mass spectrometer at normal operating temperatures. Components of citrus flavor fractions that do not distill below 100 °C under high vacuum are generally regarded as nonvolatile components. Nonvolatile components are usually separated by crystallization, distillation, or some form of liquid chromatography or thin-layer chromatography. Their mass spectra are determined off-line with a solids probe. Use of a solids probe often requires heating the sample above normal source operating temperatures which can result in decomposition of the desired component or volatilization of an impurity to give an erroneous mass spectrum. (1)

OBJECTIVES

The objectives of this study were to (i) simplify the existing methods for analysis; (ii) develop on-line techniques for faster more accurate qualitative results using electron impact ionization; and (iii) evaluate major and minor components that were previously difficult because of thermal degradation or lack of volatility. Emphasis will be placed on LC/MS because of the associated problems of introducing high molecular weight components into the ion source.

EXPERIMENTAL

This analysis involved using the EXTREL 400-2 Mass Spectrometer equipped with both a GC and a ThermoBeam™-LC/MS interface in the on-line mass spectral analysis of Oil of Orange (McCormick & Co., Inc.). The GC/MS analyses involved the techniques of purge and trap (Tenex/silica gel) of 5 microliters of the oil in 5ml of water onto a 1% SP-1000 on carbopack B column; and the injection of 1 microliter of the concentrated sample (5ml reduced to 1ml by warming) onto a SPB-5 (30m) capillary column. The LC/MS analysis was accomplished by injecting 10 microliters of the previously concentrated sample onto a C-18 (4.6mm) reverse phase column. A gradient elution program using methanol and water was used at a flow rate of 0.5ml/min.

RESULTS

The GC/MS runs show typical compound rich chromatograms (Figures 1. Purge and Trap; Figure 2. Splitless Injection, 1ul) that have been well characterized(2).

Figure 3 shows the total ion current for the LC/MS run. Spectrum 1 shows an example of a nonvolatile component of orange extract that eluted in 25 minutes (3). This component along with some others in Figure 3 did not elute in either of the GC/MS analyses. Previous techniques used to identify this component involved size exclusion HPLC (300-400 MW fraction) with further separation using reverse phase HPLC and final analysis using a solids probe introduction to a mass spectrometer (4).

This study concludes that by using LC/MS in conjunction with GC/MS techniques a broad range of volatile and nonvolatile components can be studied from flavors and fragrances in a relatively short period of time. These techniques compliment each other with regard to qualitative results.

DEVELOPMENT OF AN INTERNAL STANDARD AND A
PERFORMANCE TEST MIXTURE FOR PARTICLE BEAM LIQUID
CHROMATOGRAPHY/MASS SPECTROMETRY SYSTEMS

Thomas D. Behmyer, Thomas A. Bellar, and William L. Budde

U. S. Environmental Protection Agency
Office of Research and Development
Environmental Monitoring Systems Laboratory
26 West M. L. King Drive, Cincinnati, OH 45268

Several types of particle beam interfaces for high performance liquid chromatography/mass spectrometry (HPLC/MS) have been described. These interfaces permit a new approach to the development of a broad spectrum HPLC/MS methods for the simultaneous identification and measurement of non-gas chromatographable toxic organic environmental pollutants. Most of the work done to date has involved the use of flow injection analysis (FIA) for the evaluation of these interfaces. While FIA is a valuable technique for the rapid injection of compounds through the LC/MS interface and into an electron impact mass spectrometer, the performance data obtained by this process probably has little relevance to the performance obtained by real HPLC/MS. The performance observed with FIA is compromised in real LC/MS by the HPLC column, necessary ionic strength additives and pH buffers in the mobile phase, and variable solvent compositions resulting from gradient elution.

Factors which affect the overall response of an analyte are the operating parameters of the interface and the analyte itself. Caffeine has been proposed as a test substance for the optimization of the particle beam HPLC/MS interface operating parameters. Adjustable operating parameters for particle beam interfaces include: the position of the capillary transfer line with respect to the entrance to the desolvation chamber, the temperature of the desolvation chamber, the temperature and flow rate of the nebulization gas, and the composition of the mobile phase.

We have studied these parameters on two particle beam HPLC/MS systems: the Hewlett-Packard Particle Beam LC/MS and the Extrel Thermabeam LC/MS system. The operating parameters were varied and the integrated signal intensities of the ions for caffeine and sixteen nonvolatile compounds (see Figure 1) were measured. The compounds in this mixture were chosen to elute within a reasonable time from a reversed phase C-18 HPLC column using gradient elution of acetonitrile-water (0.01M NH_4OAc) solvent system at 0.4 ml/min. A generally good correlation was established with FIA between caffeine signal intensities and the intensities of compounds in the test mixture as long as the same mobile phase composition (e.g. 100% acetonitrile) was used for each compound. However, as the composition of the mobile phase changes, as in gradient elution, the optimum parameter settings for some compounds, in relation to caffeine, changes. Because each compound will elute under different mobile phase composition in real HPLC/MS, FIA optimization with caffeine may or may not give the parameter settings which will give optimum response for all compounds in a mixture. Compounds with volatilities different from caffeine may have maximum response at different settings. A compromise setting must be used. Therefore, through the column optimization was performed for the mixture by varying the operating parameters over several runs. By observing the performance of the whole mixture, an optimum setting which maximizes the response of all compounds in relationship to each other, can be found.

This mixture can also be used to test the performance and continuing operation of individual system components. Degradation of the HPLC column may result in peak broadening and loss of resolution between close eluting compounds. This results in loss of sensitivity for some compounds. The desolvation chamber temperature can be critical to signal reproducibility for certain compounds (i.e. late eluting compounds and volatile compounds). If the temperature fluctuates during a chromatographic run, the relative standard deviation (RSD) of the response for these compounds increases. It is also important to test the instruments ability to produce reproducible standard electron impact mass spectra. A gas chromatographable compound, decafluorotriphenylphosphine (DFTPP), routinely used in GC/MS methods to check tuning on mass spectrometers, was included in the mixture. While this compound is not ideally suited to LC/MS due to its volatility, the electron impact spectra meets EPA ion abundance criteria.

We have also investigated the use of particle beam HPLC/MS systems for quantitative analysis. Calibration curves were generated for all sixteen compounds and response factors were calculated using dichlorobenzidine-D₆ as an internal standard. Most of the compounds exhibited linear calibration curves and response factors with RSDs in the 10-30% range. However, coeluting compounds have been found, in some cases, to affect the performance of each other by either enhancing or reducing their response relative to their response when run individually. Therefore, the use of labelled internal standards, which coelute with their non-labelled counterpart, may not be possible.

Various Aspects of Ionspray Mass Spectrometry/Mass Spectrometry
K.W.M. Siu, G.J. Gardner and S.S. Berman
Division of Chemistry, National Research Council of Canada
Montreal Road, Ottawa, Ontario, Canada K1A 0R6

Ionspray (IS) or nebulizer-assisted electrospray is a relatively new ion generation technique. It is also a potentially excellent method for interfacing liquid chromatography to mass spectrometry.

One of the unique features of IS is its relative ease in generating multiply charged ions. Macroions containing some twenty charges have been reported (1,2). Yet, small triply or quadruply charged ions that exist in solution are frequently not seen by IS. In an attempt to establish if a correlation exists between ion evaporability and charge to size ratio, we have surveyed some thirty anionic species containing multi-carboxylic, sulphonic and/or phosphoric groups. These include: (A) homologs of straight chain dicarboxylic acids, (B) benzenecarboxylic acids containing two to six carboxylic groups, (C) EDTA and CDTA, (D) ADP and ATP, and (E) azo dyes containing three to four acidic groups.

Ionspraying was carried out in a solution of 70/30 methanol/water containing 1 mM ammonium acetate at pH 9.0. According to pKa data, all acidic groups in the species studied are expected to be ionized in solution. Yet, the ionspray spectra showed significant presence of ions containing undissociated acidic groups indicating that these less highly charged ions are preferentially evaporated. Further, for the more highly charged ions, evaporability is apparently a function of ion size, for example, no ions more highly charged than two were seen when benzenhexacarboxylic acid was sprayed, whereas the triply and quadruply charged ions of Ponceau S (ion mass for the 4- ion, 668.6) were intense when the azo dye was introduced. For ions of similar elemental composition, a reasonable indicator of ion size is ion mass. The main result of the survey is summarized in Fig 1 where ion charge is plotted against mass for ions that were observed and for ions that were expected but not observed. For singly and doubly charged ions, all ions that were expected were observed. For the triply and quadruply charged ions, it is quite apparent that a minimum mass or size has to be satisfied for successful ionspraying. For the types of ions that were surveyed, the cut off point is about 450 amu for triply charged and about 700 amu for quadruply charged ions. These results agree qualitatively with Born's theory of ion solvation. A larger ion may be viewed as more able to stabilize or spread its charge. For a relatively large quadruply charged ion like Ponceau S, the sulphonic groups are well separated to the extent that ion evaporation may be considered as simultaneous evaporation of four singly charged species, whose evaporation is almost always observed.

On the practical side, we have successfully applied IS MS/MS without prior chromatographic separation to the rapid determination of tributyltin (TBT) in a sediment certified reference material for trace metals, PACS-1 (NRCC). TBT is the active ingredient in marine anti-fouling paint and is toxic to shellfish. TBT was first extracted from the sediment with iso-octane or n-butanol, diluted with methanol containing 1 mM ammonium acetate, flow-injected into the ionspray interface, and quantitated by selected reaction monitoring of the daughter/parent pair of m/z 179/291 (a daughter ion spectrum of m/z 291, the most intense isotope of TBT^+ , is shown in Fig 2 (3)). The minimum detectable amount of TBT was about 5 pg Sn absolute or 0.2 μ g Sn/g sediment. PACS-1 was found to contain 1.29 ± 0.07 μ g Sn/g sediment of TBT. Fig 3 shows a standard additions run of PACS-1 extracts.

ION-SPRAY MASS SPECTROMETRY FOR THE ANALYSIS OF MARINE TOXINS*

M.A. Quilliam, S. Pleasance, B.A. Thomson¹ and G.J. Scott¹

Atlantic Research Laboratory, National Research Council of Canada, 1411

Oxford St., Halifax, N.S., Canada, B3H 3Z1;

¹Sciex, Division of MDS Health Group Ltd., 55 Glen Cameron Road, Thornhill, Ontario, Canada, L3T 1P2.

Marine organisms produce many toxic metabolites, some of which are responsible for numerous cases of seafood poisoning each year. Such toxins include domoic acid (responsible for ASP, amnesic shellfish poisoning¹), saxitoxin (a member of a family of compounds responsible for PSP, paralytic shellfish poisoning²), tetrodotoxin (the pufferfish toxin³) and okadaic acid (one of the compounds responsible for DSP, diarrhetic shellfish poisoning²).

Domoic Acid (DA)

Saxitoxin (STX)

Tetrodotoxin (TTX)

Okadaic Acid (OKA)

The most commonly used technique for detecting marine toxins in seafood is the AOAC mouse bioassay. Although this method has the advantage of being non-selective and thus all-inclusive for protection of the public, it is recognized that bioassay suffers from considerable variability and gives little information on toxin composition. Instrumental methods of analysis offer the potential of automation as well as greater selectivity and sensitivity. However, most marine toxins are polar, thermally labile compounds that are difficult to analyze by conventional methods (e.g., GC and GC/MS). High performance liquid chromatography is a preferred method of analysis, but still requires chemical derivatization for UV or fluorescence detection since most marine toxins do not have significant chromophores. Mass spectrometric methods for DA, PSP and TTX have been investigated, with fast atom bombardment (FAB) ionization being useful as a means of structural confirmation at moderate sensitivity.⁴⁻⁷

Atmospheric pressure ionization (API) is recognized as a technique which provides high sensitivity for the analysis of polar organic compounds. The SCIEX® "IonSpray™" system is a very promising API technique based on nebulizer-assisted electrospray.⁸ The ion formation mechanism in both ion-spray and electrospray, a similar technique⁹, is ion evaporation (field assisted desorption of preformed solute ions from micro-droplets of solution)¹⁰ although nebulization also plays a role in ion-spray.⁸ The technique can be used with flow rates from a few to

several hundred $\mu\text{L}/\text{min}$ and thus can be used on-line with HPLC as well as for direct sample introduction. The objective of this study was to investigate the possibility of using ion-spray mass spectrometry and LC-MS to detect trace levels of marine toxins. A preliminary report of this work has been published.¹¹

Three of the toxins (DA, STX and TTX) gave positive ion spectra with abundant protonated molecular ions and no significant fragmentation. Both DA and OKA gave negative ion spectra with $[\text{M}-\text{H}]^-$ ions. Tandem mass spectrometry (triple quadrupole) provided useful fragment ion spectra. Detection limits for flow injection analyses with selected ion monitoring were determined to be 30 pg for STX, 100 pg for DA and 200 pg for TTX. Insufficient material was available for such measurements with OKA. Combining liquid chromatography with ion-spray mass spectrometry was very easy and allowed the determination of DA and some of its isomers and derivatives in toxic shellfish tissue extracts (Figure 1).

A (VIRTUALLY) NON-AEROSOL VAPORIZATION INTERFACE
FOR LC/MS AND LC/MS/MS

L.E. Slivon, D.V. Kenny and R.A. Severance
Battelle, Columbus, OH 43201

A novel capillary LC/MS interface vaporizer has been developed which involves the condensation of high pressure steam on the surface of a low thermal mass metal capillary. The process of condensation deposits substantial energy to the capillary equivalent to the latent heat of vaporization of the working fluid (steam), resulting in rapid vaporization of the aqueous LC eluent within the capillary. Virtually complete eluent vaporization is obtained at flow rate of 1.0 ml/min, at a working fluid temperature of 160 °C. The high latent heat of vaporization of water that often limits many LC/MS interfaces is used in reverse by this interface, improving energy coupling to the aqueous LC eluent and reducing the temperature necessary for continuous LC eluent vaporization.

The prototype version of the vaporizer, shown in Figure 1, consists of a 21 cm length of thin wall 6.35 mm o.d. nickel tubing containing approximately 1 ml of water as the working fluid. A nickel capillary (0.60 mm o.d., 0.35 mm i.d.) coaxially traverses the length of the chamber serving as the transfer line from the LC column as well as the vaporization cavity. The outer surface of the capillary is in contact only with the vapor and liquid phase of the working fluid. The nickel chamber is heated with insulated resistance wire wrapped around and along the length of the chamber. A copper jacket between the resistance heater and the nickel chamber improves temperature uniformity of the nickel chamber and provides additional thermal ballast for the working fluid.

The vaporizer is currently interfaced with a TAGA 6000E tandem mass spectrometer. The vaporized LC eluent is diluted with 10-30 liters/minute of laboratory air prior to ionization at atmospheric pressure. A 22 mm o.d. glass transfer line carries the diluted vapor to the point of ionization. The glass transfer interface is wrapped with heat tape. Since vaporization is virtually complete prior to dilution with air, the transfer interface to the TAGA APCI source is maintained at sufficient temperature to prevent cold spots which may result in solute or solvent condensation.

The vaporizer can readily accommodate fluctuations in eluent flow as well as water:methanol and water:acetonitrile gradients at constant operating temperature. The equilibrium vapor phase of the working fluid condenses predominately along the outer surface of that portion of the capillary containing liquid eluent, with little condensation (energy coupling) occurring along that portion of the capillary containing vapor. Gradients and flow fluctuations rapidly result in an increase or decrease of the effective region of working fluid condensation without any need to modify the temperature of the vaporizer.

The measured temperature at atmospheric pressure of the eluent vapor 2 mm beyond the exit of the capillary is shown in Figure 2 for 100% water at various flow rates as a function of working fluid temperature. A rise in eluent vapor temperature is observed following virtually complete vaporization within the capillary. The actual temperature of the eluent vapor may be slightly higher than that indicated in Figure 2 since the jet core near the exit of the capillary is less than 1 mm in diameter, and may contain entrained cooler air at the surface.

Figure 3 illustrates a negative ion LC/MS chromatogram obtained by selected ion monitoring on the TAGA from injection of 20 µl of a 50 ppm methanol solution containing the indicated explosives. The ions monitored were m/z 46 (NO₂⁻) and m/z 62 (NO₃⁻) resulting from apparent NCI autodetachment in the TAGA APCI ion source. The column used was a 6.3 mm Dupont Zorbax C-18 eluted with a water:methanol gradient at a flow rate of 1 ml/min from a Varian 5000 LC pumping system. The working fluid temperature was held constant at 160 °C throughout the analysis. Periodic fluctuations in the m/z 46 chromatogram suggest pump pulsing effects, however, evidence of pump pulsing effects on the interface are absent from the m/z 62 chromatogram.

Initial experiments with this vaporizer suggest that it provides a very efficient method of vaporizing aqueous LC eluent at conventional flow rates of 1 ml/min without exposing the vapor to excessive temperature. The vaporizer operates at constant temperature for isocratic or gradient elution. Further work is under development to improve sensitivity with the TAGA. Versions of the interface are under development for use with a Thermospray ion source as well as in a particle beam configuration.

Atmospheric Pressure Spray Ionization for Liquid Chromatography/Mass Spectrometry (LC/MS)

Minoru Sakairi and Hideki Kambara

Advanced Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185, Japan.

Liquid Chromatography/Mass Spectrometry (LC/MS) is one of the most important analytical methods, and various types of LC/MS systems have been reported. The authors have previously developed an atmospheric pressure ionization method for LC/MS, and have continued a study for an ionization technique suitable for LC/MS. During this study, we discovered a new ionization method, that is, atmospheric pressure spray (APS) method^{1,2)}. The ionization principle is shown in Figure 1. In this method, mobile phases containing samples at a flow rate of 1ml/min are nebulized into small droplets under atmospheric pressure by the capillary which is heated up to above 400°C. Produced droplets are introduced into a drift region located between two electrodes with apertures. A voltage can be applied to this region in order to break cluster ions. Generated ions in this region are brought to a mass analyzing region.

Although APS method is a kind of thermospray method operated under atmospheric pressure, obtained APS mass spectra and operating conditions are very different from those of thermospray method. The main characteristics of APS method are as follows:

(1) Cationized molecules can be obtained for nonvolatile compounds with high cation affinities, while protonated molecules for nonvolatile compounds with high proton affinities; (2) Intense molecular ion species can be observed with few fragment ions; (3) Highly sensitive detection can be achieved for saccharides and their related compounds; (4) APS method combined with a collision induced dissociation technique at the drift region can produce many fragment ions which are very useful for identification; (5) A good stability of ion intensities can be obtained.

Figure 2 shows an APS mass spectrum of globoside, which is one of glycolipids. Since the proton affinity of this compound is not so high, abundant protonated molecules cannot be observed. However, in APS method, intense cationized molecules resulting from the binding of cations and oxygen atoms of globoside can be observed. Figure 3 shows the result of a saccharide mixture analysis from soy bean containing glucose, sucrose, raffinose and stachyose. These results reveal that LC/MS using APS method is very promising as an ionization method for LC/MS.

SHEET DIRECT INSERTION MEMBRANE PROBE FOR SELECTIVE INTRODUCTION OF
ORGANIC COMPOUNDS INTO A MASS SPECTROMETER

M.E. Bier*, T. Kotiaho** and R.G. Cooks
Department of Chemistry, Purdue University, W. Lafayette, IN 47907

Membrane introduction mass spectrometry is a simple yet sensitive technique for monitoring volatile organic compounds in aqueous media. Membranes used in these inlets have typically been mounted outside the mass spectrometer, however, exterior mounting can lead to poor response times, memory effects, and analyte dilution due to transfer effects. To overcome these problems two different types of direct insertion membrane probes (DIMP) have been built. One probe uses a capillary membrane (C-DIMP) [1], the other a sheet membrane (S-DIMP) [2], and both allow the transfer of the liquid analyte solution directly to the heated ion source of a mass spectrometer. We present here, the S-DIMP and its performance.

A schematic of the S-DIMP is shown in Figure 1. The probe incorporates a sensor and heater for temperature control of the membrane interface. The membrane used in these studies was a dimethyl-vinyl-silicone polymer (ASTM: VMQ Dow Corning, thickness 0.254 mm). MS/MS data was acquired using a Finnigan TSQ-4500 mass spectrometer.

Knowledge of the effects of temperature, flow rate, and matrix are all essential for optimum use of the S-DIMP. Figure 2 shows the ion current from m/z 78 obtained from passing an aqueous solution containing 120 ppm benzene through the probe. At least a 10 fold increase in the m/z 78 ion current is observed due to the increase in permeation rate of benzene with temperature. The signal decreases near 100°C due to the vaporization of the solution at the probe tip which causes a dilution of the analyte. Working at higher solution/membrane temperatures, below the vaporization point, is thus preferred.

Optimization of flow rate is also important in obtaining high mass transfer. A continuous monitoring experiment shows a 25 % improvement in sensitivity of THF m/z 72 at 2.1 ml/min versus 0.6 ml/min while segmented flow analysis shows increased sensitivity at low flow rates.

The chemical matrix of the solution can also have an effect on the permeation rates, ionization efficiencies, memory effects, and membrane properties. The effects of matrix compounds on permeation rates and ionization efficiencies were studied using aqueous solutions of ethanol/acetoin (%/%). EI measurements for solution A (Figure 3a) (concentrations of ethanol/acetoin in solution A (%v) : 0.1/0.1, 0.5/0.5, 1/1, 5/5, 10/10) and CI measurements for solution B (concentrations of ethanol/acetoin in solution B (%v) : 0.1/10, 0.5/5, 1/1, 5/0.5, 10/0.1) show that at higher concentrations (5-10 % V), ethanol enhances the permeation rate of acetoin. However, the permeation rate of ethanol appears to be unaffected by ethanol. CI measurements for solution A (Figure 3b) show that the signal of both compounds in a mixture is lower at high concentrations than for pure solutions. This is attributed to high analyte partial pressures in the ion source causing insufficient protonation. Memory effects are most troublesome when analyte concentrations are low compared to concentrations of matrix compounds. Full membrane recovery between injections and excellent reproducibility for S-DIMP is shown in Figure 4.

Figure 5 shows a typical CI mass spectrum of *Bacillus polymyxa* fermentation broth. The main constituents of fermentation are identified as ethanol m/z 47, acetoin m/z 89 and 2,3 butanediol m/z 73 (MH-H₂O*) by comparison of their daughter spectra with standards.

As shown in Table 1, the S-DIMP has also proven to be a sensitive device for detecting volatile organics in aqueous environmental monitoring.

Our results show that the S-DIMP is a valuable device for reaction monitoring/control and environmental analysis since it allows on-line quantitation (ppb level) and identification of unknown compounds when used together with MS/MS.

Mass Spectral Determination of Pancuronium Bromide and Vecuronium Bromide in Biological Fluids Utilizing the Moving Belt LC/MS Interface.

Timothy B. Baker and Paul Vouros

Barnett Institute and Department of Chemistry, Northeastern University, 360 Huntington Avenue, Boston MA 02115

Jeevendra A. J. Martyn

Harvard Medical School, Massachusetts General Hospital, and Shriners Burn Center, Boston, MA 02114

Pancuronium bromide and vecuronium bromide are neuromuscular blocking agents used in anesthesiology in conjunction with general anesthetics. Accurate determination of these drugs in biological fluids is required for pharmacokinetic and pharmacodynamic studies.

Previously reported assays for these compounds and their deacetylated metabolites involve the use of TLC [1], HPLC [2], GC [3], and direct insertion probe mass spectrometry [4]. The objective of this work was to develop an assay for these compounds which could be characterized by improvements in specificity, sensitivity, and sample throughput.

This method is based on syringe application of sample extracts to the moving belt surface, thermal desorption, and single metastable transition monitoring in the chemical ionization mode. This thermal process results in dealkylation of the compounds to form a free base which is subsequently protonated via Cl. Compounds, such as pancuronium and vecuronium, that are thermally dealkylated to form the same free base have identical spectra and can not be distinguished.

The most abundant metastable ion in the B/E spectrum of pancuronium is a result of the loss of acetic acid from the protonated free base (ie m/z 543 $\rightarrow$ m/z 483). Monitoring this single metastable transition provides an added degree of specificity over single ion monitoring and eliminates chemical interferences that may occur in the assay. As an example, plasma extracts contain an interference at m/z 543 which can be eliminated by monitoring the metastable transition. The analogous acetic acid loss m/z 549 $\rightarrow$ m/z 486 is monitored for the hexadeuteriated internal standard.

The assay described here has been utilized to determine the rate of post-surgical clearance of pancuronium from the plasma of human patients who are suffering from traumatic burns.

The assay has also been used to determine post-operative levels of pancuronium in urine. An eight hour urine composite for a typical patient was found to contain 1.4 ug/ml of pancuronium.

The simultaneous analysis of the deacetylated metabolites can be performed via similar metastable transition monitoring. Mono-deacetyl analogs can be determined as a unit via monitoring of the transition m/z 416 $\rightarrow$ m/z 356. The bis-deacetyl metastable transition m/z 374 $\rightarrow$ m/z 356 has similar analytical utility.

Chemical ionization and B/E spectra of the drugs d-tubocurarine, metocurine, and gallamine have been obtained using the same conditions required for compounds of the pancuronium series. This indicates the potential for the use of this assay to determine other neuromuscular relaxers in biological fluids.

The methods described here will find utility in a continuation of this work which will utilize the demonstrated detection capabilities of this method in conjunction with an HPLC separation of these compounds.

Collision Induced Dissociation Studies of Transition Metal Oxide Clusters

Simin D. Maleknia, Jeremiah D. Hogan, David A. Laude, Jr, and Keith R. Pope*,
Department of Chemistry, University of Texas, Austin, TX 78712, *IBM 11400
Burnet Rd, Austin, TX 78758.

Introduction: The interest in transition metal oxides derives largely from their use as catalysts for the oxidation of olefins and other unsaturated molecules, and as semiconducting, dielectric or insulating materials in electronic applications. Selective ion mass spectrometric techniques such as tandem mass spectrometry or FTMS are well suited to the study of metal oxides in the gas phase, especially in conjunction with process environments where complex mixtures of ionic species must be analyzed. We present here preliminary results for the ion production, collisional activation, and ion dissociation of the metal oxide clusters, $(MO_3)_n$, $M=Mo, W$, where $n=1-13$ for $(MoO_3)_n$ and $n=1-8$ for $(WO_3)_n$.

Experimental: A Finnigan triple stage quadrupole mass spectrometer (TSQ-70) was operated in negative ion mode with 1200 mTorr argon source pressure, temperature of 800°C, and 1 mTorr collision cell with argon target gas. Fourier transform mass spectra were acquired on a Nicolet FTMS-2000 dual cell spectrometer with an argon source pressure of 5×10^{-6} Torr and an analyzer pressure of 2×10^{-8} Torr. Samples were applied to a platinum or rhenium filament from a methanol suspension, and ions were produced by increasing the filament current until sufficient signal intensity was obtained.

Discussion and Conclusions: Clusters to $n=13$ for $(MoO_3)_n$ and $n=8$ for $(WO_3)_n$ were observed to the upper mass limit of the TSQ spectrometer. A TSQ spectrum for MoO_3 is shown in Figure 1. The base peak in the spectra of both oxides was $(MO_3)_3$, while the monomer, MO_3 was barely observed. The intensities of the clusters for $n>3$ generally decreased with increasing mass, although different ionization and analyzing conditions yielded different relative abundances for MO_3 clusters. FTMS spectra acquired at a pressure 10^6 less than TSQ spectra exhibited only the dimer and trimer. A representative spectrum of MoO_3 is shown in Figure 2. The isotopic distribution patterns for the clusters were verified by comparison with calculated spectra of the same ions. The CAD behavior of the metal oxide clusters was also studied, and breakdown curves were generated from the TSQ spectra of $(MoO_3)_n$ in the 60-160 eV collision offset potential range. A dominant feature of the fragmentation pathway is loss of neutral trimer, as opposed to simple loss of monomer. This behavior suggests that the clusters have more complicated bond energetics than would be expected from loosely associated gas phase aggregates. The overall fragmentation scheme is shown in Figure 3.

CLUSTER ION FORMATION BY DIRECT LASER VAPORIZATION AND PARTICLE BOMBARDMENT

John H. Callahan, Mark M. Ross and Andrew P. Baronavski
Chemistry Division, Naval Research Laboratory, Washington, D.C. 20375-5000.

Two useful methods for the formation of cluster ions are direct laser vaporization (DLV) and particle bombardment (with keV ions or atoms). However, the effectiveness of these methods is highly dependent on the material from which ions are formed. For example, DLV of metals (1) seldom produces anything beyond atomic ions or small clusters. By contrast, particle bombardment can produce high mass cluster ions from either metals or salts (e.g. CsI)(2). The situation is largely reversed in the case of graphite. DLV can produce very high mass clusters ($n > 100$, where n is the number of atoms in the cluster)(3), whereas particle bombardment only produces small clusters (up to $n=5$). The work described here considers possible mechanisms of cluster ion formation based on mass spectrometric studies of ions produced by DLV and particle bombardment.

The materials used in these studies were either metal foils or pressed pellets of single- or multi-element powders. Ions were produced by DLV with a Nd:YAG laser (532 nm or 1064 nm, 50 mJoule/pulse) or by particle bombardment with 8 keV atoms or ions. Mass analysis was performed with a VG ZAB-2F double focussing magnetic sector instrument, a Finnigan TSQ-70 triple quadrupole mass spectrometer, or by a Naval Research Laboratory constructed time-of-flight (TOF) instrument. The latter employs a modified Wiley-McLaren source and a Mamyrin-type electrostatic mirror.

As noted by Freiser and co-workers (1), DLV of polished Ag produces only Ag^+ . By contrast, the FAB spectrum of Ag produces Ag_n^+ to at least $n=11$. The differences here may result from the fact that Ag does not strongly absorb visible light, and the resultant laser induced plasma does not contain sufficient ions and neutrals to allow significant cluster formation. By contrast, DLV of Ag pressed in a graphite pellet produced not only carbon cluster ions, but nearly equal abundances of Ag^+ , Ag_2^+ , and Ag_3^+ , as well as Ag_3C_2^+ and Ag_3C_4^+ (figure 1). These results indicate that the graphite matrix allows enough energy deposition to produce a fairly dense plasma, in turn allowing formation of large abundances of higher mass Ag clusters. Particle bombardment of Ag in graphite produced considerably lower intensities of higher mass Ag cluster ions (compared to Ag alone under similar beam fluence). This may be due to the fact that some of the kinetic energy of the particle must go into breaking carbon-carbon bonds. Unexpectedly, mixed AgC species such as Ag_3C_2^+ , Ag_5C_2^+ and Ag_5C_4^+ were observed in the particle bombardment spectrum. These species suggest that ion-molecule chemistry in the seldedge may play a role in the formation of clusters by particle bombardment. Similar results were observed for Ta in graphite. DLV of Ta in graphite produced clusters of the form Ta_xC_y^+ , where $x=1-8$ and $y=0-14$. The presence of mixed TaC species with large numbers of carbon atoms supports the hypothesis that ion-molecule reactions are important. With particle bombardment of Ta in graphite, two types of clusters were observed: Ta_xO_y^+ ($x=1-8, y=0-9$) and Ta_xC_y^+ ($x=1-8, y=1-5$). Oxides would be indicative of a direct emission mechanism. TaC clusters are not expected from direct emission processes, however, and their appearance supports a partial role for ion-molecule chemistry in the seldedge region.

The role of energy deposition and the formation mechanism of cluster ions may be reflected in their kinetic energies. The kinetic energies of cluster ions have been studied using the TOF instrument by varying the delay time between the ion formation pulse (either the laser or a pulsed ion beam) and the extraction pulse. Plots of the arrival time of the cluster ions in the extraction region can be generated and from this information (and the distance the ions travel between formation and extraction), kinetic energies can be estimated. For DLV, plots of the square of ion velocity vs. the inverse of cluster mass, which yield a slope which is proportional to kinetic energy, are generally linear with cluster size. Typical values obtained are 2-4 eV. This suggests that the cluster ions are all formed in a similar environment, consistent with the formation of a plasma. The measured kinetic energies indicate a plasma temperature in excess of 10^4 K. This value is somewhat larger than expected. However, evidence from DLV of graphite shows that cluster ions are not always

characterized by a uniform kinetic energy (figure 2). For example, small carbon cluster ions ($n=1-3$) are characterized by a kinetic energy of roughly 7-8 eV, while larger clusters have energies on the order of 3-4 eV. This suggests that some component of DLV cluster formation may be influenced by a direct emission process. Studies currently underway with sputtered species suggest that kinetic energies decrease with increasing cluster size, and are similar to those produced in DLV. This may indicate that larger clusters are formed by a different process than smaller clusters.

FTMS STUDIES OF CARBON CLUSTER ANIONS

Stephen W. McElvany
Chemistry Division / Code 6111
Naval Research Laboratory
Washington D.C. 20375-5000

The chemistry and physics of covalently-bonded metal and semiconductor cluster ions is an extremely active area of research (1). Carbon clusters have been one of the most widely studied systems to date. The reactivity of small positive carbon cluster ions, C_n^+ ($n = 3-30$), have been well characterized in our laboratory (2). Collision-induced dissociation (CID) and ion/molecule reaction studies have provided structural information on these cluster ions, suggesting a linear to cyclic transition between $n = 9$ and 10. Evidence for structural isomers of the $n = 7-9$ cluster ions has also been observed by differences in reactivity and structural analysis of the product ions formed. This study is a detailed investigation of the corresponding carbon cluster anions using Fourier transform mass spectrometry (FTMS).

The distribution of carbon cluster anions produced by direct laser vaporization (DLV) of graphite is shown in Figure 1. The C_n^- ions observed ($n \leq 13$) is considerably smaller than for C_n^+ under similar conditions ($n > 200$ with $n = 7, 11, 15...$ being most abundant). The enhancement of the even cluster anions (Figure 1) is consistent with their higher electron affinity (3). The C_n^- distribution observed using molecular beam (MB)/supersonic expansion sources, however, extends to much larger n (3,4). Thus, larger C_n^- are stable species but are not formed by DLV and/or detected in the FTMS.

The predominant fragmentation observed in low-energy CID is loss of neutral C_3 . This is also the major fragmentation observed for C_n^+ (2) and in the photodissociation of C_n^- (4). There is competition between electron detachment and fragmentation for the smaller cluster anions ($n < 6$), while fragmentation of the cluster anions dominates for larger n ($n > 6$). This is consistent with the increase in electron affinity of C_n^- with cluster size (3). In a related photodissociation study of C_n^- formed in a MB source (4), different behavior was observed in which photodetachment begins to compete with fragmentation as n increases up to $n = 13$, above which photodetachment occurs exclusively. This was attributed to the predominance of cyclic isomers for larger n which have lower electron affinities (3,4). The combination of the CID and photodissociation results suggest that the anions detected in the FTMS consist exclusively of the linear isomers. The cyclic isomers may be formed by DLV but do not survive the long time-scale of the FTMS due to their low electron affinity. This would explain the truncation of the C_n^- distribution at $n = 13$ observed by DLV/FTMS.

The ion/molecule reactions of C_n^- are also quite different than for the cluster cations. For example, C_n^- are unreactive with D_2 , O_2 and small hydrocarbons, which react readily with the corresponding cations. The ion/molecule reactions of C_n^- with the highly electronegative molecules F_2 , HCN and C_2N_2 have been studied. The variation in rate constants with cluster size is shown in Figure 2 for C_n^- with HCN and C_2N_2 and also C_n^+ with HCN for comparison. The C_n^- rates decrease with increasing cluster size (higher electron affinity). Also, there is no dramatic change in rate which would suggest a structural transition as was observed for C_n^+ between $n = 9$ and 10 (Figure 2). No evidence for C_n^- structural isomers formed by DLV was observed, in contrast to the C_n^+ isomers observed previously (2) and isomers of C_{11}^- formed in MB sources (3). Differences in the product ions formed for the even (e.g. $C_n CN^-$ with HCN) and odd (formation of $C_n HCN^-$) carbon cluster anions suggest alternating cumulene (odd n) and polyacetylene (even n) structures for these species. Another difference between the cation and anion cluster reactions is the many higher-order reactions observed for the anions. For example, solvation with HCN occurs with the primary product ions $C_n CN^-$ to yield $C_n CN(HCN)_3^-$. CID results suggest that these HCN molecules are hydrogen bonded to the anion. Structural isomers of the product ion ($C_5(C_2N_2)^-$) formed in the reaction of C_5^- with C_2N_2 were detected by their reactivity: 79% of the product ions are reactive to

yield $C_5(C_2N_2)_2^-$ and 29% are completely unreactive. This behavior may be explained by the rearrangement of the postulated carbene insertion structure:

to a structure which contains no reactive carbene site.

Numerous processes employ metal oxides as catalysts for hydrocarbon oxidation. In particular, molybdenum and cobalt oxides are commonly used as industrial catalysts. Oxygen atom transfer involving oxometal groups (M-O) is a prominent mechanistic feature in these reactions. In order to gain insight into the intrinsic features of these reactions, ion/molecule reactions of cobalt and molybdenum oxide cluster ions with simple hydrocarbons have been investigated by Fourier transform mass spectrometry (FTMS). In addition, low-energy collision-induced dissociation (CID) has been employed to provide structural information.

Metal oxide cluster ions were produced by direct laser vaporization (DLV) of metal oxide pressed pellets (CoO , Co_3O_4 , CoMoO_4 , MoO_2 , MoO_3) using the 532 nm output of a Nd:YAG laser. DLV was found to be a convenient method for producing metal oxide cluster ions. Co^+ dominated the positive ion DLV spectra of CoO and Co_3O_4 , however Co_3O_4 also produced CoO^+ , Co_2^+ , and Co_2O^+ at levels sufficient for further study. The negative ion DLV spectra of both cobalt oxides (Figure 1) yielded CoO_2^- in greatest abundance, followed by Co_xO_x^- and $\text{Co}_x\text{O}_{x\pm 1}^-$, $x=1-10$. Changes in sample stoichiometry had minimal effects on cluster anion distribution, aside from the minor variations in oxygen enrichment or deficiency for ions with five or more cobalt atoms. Positive ion DLV on MoO_2 and MoO_3 yielded primarily Mo^+ , MoO^+ , and MoO_2^+ . DLV on MoO_3 also produced abundant $\text{Mo}_x\text{O}_{3x}^-$ ($x=1-4$), while MoO_2 produced predominantly $\text{Mo}_x\text{O}_{3x}^-$ ($x=1-4$) with minor amounts of $\text{Mo}_x\text{O}_{3x-1}^-$ and $\text{Mo}_x\text{O}_{3x-2}^-$ (Figure 2). Molybdenum-containing ions dominated the DLV spectra of CoMoO_4 , with some low abundance mixed metal oxide anion formation.

Small Co_xO_y^+ and Mo_xO_y^+ ($x=1,2$) yield M^+ and MO^+ under low-energy CID. Co_xO_y^- readily dissociate to produce the same anions which are most abundant in the DLV spectra (and are presumably the most stable species). In contrast, $\text{Mo}_x\text{O}_{3x}^-$ undergo little or no low-energy CID.

Ion/molecule reaction studies centered around $\text{C}_1\text{-C}_3$ hydrocarbons. No metal oxide anions were observed to react, with the exception of Co_2O_2^- which yielded the stable CoO_2^- as a major product in reactions with ethene and propene. The addition of oxo ligands increased the reactivity of Co^+ , Co_2^+ , and Mo^+ . The relatively weak $\text{Co}^+\text{-O}$ bond (84 kcal/mole (1)) is cleaved extensively during the reactions of Co_xO_y^+ with small hydrocarbons. Similar behavior has been previously reported in the reactions of FeO^+ (2) and CrO^+ (3) with hydrocarbons. Oxidative addition into C-H bonds dominates the Co_xO_y^+ reactions. Evidence exists for hydrocarbon oxidation, particularly in the reactions of Co_2O_2^+ with alkenes. In contrast, MoO_y^+ ($y=1,2$) reactions with $\text{C}_1\text{-C}_3$ hydrocarbons involve primarily dehydrogenation, with no oxygen incorporation into hydrocarbon ligands bound to the metal. The $\text{Mo}^+\text{-O}$ and $\text{Mo(O)}^+\text{-O}$ bonds are equally strong at 114 kcal/mole (1) and are rarely cleaved in these processes.

STABILITY AND REACTIVITY OF BISMUTH CLUSTER IONS

M.M. Ross, V.H. Wysocki and S.W. McElvany

Washington, D.C. 20375-5000

The study of clusters is important for an enhanced understanding of the nature of matter while having application in areas such as catalysis and development of new alloy materials. The characterization of cluster ions involves formation, mass-selection and either collision-induced dissociation or ion/molecule reaction. In this way some insight is gained into the structures, stabilities and reactivities of gas-phase cluster ions. The focus of this work is on clusters of the main group "semi-metal" bismuth. Both homogeneous bismuth clusters and heteroclusters of bismuth and antimony were studied. In addition to determination of cluster stabilities, the rates and products of cluster oxidation were measured, in order to compare with known condensed phase properties.

Cluster ions of bismuth (Bi_x^+) and of bismuth antimonide (Bi_xSb_y^+) were formed by sputtering (SIMS) in a triple quadrupole (TQMS) and sector (ZAB) mass spectrometers and by direct laser vaporization (DLV) in an FTMS. The details of bismuth cluster ion production by these methods are published [1]. This previous work revealed that the Bi_x^+ distribution has enhanced abundances at $x=3,5,7,10$ and 13 and anomalously low abundances at $x=6,9$ and 12, for $x=2$ to 14. The extent of unimolecular dissociation of each bismuth cluster ion was measured, and the aforementioned more abundant species showed less decomposition relative to that of the less abundant cluster ions in the distribution. The anomalies must arise from different cluster stabilities and, therefore, different rates of unimolecular decomposition.

The abundance distribution of Bi_xSb_y^+ heterocluster ions showed anomalies at the same cluster sizes as in the homogeneous cluster distribution, indicating that the cluster stability is determined by the number of atoms. Experiments with the FTMS were directed toward distinguishing between heterocluster ions formed by DLV (Figure 1) and neutrals (ionized by EI) produced in the laser-generated plasma (Figure 2). In addition to enhancement of the trimer species (as in the homogeneous cluster distribution), clusters with $(x+y)$ up to 5 are observed by DLV in Fig. 1 while the neutrals in Fig. 2 extend to only $(x+y)=4$. It is interesting to note that the two spectra are complementary in that the abundant species in one are nearly absent in the other. The Bi-containing heterocluster ions dominate the DLV spectrum in Fig. 1 because of lower ionization potentials while Sb-containing species are the more stable neutrals. This tendency is reflected in the products of dissociations of the heterocluster ions, where there are mostly Bi-containing fragment ions and Sb-containing neutrals lost. The heterocluster ion dissociations are characterized by production of a stable, odd-numbered cluster ion and loss of an atom, dimer or tetramer, as is the case for the homogeneous cluster ions [1].

The characteristics of cluster oxidation were investigated by (1) sputtering Bi_2O_3 , (2) oxidation of Bi_x^+ with NO_2 and (3) dissociation of Bi_xO_y^+ . Certain preferred Bi_xO_y^+ are formed by (1) and/or (2), with $(x,y)=(3,4)$, $(5,7)$ and $(7,10)$ for odd x and $(4,5)$ and $(6,8)$ for even x . In both sets, each ion arises from addition of Bi_2O_3 to the preceding species. The rates of oxidation by NO_2 for Bi_x^+ , $x=1$ to 5, are shown in Figure 3. The even-numbered cluster ions react 50 times faster than the odd-numbered species, and this is consistent with the greater stability of the latter cluster ions.

The dissociations of Bi_xO_y^+ consist of loss of Bi or BiO from the lower-oxidized species (number of O < number of Bi) and loss of BiO or Bi_2O_3 from the fully-oxidized clusters, which yield the next most stable oxide (e.g. $\text{Bi}_5\text{O}_7^+ \rightarrow \text{Bi}_3\text{O}_4^+ + \text{Bi}_2\text{O}_3$). The stable neutral Bi_2O_3 (and Bi_4O_6) represent the base units of bulk bismuth oxide. The structure of Bi_3O_4 , to which most of the oxides dissociate, most likely has a cyclic structure with bridging oxygen bonds, which would account for the enhanced stability. Such tetrahedral structures are well-known for other Group Va oxides (e.g. P_4O_6).

FORMATION AND STRUCTURE OF OXO-METAL CLUSTERS IN THE
FAST-ATOM-BOMBARDMENT OF SIMPLE SALTS OF U, Eu AND RELATED METALS

Keith R Jennings, Terence J Kemp and Paul A Read
University of Warwick, Department of Chemistry,
COVENTRY CV4 7AL, U.K.

Introduction

The fast atom bombardment (FAB) positive ion mass spectrum of uranyl nitrate hexahydrate in aqueous solution contains a series of peaks of considerable intensity above the molecular ion peak. These singly-charged positive ions have the stoichiometry $[(UO_2)_xO_y]^+$ where y has values of -1 to 6 and ions of masses corresponding to x = 1 up to 14 have been observed. As the value of x increases, the intensities of the peaks in each cluster decrease, rapidly up to x = 4 and more gradually at higher values, and the most intense peak within a cluster occurs at higher values of y. This presumably reflects the need for a greater number of oxygen atoms to stabilise higher mass ions. For example, when x = 4, the most abundant ion is $[(UO_2)_4O]^+$, m/z 1096, whereas when x = 8, the dominant species is $[(UO_2)_8O_4]^+$, m/z 2224. (Fig. 1).

These clusters were observed when the salt was dissolved in a variety of solvents, including involatile solvents such as sulpholane, and under different conditions of pH etc., leading to moderate changes in relative intensities within a cluster. Similar spectra were also observed using continuous flow FAB (dilute aqueous solution) and a single crystal of uranyl nitrate hexahydrate.

Spectra obtained using Single Crystals of Uranyl Nitrate Hexahydrate

Although spectra given by crystals initially closely resembled those given by solutions of the salt, the relative intensities of the less oxygenated species, e.g. $[(UO_2)_{x-1}(UO)]^+$ increase with time. This presumably results from the loss of lattice water of crystallisation since on removal from the mass spectrometer, the sample showed no sign of melting or loss of crystallinity.

Solvent & Concentration Effects

The relative intensities of peaks in observed spectra were essentially independent of concentration variation over the range 10^{-4} to 10^{-1} mol dm⁻³ in water,

sulpholane, acetonitrile, dimethyl sulphoxide or 0.1 mol dm^{-3} nitric acid, with the exception that the peak at $m/z = 326$ was rather more prominent at the lowest concentrations. The changes in absolute intensities of all ions with concentration in water and 0.1 mol dm^{-3} nitric acid show two linear regions, a rapid rise at low concentrations followed by a more gradual rise at higher concentrations. In each case, however, the behaviour changed in the region of 0.01 mol dm^{-3} of UO_2^+ ions, and this may reflect a change in the extent of ionic aggregation in solution. Although the behaviour in 0.1 mol dm^{-3} acid in the region of 0.01 mol dm^{-3} UO_2^+ differs somewhat, presumably due to the increased participation of protonated species in ionic equilibria in solution, no additional ionic species were observed in the spectra of samples made up with a pH within the range 0.1 - 1.6. Preliminary studies have also been made of the corresponding europium nitrate FAB spectrum which shows similar behaviour, similar species have also been reported by Kahwa et al¹.

FORMATION OF CARBON CLUSTER IONS FROM LASER ABLATION OF POLYMERS

William R. Creasy and J. T. Brenna
IBM Corp. (T43), Box 8003, Endicott, NY 13760

Many recent studies have examined the structures and reactivities of high mass even-numbered carbon cluster neutrals and ions (1), usually referred to as fullerenes. These species have been suggested to be important in systems involving flame and space chemistry (2). Most studies have emphasized the formation of fullerenes from ablation of graphite, although fullerenes have been observed by ablation of some polymers (3). These studies do not provide much information about fullerene formation in the presence of large amounts of hydrogen or heteroatoms, including reactive radicals, which could interfere with the formation of purely carbon-containing species. This lack of information limits the relevance of studies of fullerenes to problems such as soot formation.

We have observed that three very different types of materials produce fullerene ions by laser ablation (4). These materials are in addition to ablation of polyimide, which has been discussed previously (5). These materials illustrate the range of conditions under which fullerenes form.

Ions are formed by laser ablation with 266 nm radiation from a Nd:YAG laser (fourth harmonic), and are detected by Fourier transform ion cyclotron resonance mass spectrometry (Nicolet FTMS/2000). The IBM laser microprobe system, described previously (6), was used to position the sample and examine it via a light microscope.

The first polymer which was studied is a copolymer of ethylene and tetrafluoroethylene (ETFE, sold as Dupont Tefzel[®]), which is a saturated hydrofluoropolymer. The laser is observed to decompose the surface of the polymer to form a blackened layer, probably liberating HF. For the first 50-70 laser pulses near threshold power density, a fullerene distribution is observed. A sample mass spectrum is shown in Figure 1. With more laser pulses on a spot or higher power density, a low mass distribution is observed. Work is in progress to characterize the modified surface using Raman spectroscopy (7). These results may indicate the range of conditions of the modified surface for which fullerene formation is favorable.

Figure 1: Positive ion mass spectrum of laser ablation of ETFE, averaging the first fifty laser pulses.

Another polymer for which fullerene ions are observed is polyphenylene sulfide (PPS). The fullerene distribution is observed initially, and extends above m/e 4000 amu and has a smaller m/e 720 peak than the ETFE spectrum. As the polymer blackens a lower mass distribution is observed, which is more useful analytically (8).

Finally, the ablation of a diamond-like carbon film also gives a fullerene distribution, which has a mass range intermediate between ETFE and PPS. The film is 40 nm thick and was determined to contain 10 at.% hydrogen. Ablation with one laser pulse of a thickness of approximately 20 nm produces a fullerene spectrum. Of the samples studied, this is the smallest quantity of ablated material for which fullerenes are formed. Since only one pulse is used and the film is very thin, surface formation of the fullerenes is very unlikely and gas-phase condensation of the ablation fragments to form the carbon clusters is the only reasonable mechanism of formation.

For all the spectra, comparisons were made to a reference fullerene distribution from ablation of graphite. There is <1-2 amu difference in the fullerene peak masses between the graphite spectrum and the sample spectra, and the spacing between the peaks is 24.0 amu (4). Therefore, the fullerenes never incorporate significant amounts of H or heteroatoms.

The most significant result from the study of these materials is that fullerenes can form in laser ablation plasmas in the presence of hydrogen and heteroatoms such as F, S, O, and N or reactive species containing them such as CN and HF. In addition, the heteroatoms are not incorporated in detectable levels. This evidence indicates that fullerenes may be able to form in real systems which do not consist of pure carbon plasmas. This conclusion is consistent with an observation of even carbon cluster ions in flames (9).

The formation in these different systems suggests that there may be a common mechanism involved. However, the mechanism may only occur for a limited range of plasma conditions, as illustrated by the ETFE results and the fact that fullerenes are not observed for most polymer ablation (8). Studies of laser ablation of other samples, such as DLC films with a range of hydrogen concentrations, may help to delineate the range of conditions. The mass range of the fullerene distribution may also indicate the kinetics of formation in the plasma. The resolution of these questions is potentially a fruitful area of study.

TANTALUM CARBIDE CLUSTER IONS: PRODUCTION, DISSOCIATION AND REACTIVITY

Carolyn J. Cassady and Stephen W. McElvany
Chemistry Division / Code 6111
Naval Research Laboratory
Washington D.C. 20375-5000

As an extension to our studies of carbon cluster ions (1), the formation, collision-induced dissociation (CID) and ion/molecule reactions of metal carbide cluster ions ($M_xC_y^+$) have been investigated using Fourier transform mass spectrometry (FTMS). Numerous studies using Knudsen effusion mass spectrometry have shown that the early transition metals most readily form M_xC_y species, typically with enhanced abundances for $y = 2$ and 4 (2). In this study, direct laser vaporization (DLV) (1-5 mJ/pulse, 532 nm) of solid samples containing tantalum and carbon were used to produce $Ta_xC_y^+$. Tantalum was chosen because it is monoisotopic and the $Ta_xC_y^+$ species produced are higher in mass ($m/z > 180$) than the abundant carbon cluster ions (C_n^+ , $n < 15$) also produced in the vaporization process.

PRODUCTION

The ion distributions for TaC_y^+ produced from different samples are shown in Figure 1. Both Ta/graphite and Ta/amorphous carbon samples produce TaC_y^+ with up to $y = 14$. Also, Ta/amorphous carbon mixture produces more abundant TaC_y^+ than the graphite-containing sample. Larger $Ta_xC_y^+$ with $x = 1-8$ and $y = 1-14$ are also produced by DLV. In contrast, DLV of bulk tantalum carbide (TaC, Figure 1) only produces TaC_y^+ with $y \leq 5$ in low abundance. This suggests that the large TaC_y^+ ions are formed by reactions of Ta and carbon species in the laser-generated plasma. In addition, the enhanced abundance for $y = 2$ and 4 (Figure 1) is consistent with the effusion mass spectrometry studies (2). Further evidence for the reactions in the plasma were obtained using labeled carbon. DLV of a 1:1 molar TaC/ ^{13}C amorphous carbon sample produces predominantly ($> 80\%$) $Ta^{13}C_y^+$ (i.e., with no ^{12}C from the bulk TaC). This is illustrated in Figure 2, where both the statistical and experimentally observed isotopic combinations for TaC_5^+ are shown.

DISSOCIATION

Low-energy CID of TaC_y^+ results in fragmentation by loss of neutral C_n species due to the higher ionization potentials of C_n (9-11 eV). For $y < 5$, the major fragmentation is loss of C_y to form Ta^+ . For larger TaC_y^+ , however, C_3 and C_{10} loss are the observed fragmentation channels. Neutral C_3 loss is also observed in the CID of C_y^+ and is predicted to be the lowest energy process (1). The loss of C_{10} for $y \geq 10$ is intriguing since the transition from linear to cyclic structures for neutral and ionic carbon clusters occurs between $n = 9$ and 10 . Thus, the TaC_y^+ species with $y \geq 10$ may have metallocene structures. Preliminary CID studies of $Ta_2C_y^+$ suggest the presence of bridging carbido ligands, e.g. Ta-C-Ta.

REACTIONS

The ion/molecule reactions of TaC_y^+ ($y = 0-14$) have been studied with D_2 , NO and C_1 and C_2 hydrocarbons. In general, TaC_y^+ reactions are quite different than the previously studied C_n^+ reactions (1), suggesting that the reactions are initiated at the metal ion center. The hydrocarbon reactions usually involve extensive and sequential dehydrogenation which is typical for the early transition metal ions. The carbon ligand in the TaC_y^+ reactions plays an active role in the ion/molecule reactions as shown in reaction 1 for CH_4 .

Labelled experiments with $^{13}\text{CH}_4$ have shown that this reaction channel to lose C_2H_2 results in total scrambling of all the carbons ($y+1$) in the reaction intermediate. This behavior is quite surprising and suggests the presence for both mobile hydrogens and possibly a metallacyclic intermediate in the reaction.

SAMPLE INTRODUCTION CHARACTERISTICS OF FLOW INJECTION WITH ICP-MS

Guangxuan Zhu*, Changkang Pan and Richard F. Browner, School of Chemistry, Georgia Institute of Technology, Atlanta, GA, 30332-0400

ICP-MS provides multi-elemental information, excellent detection limits, simple spectra and isotope ratio values. Sample introduction systems for ICP-MS typically employ pneumatic nebulization. There is currently great interest in the development of novel sample methodology for ICP-MS. Flow injection has emerged as a powerful and adaptable method of sample introduction for ICP-MS in the last few years. Flow injection(FI) allows rapid introduction of small volume samples with reduced interference, and makes possible sample introduction for different sample types, simple dilution, matrix modification and standard calibration. However, with ICP-MS, the major problem for interfacing FI derives from limitations in coupling the sample introduction system.

In this study a flow injection apparatus was connected to a Perkin-Elmer Sciex Elan ICP-MS system, where the ICP-MS acts as a multi-elemental detector for the flow injection system. Figure 1 is a schematic diagram of FI-ICP-MS system used in this work. Li, Co, Ba and Pb were the elements selected as models for investigation of sample introduction characteristics of FI-ICP-MS. The concentration for each element was in the range of 10 to 1000 ppb. These 4 elements covered a wide range of masses from 7 to 208. A Scott spray chamber with a coolant sleeve was used for organic sample introduction. When organic samples were introduced, the organic solvent vapor was condensed at 0 °C by the coolant sleeve. The ICP/MS operation parameter was set in multielement mode. The data obtained was transferred to a IBM PC/AT computer.

Figure 1. Schematic diagram of flow injection with ICP/MS.

Figure 2. Peak integral responses vs. concentration of elements.

sample concentration for all selected elements, as shown in Fig. 2.

By carefully coupling the FI system with the ICP/MS, the sample injection system does not change the ICP/MS configuration. Optimum nebulizer flow rate remains the same as it used in normal conventional aspiration. For all the elements chosen in this study, the nebulizer flow is 0.9 - 0.95 L/min. The operating parameters can also be optimized independently, in the range as desired. One of the most important features of FI-ICP-MS is that the system requires only a small volume, typically 20 μ l to 100 μ l. This would be inadequate for a standard ICP/MS measurement with conventional nebulization. Both peak heights and the peak integral were used for quantitative analysis. It is observed, from the results obtained with Li, Co, Ba and Pb at various sample loop and liquid uptake flows, that peak area integral show a good linear response with

The combination of flow injection with ICP-MS provides an efficient sampling technique to ICP-MS with several important advantages. It readily allows operation with various types of sample solutions, such as samples with high content salt or organic samples. Fig. 3 shows a typical comparison of the salt effect resulting from a solution with high concentration of sodium by ICP/MS with conventional nebulization and FI-ICP-MS. It is clear that, in normal ICP/MS mode, samples with high content of salt will interfere with the performance of the ICP/MS, including altering plasma status, and it is difficult to recover the sensitivity of the instrument. After introducing a sample with 2000 to 5000 ppm Na for about 20 minutes, the sensitivity dropped rapidly (Fig. 3-A), the plasma status changed and the sensitivity can not be recovered. But with FI-ICP-MS, as shown in Fig. 3-B, it is possible to tolerate such types of sample solutions. In this study some experiments were also made using organic solvents. The mixtures of water/acetone and water/methanol in ratio from 100:0 to 0:100 were injected using the FI-ICP-MS system. It is interesting to observe that signal response increases when organic samples are introduced. This may be due to the evaporation of organic solvent from the aerosol droplets. Preliminary results indicate that organic samples can potentially be analyzed directly by FI-ICP-MS.

Figure 3. Influence of high content of sodium on signals. (A) Normal conventional nebulization; (B) FI-ICP-MS.

Flow injection was carried out at several sample dispersions. Dispersion may be optimized with various operating parameters, such as sample volume, sample flow rate and carrier flow rate. Signal transient time is dependent on the uptake flow rate. Memory effects in FI-ICP-MS are minimized principally through the role of exponential dilution, $C_t = C_0 \cdot \exp\{-ut/V\}$, where C_0 is the initial concentration estimated at the outlet of spray chamber, u is nebulizer flow rate, V is spray chamber volume, t is time, C_t is the concentration at the time "t". By careful choice of parameters, return to baseline may be achieved only 25 seconds after reaching the peak signal. This allows FI-ICP-MS to achieve rapid sample throughput, without loss of accuracy. To date, studies have shown great promise using synthetic mixtures. The real test of the system will, however, require the use of samples of diverse matrix configuration. Such work is currently underway.

INTRODUCTION: Complexes of the type $\text{Ru}^{\text{II}}(\text{bpy})_2\text{L}(\text{PF}_6)$ were investigated using fast-atom bombardment tandem mass spectrometry. The ligands are various types of polyaza compounds being investigated to determine the structure and conformation of various ruthenium complexes depending upon ligand denticity and geometry. The low energy collision-induced dissociation (CID) spectra provide confirmation of the structures and details about fragmentations of the complexes. Doubly charged ruthenium complex mass spectra ions were observed arising from a nitrobenzylalcohol matrix and were collisionally dissociated.

EXPERIMENTAL: Fast-atom bombardment (FAB) was used to obtain the mass spectra of the ruthenium complexes. An energetic beam of 8 keV xenon atoms was used to desorb the sample from a nitrobenzylalcohol (NBA) matrix. A VG 70-SEQ tandem mass spectrometer was used to analyze the samples and obtain the low energy CID mass spectra. The collision gas (argon) pressure was adjusted to reduce the primary ruthenium complex ion intensity to 40-50 percent of the original intensity. The collision energy of the ions was adjusted to range from 20 - 50 eV (laboratory coordinates).

RESULTS AND DISCUSSION: The FAB mass spectrum of $[\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})_2)(\text{PF}_6)_2]$ (bdmt = 3,3',5,3"-bis(dimethylene)-2,2':6,2"-terpyridine; bpy = 2,2'-bipyridine) is shown in Fig. 1. Examination of the isotope cluster at m/z 699 in the mass spectrum in Fig. 1 reveals that the following ions are formed $[\text{Ru}^{\text{II}}\text{bdmt}(\text{bpy})_2]^+$ and $[\text{Ru}^{\text{II}}\text{bdmt}(\text{bpy})_2\text{H}]^+$. The formation of $[\text{Ru}^{\text{II}}\text{bdmt}(\text{bpy})_2]^+$ presumably arises from a reduction during the sputtering process. Abundant doubly charged ions were observed in the mass spectrum. The CID of $^{102}\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})_2)^{2+}$ is shown in Fig. 2.

Fig. 1: FAB of $[\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})_2)(\text{PF}_6)_2]$

Fig. 2: CID of $^{102}\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})_2)^{2+}$

The loss of a bipyridine and a PF_5 could result in a fluoride transfer to a vacant site on the metal center (Fig. 3). The CID of $^{102}\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})\text{F})^+$ (Fig. 4) shows the loss of a bipyridine ligand as well as the loss of HF, leaving the ruthenium still with a formal oxidation state of +2.

Fig. 3: CID of $^{102}\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})_2)(\text{PF}_6)^+$

Fig. 4: CID of $^{102}\text{Ru}^{\text{II}}(\text{bdmt}(\text{bpy})\text{F})^+$

The complex $[\text{Ru}^{\text{II}}(\text{tpy})(\text{tpd})](\text{PF}_6)_2$ (tbd = 2,3,5,6-tetrapyridyl-1,4-diazine) has two pendant pyridyl groups and therefore would be expected to undergo the losses of these groups via a simple C-C bond cleavage. These losses were observed in both the FAB and CID spectra (Fig. 5). It was suspected that the terpyridine was bidentate (like

$[\text{Ru}^{\text{II}}(\text{bdmt})(\text{bpy})_2](\text{PF}_6)_2$ and therefore had a pendant pyridyl group. Examination of the FAB mass spectra (Fig. 6) revealed the loss of 79 ($\text{C}_5\text{H}_5\text{N}$) from m/z 647 and this was observed in the CID spectrum as well. Proton NMR studies of $[\text{Ru}^{\text{II}}(\text{tby})(\text{d-bpy})_2](\text{PF}_6)_2$ has confirmed that the terpyridine is bidentate. The FAB mass spectra of $[\text{Ru}^{\text{II}}(\text{tpy})(\text{tpd})](\text{PF}_6)_2$ shows the following ions. The CID spectrum of $[\text{Ru}^{\text{II}}(\text{tpy})(\text{tpd})-\text{H}]^+$ shown in Fig. 5 shows the loss of one and two pyridyl groups as well as the loss of terpyridine and one and two peridyl groups. The FAB mass spectra of $[\text{Ru}^{\text{II}}(\text{tpy})(\text{bpy})_2](\text{PF}_6)_2$ shows the following ions. The CID spectrum of $[\text{Ru}^{\text{II}}(\text{tpy})(\text{bpy})_2]^+$ (m/z 647) shown in Fig. 6 shows the loss of a pyridyl group as well as the loss of a bipyridine and a terpyridine. The predominant loss of a bipyridine suggests that terpyridine becomes tridentate and hence becomes more tightly bound.

Fig. 6: The CID spectrum of $[\text{Ru}^{\text{II}}(\text{tpy})(\text{bpy})_2]^+$

SUMMARY: The highest mass peak observed for these ions corresponded to $[\text{Ru}^{\text{II}}(\text{L})(\text{bpy})_2(\text{PF}_6)]^+$. The predominant fragment ions in the CID spectra correspond to losses of intact ligands and PF_6 . An F^- transfer was observed from the PF_6 counter ion to the metal when the ruthenium complex became less than six-coordinate. Low-energy CID of the doubly charged ions was observed to yield the simple loss of intact ligands.

ACKNOWLEDGEMENTS: We thank Dr. R. P. Thummel (UH) for kindly providing the ruthenium complexes. The Robert A. Welch Foundation is acknowledged for support of this work.

PURITY OF 1% SiH₄ AND 1% SiCl₂H₂ IN H₂:
RELATION TO DEPOSITED FILM PURITY

William D. Reents, Jr., Martin L. Green, and Dan Brasen
AT&T Bell Laboratories
600 Mountain Avenue
Murray Hill, New Jersey 07974

An analytical technique has been developed, based upon a Fourier transform mass spectrometer, to evaluate the purity of 1% SiH₄ and 1% SiCl₂H₂ in H₂. The gas is introduced into the mass spectrometer via clean stainless steel lines and a variable leak valve. Chemical ionization using the hydrogen in the sample produces simplified mass spectra. The impurities are identified by accurate mass measurement of the detected ions and knowledge of the chemistry involved to produce the ions. Impurities are quantified by the formation rate of their corresponding ions rather than by standard addition techniques. Concentrations of exotic or unstable (in pure form) components are determined. Total oxygen in the gases varies from 20 ppm in clean SiH₄ samples to 4400 ppm in dirty SiCl₂H₂ samples. These concentrations translate into 0.2% to 44% oxygen relative to silicon on a per atom basis. Likewise, carbon content varied from <1 ppm to 200 ppm which translates into <0.01% to 2% carbon relative to silicon. Table I summarizes the results for 10 gas samples analyzed. Oxygen contamination was primarily due to siloxanes in silane samples or chlorinated siloxanes in dichlorosilane samples. Carbon was present in a variety of forms, including hydrocarbons, methylsiloxanes, carbon monoxide and carbon dioxide.

The oxygen and carbon content of films deposited from these gases are evaluated by SIMS for comparison with the gas purities measured. The films were deposited by Rapid Thermal Chemical Vapor Deposition (RTCVD) at substrate temperatures of 550°C to 900°C. Incorporation of carbon and oxygen into the films varies from near stoichiometric at 550°C to weakly dependent or independent of gas composition at 900°C. Although the best quality films are grown at the highest temperatures, low temperature film growth is desirable for applications where minimal diffusion is required. It is clear that gas purity is an important parameter for obtaining consistent, high quality films at lower temperatures.

TABLE I

OXYGEN AND CARBON CONTENT OF
1% SiCl₂H₂ AND 1% SiH₄ IN H₂

Sample	Concentration Relative to Silicon (atomic ppm)		Sample	Concentration Relative to Silicon (atomic ppm)

APPLYING THE CONCERTED ISOTOPE PATTERN - EXACT MASS METHOD OF ESTABLISHING ELEMENTAL COMPOSITION

Karl F. Blom and Jeffrey G. Cummiskey
E. I. du Pont de Nemours & Co.
Medical Products Department
Experimental Station
P.O. Box 80336
Wilmington, DE 19880-0336

The purpose of this presentation is threefold:

- I. to characterize the useful limits of the CONCERTED method of analysis
- II. to develop routine instrumental strategies for acquiring the isotope data
- III. to present software for performing a CONCERTED analysis of exact mass and isotope pattern data.

I. Three factors dictate the useful limits of all mass spectrometric methods for determining elemental composition:

1. the number of different elements comprising the analyte
2. the number of occurrences of the elements (i.e., the size of the compound)
3. the accuracy and precision of the mass spectral data

Figs 1 and 2 show the number of matches found with an exact mass analysis and a CONCERTED analysis as the number of different elements is increased and as the size of the sample is increased (while the other factors are held "constant"). For those compositions containing > 6 elements or having M.W. > 800 amu the specificity of the exact mass analysis decreases rapidly and becomes problematic while that for the CONCERTED analysis is significantly better (improvements range between 10 and 30 fold). In even more difficult cases (> 7 elements or M.W. > 1600 amu) the specificity of the CONCERTED method also begins to deteriorate rapidly. Thus, the CONCERTED approach may be of greatest utility for the analysis of compounds containing 6 or 7 different elements and having M.W. between 800 and 1600 amu.

Fig. 1 Average Number of Matches vs Number of Elements for Compositions from $C_{20}H_{40}$ ($N_2 O_2 S_2 Si_2 F_2 Cl_2$)

Fig. 2 Number of Matches vs n (Number of Occurrences) for $C_n H_1 S_n N_0.3n O_0.3n Si_0.1n$

Fig 3 demonstrates how the number of matches found with a CONCERTED analysis depends on the precision of the isotope pattern moment data. Even poor isotope data can give significant improvements in specificity (a CONCERTED analysis using isotope data with a precision of $\pm 10\%$ produces 12 matches for the 7 element example while the exact mass analysis produces 65, see fig 1). The number of matches decreases monotonically with increasing precision. There are no clear breaks in the dependence; the selectivity continues to improve with increasing precision of the isotope data even at precisions of better than $\pm 1\%$.

Fig. 3 Average Number of Matches vs Deviation in M_2 for Compositions from $C_{20}H_{40}$ (N_2 O_2 S_2 Si_2 F_2 Cl_2)

Fig. 4

II. The flow diagram in Fig 4 shows a routine procedure for obtaining second moment data with an HP 5988A GC/MS at a precision of about $\pm 3\%$ or better. This strategy uses AUTOTUNE, Selected Ion Monitoring (SIM), and a Post-Acquisition Correction of the data (to factor out systematic errors). The validity of the Post-Acquisition correction is demonstrated in Table I with data for four compounds with M.W.s of about 350 amu. With this particular instrument, the AUTOTUNE/SIM routine produces second moment data with an approximately constant absolute error, 0.027 ± 0.003 amu². We presume that the magnitude and nature of the systematic error will vary from one instrument to another; but, the relative ease, speed, and apparent accuracy of this strategy should make the initial effort of characterizing these systematic errors well worth while.

Table I

SYSTEMATIC ERRORS IN MEASURING MOMENTS

Composition	Mass	Second Moment ^a	Absolute Error ^b	Relative Error
$C_{21}H_{16}O_3$	316	0.2501	-0.022	-8.87%

$C_{18}H_{15}N_2O_4Cl$	358	0.9754	-0.031	-3.18%
$C_{18}H_{15}N_3OCl_2$	359	1.7198	-0.029	-1.69%

^a Average results for 2 or 3 analyses

^b Estimated error in M_2 $M_2(\text{measured}) - M_2(\text{calculated})$

Fig. 5

Flow Diagram for CONCERT Analysis

III. A program has been written in Microsoft BASIC for implementing the CONCERTED analysis once the exact mass and isotope data have been obtained. The program will run on any IBM compatible system, is menu driven, and provides the auxiliary support needed to analyze raw data. Fig 5 shows the basic outline of the CONCERTED analysis utilized by the program. The program may be obtained in both compiled and non-compiled forms on either 3.5" or 5.25" floppy disk by writing to the first author.

INORGANIC FINGERPRINT OF RAT TISSUES

Yves Gelinasi¹, Jocelyne Ferraris² and Jean-Pierre Schmit¹,
University of Quebec in Montreal, Department of ¹Chemistry and ²Biology,
P.O. Box 8888 Station A, Montreal, CANADA, H3C 3P8

Most biochemical reactions enabling to maintain the integrity of living organisms require the presence of inorganic cofactors within a precise and narrow range of concentrations. Departing from those limits is often at the origin of pathological disorders. Surprisingly, in spite of the widely recognized biochemical importance of the inorganic cofactors and the availability of numerous independent data from very different techniques (e.g. Atomic Absorption and Neutron Nuclear Activation) in the literature, little is known on the "normal" inorganic content of living tissues down to the ppb level. This situation mainly results from the lack of a single analytical technique able to perform rapid and simultaneous determinations of the almost totality of the elements of the periodic table on the small quantities of tissue usually available in this particularly important domain of biomedical, toxicological and environmental research.

In this work, we profit of the quasi-simultaneous multielemental analysis capability of a new technique, the Inductively Coupled Plasma / Mass Spectrometer (ICP/MS), to establish the inorganic fingerprint of a series of ten major biological tissues (bone, brain, erythrocytes, heart, kidney cortex, kidney medulla, liver, lung, muscle, and plasma) from healthy male Sprague Dawley rats. Pieces of tissue (ca 250 mg) were digested in 1.50 ml of ultrapure nitric acid 8N inside a Parr microwave acid digestion bomb for 2 minutes at medium power in a standard microwave oven. Aliquots of solution were used for characterization and individual standard addition determination of elements. Rhodium (100 ppb) was added as internal standard. NBS 1577a bovine liver was used as reference. 43 elements were observed. Among this series, 27 elements in the ppb or low ppm range were determined, the others either are not currently measurable by ICP/MS (e.g. C, N, O, ...), or, due to their high concentrations, are more easily measured by atomic absorption spectroscopy (e.g. Ca, K, Mg, Na, ...).

Following discriminant analysis, principal component analysis applied on the previously defined correlation matrices was used to extract the existing relationships between the measured elements and the main discriminant sources of the different tissues. Finally, the "inorganic fingerprint" of each tissue was determined by reference to the average element profile of the studied tissues. Elements have been classified according to their normal deviate (Z) from the corresponding mean value of the tissues, as highly (+++/---, Z>6), moderately (++/--, 4<Z<6), and weakly (+/-, 2<Z<4) characterizing. A positive label expresses a concentration in excess to the mean element tissue profile while a negative label emphasizes a depletion.

ELEMENTAL COMPOSITION OF MILK: FROM THE COW TO THE CONSUMER

C. Martinez¹, M. Amer², T. Goswami¹, and J.-P. Schmit¹

¹Department of Chemistry, University of Quebec in Montreal,

²Montreal General Hospital Research Institute, Montreal, Quebec, CANADA

Milk is a known fundamental nutriment for mammals and, as such, for humans. It is a complexe mixture of elaborated organic and organometallic compounds. As such, its inorganic content represents a dietary supply of elements of prime importance in maintaining the integrity of life of superior organisms. However, although numerous studies on the most classical elements (Ca, K, Mg, Na, P, . . .) are available in the literature, there is very little, if any, compositional information on the totality of the inorganic elements contained in milk that has been carried out systematically on a single and modern analytical technique.

In this work, we took advantage of the quasi-simultaneous multielemental analysis and high sensitivity capabilities of a new technique, the Inductively Coupled Plasma / Mass Spectrometry (ICP/MS) to establish the complete inorganic content of milk along the different steps of its packaging from the cow's milk to the consumer's bottle.

In its standard configuration ICP/MS requires introduction of liquid samples through a nebulizer inlet system. To meet this requirement, an efficient methodology, based on the use of Parr microwave acid digestion bomb, has been optimized for direct and complete digestion of milk samples. The general conditions used are: 1 ml of milk sample + 1.25 ml HNO₃ + 0.25 ml H₂O₂ heated for 2 minutes in a standard microwave oven at medium power and allowed to cool for 15 minutes at room temperature.

Besides the usual C, H, O, N and P elements, preliminary screening down to the ppb level allowed characterization of thirty (30) additional elements (Ag, Al, As, B, Ba, Bi, Ca, Cd, Co, Cr, Cu, Fe, Hg, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Rb, Se, Sn, Sr, Ti, V, W, Zr and Zn) in each of the individual state of milk packaging from the cow's milk to the table of the consumer, including the various usual presentations: homogenized (HOMO), partly skimmed (2%), skimmed milks and pure cream. Due to the presence of interfering peaks (Fe, K) or because of their high concentrations (Ca, Mg and Na) some elements were determined by atomic absorption spectroscopy.

Characteristic relationships between specific elements of physiological importance and protein and/or fat content were found. This is especially the case for chromium and copper, which concentrations are proportional to the protein content, while Sr is inversely proportional to the same reference. This observation holds true when analysing cream where specific accumulation (e.g. Al, Cr, Cu, Mo) or depletion (e.g. Rb, Sr, Ti, W) of elements can be observed. This lets open the question of possible physiological nutritive consequences resulting from social habits when drinking a particular milk packaging.

Relationships between selected elements of possible physiological importance and protein content

THE DETERMINATION OF LOW-ABUNDANCE OXYGEN
IN FLUORINE GAS MIXTURES

M. E. Cisper and P. H. Hemberger

Analytical Chemistry Group
Los Alamos National Laboratory, Los Alamos, NM 87545.

Oxygen is a problematic and ubiquitous impurity in commercially available fluorine, ranging from 0.2% to more than 2% abundance relative to fluorine. The oxygen content of fluorine gas mixtures used in chemical laser systems is a critical parameter. Oxygen is often added to the gas mixture to inhibit premature $H_2 - F_2$ reaction by breaking free-radical chain reactions; on the other hand, too much oxygen limits laser output. The purpose of this work is to develop an automated mass spectrometric methodology for real-time quantitative analysis of oxygen in fluorine gas mixtures at sample pressures from 10 psia to 60 psia. Optical or chromatographic methods do not provide reliable analytical results in this application.

A UTI quadrupole mass spectrometer and Atmospheric Pressure Sampling Module were controlled by a Hewlett-Packard data system under IEEE-488 protocol. All sampling and pump-out valves were controlled with this data system via a HP 3488A Switch/Control Unit so that gas sampling, analysis, and data reduction were fully automated. Calibration curves for oxygen content were generated with oxygen/argon mixtures that were standardized by gas chromatography and magnetic sector mass spectrometry. The oxygen content in the fluorine sample mixtures was determined by comparison of the instrument response to oxygen against the working calibration curve.

The validity of the non-matrix matched standards ($O_2/Ar/no F_2$) was evaluated by preparing four fluorine gas mixtures. Each mixture contained 5% F_2 . One cylinder had no added oxygen, the remaining cylinders contained 0.1%, 0.2%, and 0.32% added oxygen. The exact final O_2 concentration in these mixes is not known because the initial amount of O_2 present as an impurity in the fluorine is not known. However, the percentage of oxygen added to each cylinder is known by measurement of partial pressures. If the use of fluorine-free standards is valid, a plot of % O_2 by mass spectrometry versus % O_2 by partial pressures should yield a regression line with near unity slope and a non-zero intercept (as a result of the residual oxygen in the cylinder with no added oxygen). This is shown in Figure 1.

In most cases, calibrations were made at the same sample pressure as the analysis. Instrument response was corrected for pressure when this was not possible. However, the response was not a fixed function of pressure. At low sample pressures (10 psia - 30 psia), the response could be corrected by linear ratio of standard pressure to sample pressure. At higher pressures (30 psia - 70 psia) the instrument response followed a 0.7th root dependence on the pressure ratio (Figure 2). This results from gas flow into the ion source changing from molecular to viscous regimes as sample pressure increases. The results of multiple independent analyses are given in Table 1. In general the precision of the method is ± 5 rsd for oxygen levels greater than 0.1%. The precision degrades as fluorine concentration increases. Trace levels of oxygen can be quantified to less than 100 parts-per-million.

MATRIX EFFECTS ON THE FAST ATOM BOMBARDMENT MASS SPECTRA OF PALLADIUM COMPLEXES

L. M. Mallis¹ and W. J. Scott

¹High Resolution Mass Spectrometry Facility
and Department of Chemistry
The University of Iowa
Iowa City, Iowa 52242

The use of palladium to catalyze the coupling of nucleophiles with electrophiles has become an increasingly important method for the formation of carbon-carbon bonds. The reaction is believed to proceed by an oxidative addition/ transmetalation/ reductive elimination scheme. While each step of the proposed catalytic cycle has precedent for the Group 10 metals, only the product of the oxidative addition step has been demonstrated to be formed under coupling conditions.

Fast atom bombardment mass spectrometry (FAB-MS) has been used to identify transient species in organic reactions. We are developing an understanding of the fragmentation characteristics of typical palladium complexes under FAB-MS conditions in order to apply this to a study of transient species which might be detected during coupling reactions.

In this paper, a study to determine the effects of matrix selection on the observed FAB spectrum is presented. These studies were performed using a VG ZAB-HF mass spectrometer equipped with an ION TECH saddle field atom gun, and an 11 250-J data system. It is important that the FAB matrix provide for an excellent ion yield while remaining inert to the coupling reaction being studied. It is interesting to note that use of a protic matrix causes the degradation of the palladium catalyst to form $Pd_xL_y^+$ ($x = 2-4$, $y = 0-3$) clusters which represents the degradation of the palladium catalyst. For example when PdL_4 is analyzed using glycerol, nitrobenzyl alcohol (NBA) or nitrophenyloctylether (NPOE), ions corresponding to $Pd_xL_yO_z^+$ ($x = 2-4$; $y = 1-3$; $z = 0-2$) are observed (see Figures 1, 2, and 3, respectively). In addition, clusters of the oxidized ligands (and complexed to the FAB matrix; see Glycerol spectrum) are observed suggesting that these more protic solvents are not reasonable choices for analyzing the catalytic process.

A spectrum of PdL_4 in triethanolamine is shown in Figure 4. Although an ion corresponding to the oxidized ligand is clearly observed, the fragment ions arising from the palladium catalyst are relatively clean of oxidized products. Recently, sulfolane has been used as a matrix for the analysis of organometallic compounds. A spectrum of PdL_4 in sulfolane is shown in Figure 5. It is interesting to note that the fragment ions present correspond unambiguously to the structure of the palladium catalyst. Investigation into the intermediates involved in the palladium catalyzed coupling reaction using sulfolane as the FAB matrix are currently underway.

FAST ATOM BOMBARDMENT ANALYSIS OF SPECIES FORMED BY
THE INSERTION OF CARBON DISULFIDE INTO Mn-H BONDS

Steve J. Schauer, Darrell P. Eyman and Larry M. Mallis¹

¹High Resolution Mass Spectrometry Facility
and Department of Chemistry
The University of Iowa
Iowa City, Iowa 52242

Carbon disulfide is known to insert into metal hydride bonds.^{2,3} This paper reports the use of fast atom bombardment mass spectrometry (FAB-MS) to monitor the decomposition of an organomanganese compound which can be formed by two synthetic routes. $\eta^6\text{-(C}_6\text{Me}_6\text{)Mn(CO)}_2\text{H}$ will react with CS_2 in THF solvent to produce $\eta^6\text{-(C}_6\text{Me}_6\text{)Mn(CO)}_2\text{S}_2\text{CH}$ (**1**) by insertion of CS_2 into the Mn-H bond.⁴ In addition, the dithiormate may be synthesized by reacting $\eta^6\text{-(C}_6\text{Me}_6\text{)Mn(CO)}_3^+ \text{PF}_6^-$ with KS_2CH and Me_3NO in THF.⁵

In the FAB mass spectrum of **1**, an ion corresponding to the protonated molecular ions is observed at m/z 351 (see Figure A). Several structurally significant fragment ions are also observed in this spectrum. The base peak in this spectrum at m/z 294 is assigned as loss of 2 CO groups from the neutral molecule ($[\text{M} - 2 \text{CO}]^+$). The ion at m/z 273 corresponds to loss of the dithiormate group (S_2CH) while the ion at m/z 217 is assigned as loss of both CO groups and the dithiormate group (hexamethylbenzene manganese). It is interesting to note that the ion at m/z 161 is assigned as loss of Mn-H from the ion at m/z 217.

An aged sample of **1** also produces ions as described above. In addition, an ion assigned as a bimetallic species derived from **1** is observed. Repurification of **1**, followed by immediate FAB, analysis, showed a marked decrease in the ion corresponding to the bimetallic species and a corresponding increase in the protonated molecular ion. After one hour, FAB analysis established that the ion arising from the bimetallic species had again increased, demonstrating that the bimetallic species is being formed by a reaction of **1**, in the solid phase. This observation is enhanced when the bimetallic species is dissolved in THF (or the FAB matrix; i.e., nitrobenzyl alcohol) and heated for an extended period of time (30 - 60 minutes) under FAB ionization conditions. Figures A through E contain the FAB mass spectra for **1** dissolved in THF/NBA and bombarded for up to 60 minutes. By plotting the percent total ion current against the time of spectral acquisition, the relationship between the ions at m/z 623 and m/z 349 have been established. A proposed mechanism for the formation of m/z 623 and the fragment at m/z 349 are presented in Figures 1 and 3, respectively. Further studies to elucidate the exact structure of the ion at m/z 623, using FT-IR and MS/MS experiments, are currently underway.

EVALUATION OF A DOUBLE-QUADRUPOLE SPECTROMETER SYSTEM
FOR GLOW DISCHARGE MASS SPECTROMETRY

Douglas C. Duckworth and R. Kenneth Marcus
Department of Chemistry,
Howard L. Hunter Chemical Laboratories
Clemson University
Clemson, SC 29634-1905

As the technique of glow discharge mass spectrometry evolves into a more widely applied and accepted method of direct solids elemental analysis, two fundamental obstacles remain for the practitioner: 1) the requirement that the sample be conductive in nature and 2) the presence of isobaric interferences, specifically those related to molecular species. While nonconducting powders may be mixed intimately with a metal powder and a suitable sample disk press-formed, not all insulators occur in powder form. This problem has been addressed in our laboratory by the development of a radio frequency (rf) powered glow discharge device which allows the direct analysis of nonconductors without matrix modification. The desire to remove molecular isobars would suggest a couple of remedial measures. Double-sector instruments are useful in resolving atomic isobars, but many molecular interferences require resolving powers of $>10,000$. The second apparent option is the use of collision-induced dissociation (CID) schemes to remove molecular species. We describe here the use of a relatively simple double-quadrupole spectrometer for the removal of molecular species from rf-glow discharge mass spectra through collision-induced dissociation.

EXPERIMENTAL

Figure 1 is a diagrammatic representation of the double-quadrupole instrument employed in this laboratory. Ions exiting the ~ 0.3 torr ion source region pass through a differential pumping stage and into the analyzer region. These ions are focussed into the collision cell by a three-element lens system. The collision cell and mass analyzer are equipped with Extrel 3/8" quadrupole assemblies powered by 1.2 MHz generators. Argon is employed as the collision gas with its pressure monitored through the analyzer region ion gauge. Ions traversing the rf-only quadrupole are directed into the analyzer by a single-element lens. All of the spectrometer scan functions, ion lens/pole offset potentials, and ion detection were controlled by an Extrel C-50 mainframe. Due to the variations of mass throughput characteristics of the double-quadrupole arrangement, which are a function of the relative quadrupole d.c. offsets, spectra were taken at fixed collision cell offset potentials with the cell evacuated and then pressurized to assess the extent of molecular species removal. A rf-powered glow discharge source was employed in these studies with typical operating pressures of ~ 0.3 torr and powers of ~ 10 watts.

Figure 1. Double-quadrupole glow discharge mass spectrometer system.

RESULTS AND DISCUSSION

The first parameter investigated in the double-quadrupole CID-GDMS studies was the effect of collision cell pressure on the degree of dissociation of molecular species produced when sputtering a copper cathode. It was found that cell pressures corresponding to 4×10^{-4} in the analyzer chamber were the best compromise between dissociation and losses of analyte due to scattering. Studies were performed at collision energies (E_{lab}) of 20 and 40 eV. These values correspond to center-of-mass energies (based on a copper dimer species) of 4.8 and 9.6 eV. While both of these values should be sufficient to dissociate most of the molecular species, the latter proved to be more efficient. At this energy, each of the studied interferents (Ar^{2+} , $CuAr^+$, and Cu_2^+) were reduced to levels indistinguishable from background noise.

Shown below are a pair of mass spectra obtained from an Alcan 3004 AD aluminum alloy. In the "no CID" spectrum, the dimer of Al is seen at mass 54 as an isobar to the minor Fe isotope, with the aluminum argide ($AlAr^+$) present at mass 67. Employment of collision-induced dissociation to this sample eliminates both the dimer and argide molecular species. It should be pointed out that, while the CID does simplify the observed spectrum, the loss of the Al matrix ion signal is on the order of 80%. The actual noise level of the detector does not change when the cell is pressurized, the primary noise source seems to be from photons emitted from the plasma.

Studies performed on this system indicate that the relatively simple, double-quadrupole spectrometer geometry is a viable means of reducing the contribution of molecular species to glow discharge mass spectra. Future studies in CID-GDMS will focus on the reduction of the photon noise so that a dynamic range suitable for routine analyses can be achieved. Modifications of the interquadrupole lens will be made such that more uniform mass transport characteristics can be achieved. This is necessary in order to study the degree of molecular species dissociation as a function of collision energy.

The Relative Role of Penning Ionization in Glow Discharge Devices

David Serxner, Rebecca Smith, and Kenneth Hess*

Department of Chemistry
Franklin and Marshall College
Lancaster, PA 17604

The use of glow discharges as ion sources for elemental mass spectrometry is a rapidly expanding field (1). In order to develop adequately glow discharge mass spectrometric methodologies, the fundamental mechanisms responsible for the creation of analytical ions is of interest. Two major mechanisms are believed to be responsible for the ionization of sputtered atoms, electron impact ionization and Penning ionization. Electron impact results from an energy transfer from an energetic electron, while Penning ionization results from a potential energy transfer from an excited metastable state of the discharge gas.

Electron impact ionization: $M^0 + e^- \rightarrow M^+ + 2e^-$

Penning ionization: $Ar^* + M^0 \rightarrow M^+ + Ar^0 + e^-$

In order to elucidate the ionization mechanisms present in the glow discharge, experiments were designed to quench the metastable levels of the rare gas and measure the resulting decrease in ion emission from a sputtered copper population (2). A glow discharge was operated in a 2.75 inch six-way cross at pressures of 0.3 - 1.2 torr, 0 - 4 mA, and 500 - 3500 volts. The cathode consisted of a 1.5 mm diameter brass pin with 5.0 mm exposed to the discharge. The optical system employed for atomic absorption and emission experiments consisted of an Instruments SA 0.32 m monochromator with a Hamamatsu 752 photomultiplier tube. A Pacific 124 photometer provided high voltage to the PMT and served as the readout device for atomic emission. For atomic absorption measurements, output from a pulsed hollow cathode lamp traversed the negative glow region of the discharge and the signal was monitored by a EGG PAR 5209 lock-in amplifier.

Figure 1

Figure 2

Methane was employed as the metastable quenching agent. As illustrated in Figure 1, low levels of methane added to an argon glow discharge will result in the removal of the Ar^* states without significantly impacting the ground state copper population. Under these conditions, the Penning ionization process should be removed, allowing ionization only through electron impact. Determination of the reduction of ion signal with methane relative to the signal present with pure argon should provide a measure of the relative role of Penning ionization in the glow discharge.

Figure 2 illustrates the behavior of copper ion signal as a function of discharge current for both pure argon and a discharge operating with 10% methane in argon mixture. The signal generated with the addition of methane shows the decrease due to the quenching of the argon metastable states. When the signals are corrected for the lower ground state copper population present with methane, a relative value of Penning ionization vs. current can be calculated. Penning ionization is observed to decrease linearly with increasing current, falling from 78% at 0.5 mA to 42% at 3.5 mA. Figure 3 exhibits the effect of pressure on the copper ion signal for both pure argon and the methane/argon mixture. The role of Penning ionization is clear in this figure, with the ion signal profile in argon peaking at 0.8 torr, matching the behavior of the Ar^* population, illustrated in Figure 4. With methane present in the discharge, the ion signal is reduced, and the profile matches that of the copper ground state, Figure 4. Again the relative role of Penning ionization vs. pressure may be calculated and it is found to rise from 0 at 0.3 torr to 60% at 0.8 torr, then level off up to 1.2 torr, the maximum pressure investigated.

SEPARATION OF ATOMIZATION AND IONIZATION PROCESSES IN GDMS: C.M. Barshick and W.W. Harrison, University of Florida, Gainesville, FL. 32611. USA.

INTRODUCTION

Glow discharge mass spectrometry relies on a population of positive ions representative of the elemental composition of the sample cathode. While the intrinsic two-step sputter/plasma process offers the advantage of needing no secondary source of atomization or ionization, studying one process separate from the other is difficult, if not impossible. Limited success has been achieved in prior studies by focusing on correlations between discharge parameters (pressure, voltage, current, etc.) and ion signal. An alternative approach is to use one technique to generate a source of primary atoms in conjunction with a complementary glow discharge acting as the ionization source, incident energy and source pressures approximating the conditions present in the glow discharge.

EXPERIMENTAL

As the atom generator we have investigated two sources: (1) an excimer pumped dye laser and (2) a fast-atom source. Figure 1 illustrates the quadrupole mass analyzer and the position of the sample target relative to the laser and FAB beams. The dye laser output consisted of 10 nsec pulses in the 0.1 - 1.0 mJ range at 100 Hz. By focusing the beam to spot diameters of 100 micrometers, power levels of $10^8 - 10^9$ W/cm² were obtainable. Rhodamine 590 laser dye was used in all the studies at the wavelength of maximum power (583.0 nm). At these power levels there is essentially no wavelength dependence on the ablation process. An Ion Tech saddle field gun was used as the fast-atom source. The beam consisted of ca. 4 - 8 keV fast argon atoms at a current density of 1 - 10 μ A/cm². Machined conical pins (5.0 mm at the base and cut at a 45 degree angle)

Figure 1.

and pressed disks (5.0 mm in diameter) were position on the end of a rotating sample holder 5 mm from the ion exit orifice. The samples were rotated at a constant 2 rpm. The laser and fast-atom beams were directed from a region of high vacuum (ca. $1 \times 10^{-7} - 1 \times 10^{-4}$ Torr) to a region of low vacuum (ca. 0.1 - 1.0 Torr) through a 0.5 mm aperture. In order for the fast-atom beam to impact the target it must traverse a distance of 1 cm through the high pressure region. The mean-free path is 0.5 cm through 1.0 Torr of rare gas at 8 keV. An auxiliary discharge was formed about a 1.0 mm diameter tungsten electrode positioned 180 degrees off the auxiliary atomizer axis, directly behind, and slightly above the target. The ions formed at the surface of the target and/or in the discharge plasma were extracted through a 1.0 mm orifice and focused into a quadrupole mass spectrometer.

RESULTS AND DISCUSSION

High vacuum sputter/ablation. The initial series of studies was performed under best vacuum conditions to determine the effect of laser pulse energy and FAB beam energy on typical metal/alloy materials; collision and redeposition processes are minimized in this way. Vacuum sputter/ablation studies were conducted at 2×10^{-7} Torr as measured in the analyzer chamber. ⁶³Cu ion signal was measured as a function of laser pulse energy and FAB beam energy. Laser pulse energy was varied from 0.05 - 1.0 mJ/pulse at a constant repetition rate of 100 Hz, and FAB beam energy from 4 - 8 keV. Ion signals showed linear increases as both pulse energy and beam energy were increased. Present orientation of the sample probe with the exit orifice limits sensitivity somewhat. Absolute copper ion signal ranged from ca. 2000 - 12000 counts/sec for laser ablation and ca. 50 - 500 counts/sec for fast-atom bombardment. These studies showed us that our experimental conditions permitted work in a linear response region of the sputter/ablation process.

Buffer gas. Introduction of a buffer gas into the sputter/ablation chamber produces collisions with the sputter-ablated atoms causing a fraction to be redeposited, analogous to the redeposition effects found in GDMS. With the controlled sputter/ablation studies performed here, the effect of increasing pressure is more clearly seen than in the glow discharge, where changing pressure also changes ion energy. Ion signal was monitored for the pressure range 0.0 - 1.0 Torr at (1) a constant laser pulse energy of 1.0 mJ/pulse at 100 Hz, and (2) a constant FAB beam energy of 8 keV. Figure 2A and 2B are plots of ^{63}Cu ion signal vs. pressure for the laser and fast-atom sources, respectively. As the pressure is initially increased, the ambient gas acts to contain the sputter/ablated atoms longer and to increase the probability for ionizing collisions. At ca. 0.4 Torr, the competing processes of containment redeposition, and ion neutralization through recombination create a maximum ion signal. As the pressure is increased above 0.4 Torr redeposition and recombination quickly dominate, as is evidenced by the sharp drop in ion signal.

LASER ABLATED ION SIGNAL VS. PRESSURE

Figure 2A.

FAST-ATOM ABLATED ION SIGNAL VS. PRESSURE

Figure 2B.

Sputter/ablation into a secondary discharge. The use of a secondary source of atomization in combination with an auxiliary glow discharge affords the opportunity to study two problems inherent to the discharge: (1) the inability to separate the sputter-atomization process from the ionization process, and (2) the inability to analyze nonconducting samples directly, since cathodic-samples must be conducting. The efficiency of a glow discharge in ionizing the ablated atoms should be dependent on the discharge current. Changes in the current at constant pressure should only affect the discharge and not the auxiliary atomization process. A plot of ion signal vs. discharge current for the laser ablated/secondary discharge system shows a sharp increase in ion signal up to ca. 4.0 mA, and then a steady decrease above this value. The changes in the observed ion signals are attributed to differences in the ionization efficiency. Higher currents and the corresponding higher electron densities would be expected to increase the ionization rate of the laser generated material. This is possibly the effect observed as the current is increased up to 4 mA. Above 4 mA there appears to be some competing processes that reduce the collection and/or ionization efficiencies. However, the discharge plasma changes in configuration with increasing current, and this could affect the extraction efficiencies also. Alteration in argon metastable population may also be created affecting ionization.

Nonconducting sample analysis. With the atomization/auxiliary discharge employed in these studies, a nonconducting sample can be analyzed directly without the need for a conducting matrix. This eliminates problems in finding a suitable contaminant free matrix. Preliminary results show a 10 fold increase in ion signal between the laser/auxiliary discharge system and the laser alone, indicating a potential for the direct analysis of nonconducting samples. The present electrode configurations are not optimized for maximum ion yield, so further increases in enhancement are anticipated.

STUDIES OF THIN FILMS IN GLOW DISCHARGE MASS SPECTROMETRY

P.H. Ratliff and W.W. Harrison

Department of Chemistry, University of Florida, Gainesville, FL 32611 USA.

INTRODUCTION

The study of thin films includes the analysis of semi-conductors, micro-electronics, and other specialized systems. While some X-ray and electron spectroscopic techniques offer the advantage of non-destructive analysis, the sample is determined indirectly by detection of secondary electrons or X-rays generated from the sample. A second method used is that in which ions coming directly from the surface of the sample are detected. These methods use techniques in which atoms are sputtered from the surface of the sample, ionized and then detected. Falling in this class is glow discharge mass spectrometry (GDMS), which is the method of choice for these experiments. The disadvantage of this technique is that the sample is destroyed in the course of the analysis. An advantage is that actual atoms coming off from the surface are detected directly.

EXPERIMENTAL

GDMS has found use primarily in the analysis of bulk metal samples in the form of machined pins or pressed disks. A problem in looking at thin metallic films was the unavailability of a suitable sample holder. The plasma will sputter any portion of the sample exposed to the impinging gas atoms. When analyzing thin films it is desirable to sputter only the top of the sample because sputtering the edges will produce an ion signal from the lower layers in the sample. To solve this problem a sample holder was designed that would

Figure 1.

shield the edges of the sample in the dark space of the plasma, not allowing bombardment by the gas discharge atoms. The holder was designed to attach the sample and its substrate onto the end of a direct insertion probe. Samples of approximately 5 mm square were held in place by a flexible tantalum fitting. The sample and holder were covered with a cylindrical Macor shield with a 4 mm hole allowing the discharge to sputter a circular area on top of the sample. A cross-sectional illustration of the sample holder with sample in place is shown in Figure 1.

The films analyzed were deposited on a variety of substrates including: silicon, sapphire, Kapton (a polyimide film), and gallium arsenide. Samples were in the thickness range of 500-10,000 angstroms, consisting of single element/single layer, multi-element/single layer, single element/multi-layer, and the matrix film. The metals analyzed were aluminum, copper, gold, and the alloy Cu₃Au. The analyses were carried out by monitoring the sputter profiles acquired as the metal was sputtered away from the surface. When looking at layers of 1000 angstroms or less the samples were studied using both argon and helium to compare the speed and results of the two different methods.

HELIUM DISCHARGE EXPERIMENTS

A second problem in GDMS is the fast sputter rate in an argon glow discharge. This problem became significant when looking at layers less than 1000 angstroms. The sputter times for layers of this thickness were on the order of 30 seconds or less. With large sputter rates, sputter profiles of very thin layers may provide poor results. If a layer is sputtered away in a short time period, any differences in the time from study to study will have a large overall error. This problem was solved by the use of an alternative discharge gas. The sputter rates of discharge gases vary due to a variety of parameters. The most predominant is the size of the gas atoms compared to the

sample atoms. Thus a larger gas atom will sputter a sample faster than a smaller gas atom. Helium was chosen because of its low cost, high purity, and availability. When using a helium discharge, the sputter rate is on the order of seven to eight times slower, thus the sputter profile will be spread out and the sputter time of a layer may be obtained more precisely. The plasma shape is unusual using helium because a sharp beam-like plasma was observed coming through the Macor hole. The size of the sampled area is the same, but the discharge seems to be concentrated at the center indicated by a deeper crater. A 1,000 angstrom Au/GaAs sample was analyzed using both argon and helium. Figure 2 shows the comparative sputter profiles for gold in both gases.

ANALYSIS OF MATRIX MATERIALS

Experiments to determine matrix composition were done for two reasons: (1) to see if there was anything present that might interfere with the analysis of the films and (2) to examine an organic polymer. Since sputter ablation of most films occurred rapidly, a complete mass spectrum of the elemental layers was not obtained. Any matrix interferences present could alter the analysis of the films since only one peak was monitored. If an interferant was present at a mass under investigation, the ion signal observed would not reflect the true value. The Kapton was considered non-conducting, so no discharge was expected to form about this material. When the discharge was formed with the samples on Kapton, it was thought that the metal was conducting enough current to cause formation of the plasma. After the metal was sputtered away the discharge remained, so redeposited metal may have caused the plasma to be maintained. In a later experiment the pure polymer was examined and found to sputter on its own.

RESULTS AND DISCUSSION

The sputter rate of the alloy Cu_3Au was found to be in the range of 35-40 angstroms per second monitoring the component metals, while the sputter rates of the pure metals are higher, copper being approximately 42 angstroms/second and gold about 63 angstroms/second. Comparable samples of aluminum had a rate of approximately 9.8 angstroms/second. Since the hole size in the Macor shield gets subsequently larger with each run the data were normalized by calculating the total volume sputtered in a given time. The calculated sputter rates for all of the thin films under investigation are shown in Table 1.

CONCLUSIONS:

1) A technique was developed for thin film analysis of a relatively small area of 10 mm^2 or less. 2) Small portions of a sample under investigation will be destroyed for each analysis. 3) Sputter rates on the order of 50-100 angstroms/second will not allow accurate analysis of samples less than 500-1,000 angstroms. 4) Alternative discharge gases such as helium may be used to slow the sputter rate for the study of thinner films.

Figure 2.

TABLE 1: SPUTTER RATES FOR VARIOUS METALS

GAS	SAMPLE	ION	SPUTTER RATE (micrometer/second)
Argon	Al/Si	Al ⁺	8.7×10^{-1}
Argon	Au/GaAs	Au ⁺	7.0×10^{-4}
Argon	Au/Cu/Au/Si	Au ⁺	6.0×10^{-4}
Argon	Au/Cu/Au/Si	Cu ⁺	4.0×10^{-4}
Argon	Cu_3Au /Kapton	Au ⁺	3.8×10^{-4}
Argon	Cu_3Au /Kapton	Cu ⁺	3.5×10^{-4}
Helium	Au/GaAs	Au ⁺	9.3×10^{-3}
Helium	Cu_3Au /Kapton	Au ⁺	5.4×10^{-3}

ANALYSIS OF POWDERED METAL OXIDES
USING RADIO FREQUENCY GLOW DISCHARGE MASS SPECTROMETRY

J.A. Klingler and W.W. Harrison

Department of Chemistry, University of Florida, Gainesville, FL 32611 USA.

INTRODUCTION

Conventional glow discharge mass spectrometry (GDMS) allows a sample to be sputtered by applying a direct current (DC) to the sample while it is submerged in a noble gas. This limits the sample material to conductors such as metals or non-conductors mixed into a conducting matrix. An alternative method is to apply an alternating potential in the radio frequency (RF) range to the sample.

When a potential is applied to a nonconducting sample it will act like a capacitor. If the applied RF voltage drives the sample negative, positive ions begin to bombard the surface. Before the sample potential can reach zero, however, the applied RF voltage swings to a positive value and electrons begin to strike the surface. Since electrons are more mobile than ions, the surface potential quickly reduces to zero. As the process repeats itself, the difference in mobilities builds up a negative bias on the sample. This allows the sample to be almost continuously bombarded by positive ions.

EXPERIMENTAL

The RF system used in this study utilizes a wave-form generator to control the output of a RF amplifier, which in turn feeds the high voltage signal into an impedance matching box. A pi-network is used to match the impedance of the RF signal to the discharge impedance. The operating frequency of the RF source (here 6.2 MHz) is determined by the resonance frequency of the matching system.

To control the plasma and protect the holder from being sputtered the shield and grounding configuration in Figure 1 was used.

Figure 1.

RESULTS AND DISCUSSION

A comparison of DC and RF discharges using a copper disk shows that although the DC and RF spectra are similar, the RF spectrum shows a smaller sputtered species signal and enhancement of the water and gas peaks. This effect may be due to increased ionization of the contaminate gases in the RF discharge or reduced sputtering efficiency due to lower energy argon ions striking the surface. A weight loss study revealed that during sputter intervals of 30 minutes, the RF discharge demonstrated a weight loss of 1 microgram per second, slightly higher than the 0.7 microgram per second for the DC discharge. This indicates that the differences in DC and RF spectra originate in the steps beyond atomization.

Metal oxides are an example of a nonconducting material that can be directly sputtered with RF glow discharges. One concern in analyzing metal oxides is the effect of different plasma parameters on the amount of dissociation of the metal-oxygen bond. To study both RF plasma characteristics and their effect on oxides, this study focused on lanthanum oxide (because of its high bonding energy to oxygen), uranium oxide (which produces both monoxide and dioxide species when sputtered) and stannous oxide (which has a more "typical" bonding energy).

Powdered metal oxides have a large amount of water absorbed on their surfaces. Even after extended drying in an oven, samples made from compressed metal oxide powders can release water into the glow discharge for several hours. The amount of water present during an analysis will influence the dissociation of metal oxides. One possible explanation is that while the water is present

in large amounts, it is the primary current carrier. Water may not sputter the sample as efficiently as argon ions and the presence of water may quench metastable atoms capable of breaking the metal-oxygen bond.

The signal intensities of all the oxides in this study appear to follow the same pattern in relation to the distance from the sample to the exit orifice. By maintaining a constant pressure of 0.4 torr argon and 10 watts of power, the dark space for these samples was approximately 0.5 cm in length. The maximum signal appears to be within 1.5 mm of the dark space. As the distance to the exit orifice is increased, the oxide signals begin to go down at a faster rate than the metal signals. This effect may be due to the monoxide and dioxide species being broken up or scattered.

Increasing the applied power results in different responses for the oxide species depending on the current plasma environment. For stannous oxide, increased power yields an improved metal signal. Uranium oxide also shows an improved signal but the strongly bonded dioxide and monoxide dominate. Lanthanum oxide species lose signal strength with increasing power. Water may play an important role in each of these responses. In both the uranium oxide and stannous oxide, water is the most outstanding feature, whereas in lanthanum oxide the water signal is steadily decreasing.

Increasing the pressure of the glow discharge results in an increase in both metal and metal oxide signals. This is followed by a pressure range where the metal oxide peaks tend to lose intensity faster than the dissociated metal species. Uranium dioxide in particular loses signal intensity more rapidly than the monoxide species, an effect probably due to this molecule's larger size. The point where the analyte signal begins to decrease varies among the oxides studied. Factors influencing this inflection point include dissociation energy, collisional cross section and the amount of water in the discharge.

Many parameters of the RF glow discharge and their effect on the analysis of powders still remain undefined. In particular, clarification of the plasma conditions which can control the effects of water and other gas contaminants is to be investigated. Future experiments include the use of gettering agents in the discharge, the effects of changing the frequency of the discharge and the use of a second glow discharge to influence the ionization of the RF glow region. The extent of dissociation as the metal oxide is sputtered compared to recombination in the plasma will also be investigated.

CONCLUSION

This paper reports the initial results of sputtering powdered metal oxide samples using a small sample holder and non-conventional radio frequencies. Water and other contaminants appear to be strongly ionized in the RF system and introduce continually changing conditions that further complicate oxide analysis. Although the RF glow discharge appears to offer a convenient method to study non-conducting samples without a conducting matrix, the mechanisms which control the degree of dissociation of the metal-oxygen bond must still be investigated.

GETTERS AS PLASMA REAGENTS IN GLOW DISCHARGE MASS SPECTROMETRY (GDMS)
Yuan Mei and W.W. Harrison,
Chemistry Department, University of Florida, Gainesville, Florida 32611 USA.

INTRODUCTION: The use of compacted samples in glow discharge mass spectrometry (GDMS) for elemental analysis has extended the application of the technique. Non-conducting samples such as geologicals can be analyzed in compacted disc form by mixing them with certain metal powders. The presence of water, caused by its inevitable compression into the sample disc during the sample preparation process, is inherent to the method and quenches the signal to a considerable degree. In order to solve this problem, gettering materials have been chosen as the host matrices for their high performance in reducing gaseous impurities.

EXPERIMENTAL: Three metals with useful gettering properties were chosen to be sample host matrices: Ti, Ta and W. A mixture consisting of 10% La_2O_3 was prepared in a getter matrix. The mixture was shaken on a Wig-L-Bug for 3-5 minutes. A 4mm diameter disc was pressed at a pressure of 800-1000 psi and then mounted into a copper cup fixed on a probe tip. The probe was inserted into the ion source of a quadrupole mass spectrometer. An argon glow discharge was formed about 2-3 mm of the sample. Discharge parameters used were: 900 volts, 2.7 milliamps, 1.0 torr.

RESULTS AND DISCUSSION: Lanthanum oxide (La_2O_3) has been used as an analyte to evaluate the quality of several metals' "gettering" abilities. When sputtered into the discharge, La_2O_3 is detected by the mass spectrometer in two forms: La^+ and LaO^+ . The chemical components of the plasma, especially oxygen-bearing species such as water, have direct influence on the distribution of these two forms. Ratio R is defined as the atomic fraction: $R = \text{La}/(\text{La} + \text{LaO})$. Larger R, which is desirable for higher sensitivity of elemental analysis, can be achieved by the use of getters.

Figure 1

Metals of different gettering ability (Ag, C, W, Ta and Ti) have been mixed with 10% (weight percent) La_2O_3 ; matrix-dependent and time-dependent studies have been carried out. The "gettering" ability has shown an increase in the following order: $\text{Ag} < \text{C} < \text{W} < \text{Ta} < \text{Ti}$. Data are shown in Figure 1.

The mechanisms that getters undergo in the glow discharge have been studied with Ti. It is believed that sputtered Ti particles react with OH and H_2O as well as other "OH" involved clusters and remove them from the plasma. TiO , $\text{Ti}(\text{OH})_2$, $\text{Ti}(\text{OH})_3$, and $\text{Ti}(\text{OH})_3(\text{H}_2\text{O})$ molecules have been detected at early stages of sputtering. The decrease of these species along with sputtering time is accompanied by a simultaneous increase of R. This relation is shown in Figure 2 with TiO as an example. A chemistry process of La_2O_3 in the glow discharge is proposed to explain this phenomena in the following section.

Figure 2

At early stages of sputtering when a large amount of the current carriers is water-dissociated H_n^+ ions, both sputtering and ionization are insufficient. Fewer Ti atoms are introduced into the plasma at this time. La atoms, if sputtered off the target surface, are recombined with oxygen atoms when going through the oxygen-rich plasma to the exit orifice. These oxygen atoms come from two sources: water dissociation and preferential sputtering from the sample. Gaseous impurities decrease as gettering reactions of Ti continue. More

Ar^+ atoms become the majority of the current carriers resulting in higher sputtering rate. The atomization of Ti is enhanced, which, in turn, speeds up the gettering process. As the point in time is reached when the plasma is composed of more Ti atoms than oxygen-bearing species, the recombination of La and O becomes less competitive resulting in a fast increase of R. Since the water contained in the ion source can be treated as two parts: in the plasma and on the sample surface, experiments were also carried out to study which part was more crucial to the formation of LaO . As shown in Figure 3, a Ti disc with 50% La_2O_3 was sputtered at a relatively low power ($V=520v$, $I=0.7mA$, $P=1.0torr$). Signal ratios of H_3O^+/Ti and LaO^+/La decreased to 10 and 1.0 respectively after 250 minutes of sputtering. Discharge power was manually raised up to 900v, 3.0mA 50 minutes later. This action enhanced the absolute signals of H_3O^+ , Ti^+ and LaO^+ resulting in an increase in both H_3O^+/Ti and LaO^+/La intensity ratios simultaneously. Both ratios dropped to less than 0.05 after another 200 minutes. It suggested that being a major oxygen carrier, water affected the formation of LaO more directly when present in the plasma than on the surface.

Figure 3

The ability of getters to eliminate gaseous interferences in the glow discharge offers potential in the analysis of compacted materials. Metal oxides with high bonding energies, when mixed with gettering reagents, can be analyzed in atomic form. Detection limits are thus increased. With getters generating a plasma which is relatively free of gaseous impurities, a better understanding of the chemical process that metal oxides undergo in the glow discharge is realized.

Future investigation will emphasize on:

- (1) Ionization of La from La_2O_3 by introducing argon metastable quenchers into the plasma after the "clean" point is reached.
- (2) Time-resolved studies on gettering process in GDMS.
- (3) Further quantitative analysis of non-conductive material by using getters.

KINETICS OF ETHYLIDYNE FORMATION USING LITD/FTMS

C. L. Pettiette-Hall, D. P. Land, R. T. McIver, Jr. and J. C. Hemminger,
Institute for Surface and Interface Science and Department of Chemistry,
University of California, Irvine, CA 92717

Introduction

Our primary research goal is to probe the kinetics of chemical reactions on well-characterized surfaces and to identify the reaction intermediates which are present on these surfaces. We have approached this problem by coupling the techniques of laser-induced thermal desorption and Fourier transform mass spectrometry. The LITD/FTMS instrument uses an excimer laser to desorb molecular species from the surface and then ionizes and detects them with FTMS.¹ We present kinetic data on the conversion of ethylene to ethylidyne on Pt(111) which demonstrate that LITD/FTMS is well suited to the study of surface reaction kinetics.

The chemistry of ethylene on the Pt(111) surface is well characterized.² At low temperature (200K), ethylene molecularly adsorbs on Pt(111) with the C-C bond parallel to the surface. When the crystal is warmed to about 240K, the stable intermediate ethylidyne (CCH_3) is observed. At saturation coverages, thermal desorption of ethylene is observed with a peak maximum near 285K. The ethylidyne intermediate is stable on the surface up to temperatures near 450K, where it begins to lose hydrogen. Eventually complete dehydrogenation occurs, leaving only carbon on the surface.

We have measured the rate constant for the conversion of ethylene to ethylidyne on the Pt(111) surface at several surface temperatures (236K-274K) by using LITD/FTMS to monitor the change in the amount of ethylene on the surface as a function of time.

Experimental

The surface analysis LITD/FTMS instrument used for our experiments is a UHV chamber consisting of a bell jar and a side arm extension. The base pressure of the instrument is typically $< 7 \times 10^{-11}$ Torr. The bell jar is equipped with standard surface analysis equipment. The FTMS analyzer cell is located in the side arm extension, which is situated between the polecaps of a 0.6T electromagnet.

An experiment is begun by cleaning the Pt crystal and then cooling it to 210K. A near saturation coverage of ethylene is dosed onto the cold crystal, and it is moved 56cm down the side arm extension and positioned at a hole in one of the FTMS analyzer cell plates. A focused excimer laser beam (248nm) passes through another hole in the opposite cell plate and strikes the crystal. Low laser power is used ($\sim 2\text{mJ}$, focused to roughly $20\text{MW}/\text{cm}^2$) so that only neutral molecules desorb from the surface. The desorbed molecules are ionized by an electron beam, trapped in the analyzer cell by the magnetic field, and subsequently mass analyzed and detected by FTMS.¹ A complete mass spectrum from m/z 10 to 250 is acquired for each laser shot. The laser optics are adjusted so that the laser beam will hit a new spot on the crystal, and another LITD/FTMS spectrum is acquired. Several mass spectra are taken at 210K, then the crystal temperature is ramped (3-5 K/s) to the desired reaction temperature (between 236K and 274K) and is stabilized at that temperature while mass spectra are acquired from different spots as a function of time. As many as twenty non-overlapping spots can be probed during a given experiment. At the end of an experiment, the crystal is retracted into the bell jar and subjected to the cleaning and ethylene dosing procedures in preparation for another experiment.

Results

The rate of conversion of ethylene to ethylidyne was monitored by following the decrease in the laser-desorbed ethylene signal as a

function of time. Figure 1 shows the natural log of the absolute peak height for $C_2H_4^+$ as a function of time at five different isothermal reaction temperatures. The lines through the points are linear least squares fits to the data. Eight reaction temperatures were studied over a range from 236K to 274K. In each case, the ethylene was adsorbed at 210K, and the time $t = 0$ corresponds to the beginning of the crystal temperature ramp. Only data points accumulated after the crystal had reached the desired isothermal reaction temperature are plotted and fit. The decrease in the ethylene signal as a function of time is due to the conversion to ethylidyne. The reaction is expected to be first order with respect to ethylene coverage, and this is supported by the linearity of the kinetic data in Figure 1.

All the rate constant data were used to generate the Arrhenius plot in Figure 2. This plot gives an activation energy of 14.9 ± 1.4 kcal/mol and a preexponential factor of $4 \times 10^{10 \pm 1.2}$ /sec for the conversion of ethylene to ethylidyne on Pt(111). Recently T-NEXAFS³ and FTIR⁴ methods have been used successfully to probe this conversion reaction by directly monitoring the growth of the ethylidyne intermediate. Our results are in good agreement with both of these methods. ($E_a = 15.0 \pm 1$ kcal/mol and $\nu = 3.6 \times 10^{10}$ /sec by T-NEXAFS;³ $E_a = 14 \pm 1$ kcal/mol and $\nu = 10^{10 \pm 1}$ /sec by FTIR⁴).

Conclusion

We have presented the first rate constant measurements for a surface reaction using the technique of LITD/FTMS. The kinetic data show that FTMS is a sensitive and quantitative detection method and the combination of laser desorption with the FTMS detection provides a very powerful tool for studying surface reaction kinetics. LITD/FTMS is capable of following surface reactions on a short timescale, and because a complete, high resolution mass spectrum is obtained for each laser shot, the instrument can provide new insights on surface reactions which involve complex molecules or several surface species.

Laser Desorption on Pt Surfaces: Experiment and Theory

Diana T.-S. Wang, Donald Land, Claire Pettiette-Hall
John C. Hemminger and Robert T. McIver, Jr.
University of California, Irvine
Department of Chemistry

A computer model has been developed to calculate the temperature jump on a metal surface resulting from a pulsed laser irradiation. Using this model, one can calculate the temperature rise as a function of time and position. From the calculated temperature rise, the probability of desorption of surface species can be obtained. By comparing the calculated desorption probabilities as a function of the absorbed power density to experimentally obtained values (using LITD/FTMS spectrometer), we could obtain the activation energy and the pre-exponential factor for the desorption of ethylene and the decomposition of ethylidyne on a Pt (111) surface.

Many surface chemical studies are performed by heating a surface with an adsorbed overlayer to induce surface reactions and/or desorption of the adsorbates. The probability that a species desorbs or reacts is determined by the instantaneous relative rate for these two processes. We consider here only first order desorption and reactions (eg. dehydrogenation). The rates can then be represented by the Arrhenius rate law $k = \nu \exp(-E_a/RT)$ where T is the temperature of the surface and E_a and ν are the activation energy and the pre-exponential factor, respectively. For specific processes, values for E_a and ν are available either from literature or can be approximated. Values for T can be calculated from the differential equation of heat flow. The basic assumptions for laser heating are: 1) once laser radiation is absorbed by the substrate, and the energy is converted to heat instantaneously. 2) The energy is considered to be deposited on the surface, and the lateral diffusion of the heat is small compared to the size of the laser beam.

Based on these assumptions, the temperature jump induced by the laser on the Pt surface can be calculated. Figure 1 shows the calculated surface temperature, rate of desorption reaction and the desorption flux on a Pt crystal as a function of time and power density. It is clear that the maximum rate of reaction occurs at 20 nanosecond, i.e. at the end of the laser pulse, where the maximum temperature occurs. However, the maximum desorption flux does not always occur at the end of the laser pulse. At high laser power density, the surface temperature increases quickly enough so that the maximum desorption flux occurs before the end of the laser pulse, and most of the molecules on surface can be desorbed. In contrast, if the laser power is relatively low, the maximum desorption flux would occur where the temperature is the highest. This effect of the laser power density on the desorption flux is illustrated in Figure 1.

The spatial distribution of the laser beam also affects the spatial desorption probability. Figure 2 depicts the desorption probabilities as a function of power density for different spatial laser profiles: rectangular and Gaussian beam profiles. For the rectangular beam, the temperature rise is the same across the laser spot, but for Gaussian beam, the temperature has a Gaussian distribution across the laser spot. Therefore, with the same laser power density, the rectangular beam would have higher desorption flux than the Gaussian beam. This is seen in Figure 2, where the desorption probability increases more rapidly in the rectangular spatial profile. From this effect, one could determine the shape of the laser beam used in the laboratory by matching the theoretical results with the experimental data. This is advantageous for determining the spatial profile of a laser beam which is difficult to determine in the laboratory.

By extending this method, one finds that varying the activation energy and the pre-exponential factor of a desorption reaction also affects the shape of the desorption probability vs. the absorbed power density plot. One can match the calculated results to the experimentally obtained data, and the activation barrier and the pre-exponential factor can be obtained. Figure 3 shows this type of matching for ethylene desorption. The activation energy and the pre-exponential factor are found to be 13 kcal/mole and $5 \times 10^{12} \text{ s}^{-1}$, respectively. Similarly, the activation energy and the pre-exponential factor of the laser driven decomposition of ethylidyne are 25 kcal/mole and $5 \times 10^{12} \text{ s}^{-1}$. The estimated error for these values is approximated 15 % due to the uncertainty in the measurement of the absorbed power density in the laboratory.

Laser power density, spatial distribution of the laser beam, and the activation energy and pre-exponential factor of a reaction all affect the desorption probability. One can take advantage of these variables and match the calculations to the experimental data. As a result, one can obtain information about the spatial profile of the laser beam and the kinetic parameters of a reaction in a real experiment.

TOF-SIMS of Polymer Materials

D. van Leyen, B. Hagenhoff, E. Niehuis, A. Benninghoven
Physikalisches Institut, Universität Münster
Wilhelm-Klemm-Str. 10, D-4400 Münster, FRG

TOF-SIMS has turned out to be a promising technique for the surface analysis and structure characterization of polymer materials[1,2,3]. Systematic investigations have been performed for standard polymer samples of polystyrene (PS), polymethylmethacrylate (PMMA), polyethyleneglycol (PEG) and krytox with average molecular weights of $M_n = 10^3 - 10^6$ u

High molecular fragments and oligomers up to 10,000 u are preferentially emitted from noble metal supported polymer films. Maximum yields of cationized secondary ions (SI) are obtained from etched silver substrates with a surface coverage of $1 \mu\text{g}/\text{cm}^2$.

For polymers with $M_n < 10,000$ u fragment ions are usually formed by a single chain scission of the polymer backbone. Fragment ion formation of polymers with $M_n = 10^4 - 10^6$ u can be explained by multiple chain scission events. The distribution of molecular ion peaks ($n \times \text{monomer} + \text{endgroups} + \text{Ag}$)⁺ represents the oligomer distribution of the sample.

Transformation probabilities of PS- and PMMA- oligomers, i.e. the probability of a certain oligomer to be emitted as an intact molecular ion, decrease by almost two orders of magnitude between 1000 and 7000 u. For PEG a corresponding decay is observed in the mass range $m = 1500 - 4500$ u.

Primary ion bombardment (Ar^+ , 12 keV) of a monolayer of polymer material results in an exponential decay of SI-intensities with time: $I = I_0 \exp(-\sigma j_p / e \cdot t)$. Damage cross sections σ of cationized oligomers increase proportionally to the molecular ion mass from $\sigma(1000 \text{ u}) = 3 \times 10^{-13} \text{ cm}^2$ to $\sigma(7000 \text{ u}) = 15 \times 10^{-13} \text{ cm}^2$. The same values of σ are observed for cationized fragments of corresponding chain length.

Stable, reproducible SI-spectra of insulating bulk polymers (foils, powders, liquids) are obtained by TOF-SIMS with a self-adjusting charge compensation system [4]. Damage effects by the compensating electrons (20 eV) can be neglected in all cases.

SI-emission from polymer surfaces is usually restricted to the low mass range $m < 300$ u (PS, PMMA). A different behaviour is, however, observed for some F-containing polymers. For the krytox samples a C-O-bond cleavage with charge separation results in the emission of intense positive and negative fragment ion series with m between 200 u and 6000 u (see figure 1).

PI-bombardment of the krytox oils in the dose regime of $10^{12} - 10^{13}$ PI/cm² has no influence on absolute and relative peak intensities. A regeneration of the polymer surface by diffusion may be responsible for this effect.

An exponential decay of fragment ion yields with increasing PI-dose density is found for PMMA. Corresponding damage cross sections are in the range of $\sigma(31 \text{ u}) = 0.3 \times 10^{-13} \text{ cm}^2$ to $\sigma(185 \text{ u}) = 1.3 \times 10^{-13} \text{ cm}^2$.

TOF-SIMS spectra of bulk polymers with typical dose densities of 10^{11} PI/cm² can generally be attributed to the undestroyed polymer surface.

Figure 1: Neg. TOF-SIMS spectrum of a thick film of krytox ($M_n = 3900 \text{ u}$)

The Effects of Polyatomic Primary Ions on the Yield and Extent of Fragmentation
of Secondary Ions in Molecular Secondary Ion Mass Spectrometry

Owen W. Hand, Tapan K. Majumdar and R. Graham Cooks
Department of Chemistry, Purdue University
West Lafayette, Indiana 47907 U.S.A.

The translational energy, mass, and polyatomicity of the bombarding ion affect the yield and extent of fragmentation of secondary ions in molecular secondary ion mass spectrometry (SIMS). These effects are examined using Ar^+ , N_2^+ , CO_2^+ , CF_3^+ and SF_5^+ primary ions with analytes which included ammonium, arsonium, and phosphonium salts. As the energy of the bombarding ion is increased from 0.5 to 5.0 keV, the observed abundance of secondary ions increases, but the extent of fragmentation of the desorbed ions decreases. The SIMS spectra of $(\text{C}_6\text{H}_5)_4\text{PBr}$ at 0.5 and 5.0 keV CF_3^+ primary ion energies are shown in Figure 1. The intact cation (C^+) at m/z 339 and a $\text{C}_{12}\text{H}_9\text{P}^+$ fragment ion at m/z 183 are observed. As the CF_3^+ ion energy is increased from 0.5 to 5.0 keV, the observed secondary ion signal shows a forty-fold increase. The extent of fragmentation (339⁺/183⁺ ratio) decreases slightly as the CF_3^+ energy is increased. The SIMS spectra of $(\text{C}_6\text{H}_5)_4\text{PBr}$ at 0.5 and 5.0 keV Ar^+ primary ion energies are shown in Figure 2. As the Ar^+ energy is increased from 0.5 to 5.0 keV two dramatic effects are observed: (i) the observed secondary ion signal increases by a factor of ten and (ii) the extent of fragmentation decreases dramatically.

Figure 3 shows the observed ion abundance of the intact cation (C^+) of $(\text{C}_6\text{H}_5)_4\text{PBr}$ at 0.5, 1.0, 2.0, 3.0, 4.0 and 5.0 keV Ar^+ , N_2^+ and CF_3^+ ion energies. CF_3^+ is more efficient than either Ar^+ or N_2^+ at desorbing this ion. The efficiency of secondary ion production follows the general order: $\text{SF}_5^+ > \text{CF}_3^+ > \text{CO}_2^+ > \text{Ar}^+ > \text{N}_2^+$, which is the order of masses of these ions: 127 > 69 > 44 > 40 > 28. This suggests that the efficiency of secondary ion production is controlled by the primary ion momentum and not the number of atoms in the bombarding ion. Diatomic N_2^+ ions are less efficient at secondary ion production than monoatomic Ar^+ ions.

The extent of fragmentation increases with decreasing bombarding ion energy as a result of increased internal energy deposition at lower bombarding ion energy [1]. Figure 4 shows the ratio of the intact cation at m/z 339 to the fragment ion at m/z 183 from $(\text{C}_6\text{H}_5)_4\text{PBr}$ at 0.5, 1.0, 2.0, 3.0, 4.0 and 5.0 keV Ar^+ , N_2^+ and CF_3^+ ion energies. When Ar^+ or N_2^+ ions are employed, the extent of fragmentation decreases significantly as the energy is increased, but when CF_3^+ is employed, it decreases only slightly (as shown in Figure 1). At a given primary ion energy, the extent of fragmentation follows the general order: $\text{Ar}^+ < \text{N}_2^+ < \text{CO}_2^+ < \text{CF}_3^+ < \text{SF}_5^+$, which does not follow the order of increasing masses of the primary ions. Ar^+ is associated with the least amount of fragmentation even though N_2^+ has a lower mass. This effect is attributed to the polyatomicity of the primary ions. At a given energy, the extent of fragmentation is directly related to the number of atoms contained in the primary ion. For example, diatomic N_2^+ ions induce more fragmentation than monoatomic Ar^+ ions. This effect is attributed to the independent actions of the constituent atoms in the ion. For example, a 5.0 keV N_2^+ ion acts like two 2.5 keV N^+ ions during energy deposition into the analyte molecules at the surface, thus promoting more fragmentation of the secondary ions. This effect is even more pronounced when primary ions composed of more atoms, such as SF_5^+ and CF_3^+ are employed.

The decrease in the extent of fragmentation is directly proportional to the velocity (v), but is inversely proportional to the mass (m) and the number of atoms (n) in the primary ion. Figure 5 shows plots of the intact cation/fragment ion ratios of $(\text{C}_6\text{H}_5)_4\text{PBr}$, $(\text{C}_6\text{H}_5)_4\text{AsCl}$ and $(\text{C}_4\text{H}_9)_4\text{NBr}$ with respect to the factor v/mn . This factor accounts for the effects of kinetic energy, mass and polyatomicity of the primary ion. In each case, the extent of fragmentation decreases approximately linearly as v/mn increases.

ORGANIC SURFACE ANALYSIS WITH A TIME-OF-FLIGHT SECONDARY ION MICROSCOPE

B. Schueler, P. Sander, and R.W. Odum, Charles Evans & Associates,
301 Chesapeake Drive, Redwood City, CA 94063, USA

The analysis of organic surfaces by secondary ion mass spectrometry requires low primary ion exposures of the surface in order to avoid irreversible sample damage. Mass spectral analysis and measurement of ion distributions on biological samples is especially critical in this respect since the primary ion beam can cause topographical, as well as mass spectral changes of the substrate.

We have used a time-of-flight (TOF) secondary ion microscope for ion imaging and mass spectral analysis of such surfaces. The instrument is capable of transporting a magnified stigmatic image of the secondary ions produced at the sample surface to an imaging ion detector during the acquisition of the mass spectra. Secondary ion images and mass spectra can be acquired at primary ion doses of less than 10^{12}cm^{-2} , i.e. less than 0.1% of the sample surface is affected by the primary ion beam. The TOF ion microscope can be operated with imaged sample areas of $200 \mu\text{m}$ (magnification $m=60\times$) or $60 \mu\text{m}$ ($m=270\times$) diameter with lateral resolutions of up to $1 \mu\text{m}$. The mass resolution of the instrument is presently 3100 at mass 28. A detailed description of the experimental conditions is given by the authors in these proceedings.

This TOF-SIMS instrument can produce both elemental and molecular secondary ion images. Figures 1 through 3 illustrate the organic microanalytical capability of this instrument. Figure 1 is a positive ion TOF-SIMS mass spectrum of a residue of acetylcholine chloride (ACh-Cl) dispersed onto a silicon substrate. This spectrum contains the peaks at m/z 146, 129, 104 and 87 which are characteristic fragment ions produced in static SIMS analyses of ACh-Cl residues. The most intense peak in this group of fragments is the $(\text{M}-\text{Cl})^+$ ion at m/z 146. Figure 2 is a section of a positive secondary ion mass spectrum of thin sections of rat brain tissue. The sample was prepared by shock freezing and cryomicrotoming thin sections ($\sim 5 \mu\text{m}$ thick) which were subsequently freeze dried. The mass spectrum in Figure 2 was produced from the caudate putamen region which had been doped with approximately 2×10^{-7} moles/ cm^2 of acetylcholine Cl. The mass spectrum in Figure 2 also shows mass signals at m/z 104 and 146 which are characteristic for acetylcholine. Figure 3 shows three secondary ion images from the same region. These images were acquired using a specially modified resistive anode encoder (RAE) which provides a pulse counting, ion imaging detection capability. The intensities in the images shown are displayed in a gray scale. High secondary ion intensities correspond to darker regions of the images, whereas the white regions indicate that no ion was detected at this position.

The three positive ion images of Figure 3 include the total ion image along with the m/z 104 and the 146 cations produced from the ACh-Cl residue in the tissue. These images were acquired over a $200 \mu\text{m}$ diameter analysis area. If one assumes that the acetylcholine chloride doping of this tissue dispersed uniformly over the sample, these ion images represent sampling approximately 10^{-11} moles or less of the compound. The intensity distributions in the m/z 104 and 146 images correlate very well indicating that these ions are produced from the same regions on the sample surface. The lateral resolution in these images is on the order of $2 \mu\text{m}$ suggesting that molecular ion images of ACh-Cl could be produced at the cellular level. The signal of m/z 104 is, however not necessarily produced by a fragmentation of acetylcholine chloride since it could also be found in undoped regions of the rat brain section, as well as in other biological thin sections. The ion signal due to m/z 146 is not observed in the analysis of undoped caudate putamen regions of the rat brain (or other samples investigated) and is believed to be specific for ACh-Cl. We are currently exploring the use of the imaging TOF-SIMS technique for the localization of various catecholamines (e.g., dopamine, ACh-Cl, epinephrine and norepinephrine) within cellular regions of cancerous adrenal tissues (pheochromocytoma).

EVIDENCE FOR ION NEUTRALIZATION BY ELECTRON TUNNELING
IN THE DESORPTION OF SPECIES FROM POLYMER SURFACES

R.F. Nord and R.D. Macfarlane

Department of Chemistry, Texas A&M University
College Station, TX 77843

The desorption-ionization process in ^{252}Cf plasma desorption mass spectrometry (PDMS) has been found to be extremely surface sensitive(1). A molecule can give a small to nonexistent signal on one surface but may yield a significant peak when deposited on another surface. Little is known about these surface effects and how they influence the desorption-ionization process of different species. Molecules may desorb as neutral particles before being ionized or they may be desorbed as ions. Since molecules have several fundamental properties, there is likely to be a variety of desorption-ionization mechanisms based on a molecule's size, shape, composition, polarity etc. In this study the desorption-ionization process of I^- and CF_3SO_3^- from polyethylene terephthalate (PET), nitrocellulose (NC) and poly-3-methylthiophene (PMeT) and their modified surfaces have been investigated.

Samples were prepared by electrospraying(2) $10\text{nmol}/\text{cm}^2$ of salt onto the surface of interest. Surfaces were either the unmodified polymers or these polymers sputter-coated with 0.5 to 10nm of gold.

I^- exhibits very unusual behavior when deposited on PET and 0.5nm gold-coated PET. When CsI is deposited on PET the Cs $^+$ peak is easily seen while the I^- peak is very weak (Fig. 1a). If the PET surface is altered slightly by depositing 0.5nm of gold on it before depositing the salt, the I^- intensity increases by over 40 fold (Fig. 1b). The Cs $^+$ peak also increases but only by 8 times over that observed for the bare PET. If heavier coatings of gold are deposited onto the surface the intensities of I^- and Cs $^+$ start to decrease (Table 1).

The positioning of the gold layer is important. Experiments were performed in which CsI was electrosprayed onto 1nm gold-coated PET or in which 1nm gold was deposited onto the previously deposited salt. Both Cs $^+$ and I^- are attenuated when the gold layer is deposited over the salt but the Cs $^+$ peak was only attenuated by 13% while the I^- peak decreased by 83% (Table 2).

To see how other polymer surfaces effected this desorption process NC, oxidized PMeT, and reduced PMeT along with these surfaces coated with 0.5 or 10nm of gold were investigated. The important result obtained here is that all three surfaces showed an increase in I^- and Cs $^+$ intensity when going from their unmodified surface to their surface coated with 0.5nm of gold. There was no clear trend when CsI was deposited on 10nm gold-coated polymer but the ions of interest generally decreased on these surfaces.

LiSO_3CF_3 was also examined on PET, 0.5nm gold-coated PET and 10nm gold-coated PET. A similar but not as dramatic trend was observed as in the case of CsI. Although the initial CF_3SO_3^- peak was intense on the bare PET, the 0.5nm gold coating effected the desorption of CF_3SO_3^- as well as Li^+ enhancing each of their signals by 1.5 times that of the uncoated PET surface. When LiSO_3CF_3 was electrosprayed onto 10nm gold-coated PET the Li^+ and CF_3SO_3^- intensities were smaller than those of the salt deposited on uncoated PET. This decrease in ion intensity with an increase in gold coverage could be due to the fact that with heavier coatings of gold, gold can now act as a dissipator of energy and hinder the desorption process.

The above results can be explained in terms of electron tunneling through one of the proposed mechanisms. In the first case neutral species are desorbed from the surface. If an iodine atom desorbs, it must extract an electron from the surface. Since the electrons in the polymer surface are tightly bound it is difficult for the iodine atom to remove an electron. When gold is present, electrons are available

near the surface which can tunnel from the gold to the iodine atom forming a detectable species. On the other hand, Cs^+ has to lose an electron to the polymer surface and does this rather easily as seen by its intense peak on the PET surface; however, if gold is present Cs^+ can donate its electron more readily to gold's conduction band and is enhanced by this process. Thus in this case, gold can donate or receive electrons and enhance ion formation.

A second possible mechanism is that ions are desorbed from the surface and that the presence of gold prevents their neutralization. If I^- is desorbed a positive charge is left behind and there is the possibility for the electron in I^- to tunnel back into the surface. If gold is present, gold is able to donate its electrons to the positively charged site decreasing the probability of an electron tunneling from I^- . When Cs^+ departs the surface a negative charge remains. For this situation, an electron from the surface can tunnel to Cs^+ neutralizing it but when gold is present the excess electrons on the surface can be accommodated by gold and the neutralization of Cs^+ can be avoided. In this case, gold acts as a donor or recipient of electrons at the surface and prevents the neutralization of ions.

Electron tunneling is one possible mechanism for ion activation/deactivation. This study has shown that of the polymer surfaces examined, electron tunneling can occur and is influenced by the presence of small amounts of gold.

Figure 1. CsI electrospayed on (a) PET and (b) 0.5nm gold-coated PET. The presence of the gold enhances the I^- peak by more than 40 times.

Enhancement of Static FAB Spectra
Data of Azo Sulfonated Dyes

Shimanskas, C. Ng, K. Karliner J. and Jho, C.
Analytical Research Department

CIBA-GEIGY Corporation, Saw Mill River Rd., Ardsley, N. Y.

A study was initiated to find a matrix or procedure that would improve FAB spectral quality of polysulfonate and/or polysulfonic acid compounds, especially those of azo dyes. A commercially formulated sample, "Pergasol Red Mix76" exhibits a good FAB spectrum. The commercial sample is an aqueous solution of a disulfonated azo dye containing a small amount of triethanolamine. Intense ions relative to the glycerol matrix ion at m/z 551 were observed at m/z 526 and m/z 527 (figure 1). These ions represent the $(M-H)^-$ and $(M)^-$ ions respectively. Sodium adduct ions are also evident in the spectrum. Less intense ions relative to the glycerol ion were observed when the neat sample was analyzed (figure 2). The analyte of each sample was also found to have a significantly different surface activity in glycerol. When a glycerol matrix containing an azo dye is modified, its FAB spectrum may be enhanced. Figure 2A is an example showing the Pergasol Red neat material in a glycerol/DMF matrix. Its FAB spectrum and surface activity is better than that of the neat material in glycerol alone.

Fig. 1. Negative FAB spectrum of Pergasol Red "Mix76" in glycerol
(Surface Activity = 10.6 dyne/cm).

Fig. 2. Negative FAB spectrum of Pergasol Red neat material in glycerol
(Surface Activity = 2.1 dyne/cm).

Fig. 2A Negative FAB spectrum of Pergasol Red in glycerol/DMF
(Surface Activity = 2.2 dyne/cm).

Modifying the glycerol matrix appears to influence the surface activity of Pergasol Red and in turn its FAB spectral ion intensity.

Initially the commercially formulated sample labeled Pergasol Red "Mix76" revealed significant surface activity along with intense FAB spectral ions. After a prolonged period of time the surface activity and spectral ion intensity diminished. A laboratory formulation paralleling the commercial sample was prepared but did not duplicate the results of the original material.

An unknown highly surface active but volatile component is suspected to have been present in the original sample which has evaporated on standing. Work is planned to investigate the change in sample behavior with time and its possible connection to the presence of a volatile component.

A dramatic enhancement in spectral quality was achieved when an aqueous solution of the polysulfonic acid or sulfonate azo dye was passed through a cationic exchange resin column (1) prior to FAB mass spectral analysis (figures 3 and 4). Cibacron Red, which is a trisulfonated azo dye (empirical formula $C_{31}H_{24}ClN_7O_{10}S_3$) exhibits only low intensity high mass ion clusters in its FAB spectrum relative to the glycerol matrix peak at m/z 183. The material analyzed after column treatment exhibits a pronounced peak at m/z 784 corresponding to the $(M-H)^-$ ion of the free acid azo dye.

ON THE DYNAMICS OF LOW AND MEDIUM ENERGY COLLISION-INDUCED
DISSOCIATION OF IONS

Anil K. Shukla, Kuangnan Qian, Stephen L. Howard,
Stephen G. Anderson and Jean H. Futrell
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716.

Collision-induced dissociation (CID) of ions has greatly enhanced the role of mass spectrometry in analytical and structural chemistry over the past two decades. It has been the subject of numerous studies characterizing the process and the effect of various parameters, viz. collision energy, collision gas and gas pressure, internal energy, and angular scattering. With the advent of new ionization methods and high mass range mass spectrometers, CID has been extended to study large biological molecules. Our understanding of the CID process, though sufficient to apply it successfully for analytical applications, is incomplete except for diatomic and probably triatomic ions. It is essential to understand the dynamics of the collisional activation and dissociation process if it is to be applied universally to large polyatomic ions. In this paper we present some results on the dynamics of the CID process for acetone molecular ion in the medium and low energy range.

Experiments were performed on a tandem hybrid mass spectrometer described earlier [1]. Briefly, a high energy (3keV) ion beam from VG7070E double focusing mass spectrometer generated by 70 eV electron impact ionization is decelerated to the desired final energy and focused at the collision region where it collides with a supersonic neutral beam at right angles. Fragment ions are energy and mass analyzed at a series of scattering angles using a hemispherical energy analyzer and a quadrupole mass filter. Data are presented in the form of center-of-mass (CM) velocity contour maps.

Figures 1 and 2 show velocity contour maps for the dissociation of acetone molecular ion to acetyl ion at 40.9 and 10.3 eV collision energy respectively. The intensity maxima in both the figures lie in the forward scattering region at non-zero angles. The energy transfer into acetone ions (>4 eV), derived from P(T) curves, is many times more than the thermochemical threshold (0.65eV) even though the ions were generated by 70 eV electron impact. These results confirm an earlier observation [2] from CID of 5 keV acetone ion that the dissociation proceeds via low impact parameter collisions with extensive momentum transfer.

As the collision energy is lowered, the intensity maximum shifts from forward scattering to the backward scattering region and at energies close to thermochemical threshold almost all the ions are backscattered. Figure 3 shows such an example at 0.65 eV collision energy. This is the first observation of backward scattering in a CID process suggesting that very low impact parameters (nearly head-on collisions) can be accessed in low energy collisions. The consequence of such a phenomenon on the collection efficiency in CID would depend strongly upon the experimental conditions. Clearly the role of this new parameter in CID needs to be examined in detail. Experiments are currently in progress in our laboratory to explore whether this kind of mechanism is generally important in low energy CID.

DETECTION OF LONG-LIVED EXCITED STATES OF POLYATOMIC IONS IN MOLECULAR
BEAM STUDIES OF COLLISION-INDUCED DISSOCIATION PROCESSES

Kuangnan Qian, Julie Biggerstaff, Stephen Anderson, Stephen Howard,
Anil Shukla and Jean Futrell

University of Delaware, Newark, DE 19716

The energy distributions of product ions in ion-molecule reactions provide a direct assessment of energy available in the primary ions and utilized to drive these reactions. If the reactant ions is initially electronically or vibrationally excited, less translational energy is required to overcome the endoergicity of a reaction than in the case of ground state ions. The presence of such excited states can therefore be identified by measuring the relative translational energy differences between reactant and product ions. We have used this method to discern the role of internal excitation in collision-induced dissociation (CID) of acetone and methane molecular ions.

CID of acetone and methane molecular ions was studied by two different instruments. Acetone ion CID was performed on a recently developed hybrid tandem beam mass spectrometer[1] where a VG 7070E double focussing mass spectrometer generates a high energy (3 KeV) primary beam of acetone molecular ions. The ion beam was decelerated to the desired energy at the collision center by a series of cylindrical and rectangular tube lenses and then collided with a vertically moving supersonic beam of He neutrals. The fragment ions were energy and mass analyzed by a hemispherical energy analyzer and a quadrupole mass filter at different laboratory scattering angles. Methane ion CID was studied using a different crossed-beam apparatus[2]. The high-pressure ion source customarily used in this apparatus was replaced by a low pressure source to generate a methane ion beam with LAB energy 750 eV. The ion beam is decelerated to its final collision energy by an exponential lens and crossed at 90° with a supersonic neutral beam of Ar seeded with He. Energy and mass analysis of fragment ions were done by a 90° cylindrical energy analyzer coupled with a quadrupole mass filter.

Figs. 1 and 2 show the center of mass (CM) velocity contour maps for the dissociation of acetone ion into acetyl ion at CM collision energies of 0.65 and 0.45 eV respectively which are equal to and slightly below the thermochemical threshold of the reaction. If contributions of internal energy of acetone ion to the CID reaction are taken as negligible, the CID products will be observed only at the CM in the 0.65 eV experiment (with small reaction cross section) and no products will be observed in the 0.45 eV experiment. The fact that acetyl ions were observed in both experiments indicates that internal energy of acetone ion plays a key role in the CID process. The important and surprising observation from these contour maps is that acetyl ions are predominantly backward scattered with intensity maxima lying well outside the elastic scattering circle (ESC). This can only occur as a result of nearly head-on collisions with conversion of excess internal energy into kinetic energy. Analysis of the recoil kinetic energy of the CID product ions indicates that the conversion energy (internal to translational) is about 2.9 eV, which matches the internal energy content of acetone ions formed in the first electronically excited A-state. This observation strongly suggests the possibility of potential curve crossing which cause the de-excitation of acetone ions (A → X transition) with excess energy being released as kinetic energy. The superelastic backward scattered peak totally disappeared when the electron energy to generate acetone ions was lowered from 70 eV to 12.5 eV as shown in Fig. 3. Most of the observed CID products fell within the ESC and near the CM, confirming the excited state mechanism we propose.

Methane ion CID, on the other hand, shows three distinct maxima in the contour map (Fig. 4). The most important observation here is the peak beyond the ESC in the direction of the ion beam. This could be explained only by the existence of a long-lived excited state (2E (D_{2d})) of CH_4^+

which dissociated to the ground states of CH_2^+ and H_2 with excess energy released as the relative translational energy[3].

The above two cases demonstrate that the excited states of primary ions can play an unique role in CID processes which have not been realized before. More studies are required before a generalized explanation can be proposed.

ANGLE AND ENERGY RESOLVED COLLISION-INDUCED DISSOCIATION STUDIES
OF THE PROPANE MOLECULAR ION.

Stephen G. Anderson, Kuangnan Qian, Thomas H. Lehman, Anil K. Shukla,
and Jean H. Futrell: University of Delaware, Newark DE 19716.

The CID of propane was studied at high (keV) and low energies (<100 eV) using a triple sector tandem mass spectrometer and a hybrid crossed beam tandem mass spectrometer, respectively. The hybrid instrument uses a rotatable energy analyzer and quadrupole mass filter that characterize the CID daughter ions by energy, angle, and mass. The angular and energy distribution of each daughter ion can be observed and then mapped in center of mass (CM) coordinates.

Propane molecular ion is representative of polyatomic ions whose unimolecular decomposition is well described by the quasi-equilibrium theory (QET) of mass spectra. The collision-induced dissociation (CID) of the propane molecular ion is characterized by a quick vibrational excitation followed by a slow unimolecular decomposition. The results obtained are consistent with statistical (QET) predictions for ions with a significant amount of internal vibrational excitation. A modest amount of additional energy must be deposited by collision to induce dissociation. The daughter ions are forward scattered close to the elastic scattering circle (ESC). All daughter ions have maximum intensity at non-zero scattering angles. The amount of energy deposited in the collision process increases with the scattering angle. More endothermic daughter ions are scattered at larger angles and appear farther inside the ESC.

Figure 1 shows the distribution of $C_2H_5^+$ from the CID of propane ions with argon collision gas at 100 eV lab. The CM coordinate system is used and shows the ion intensity as a function of velocity about the CM. The CM collision energy is 47.5 eV and the radius of the ESC is 9,950 m/s. The maximum is at a CM scattering angle of 4 degrees and is 700 m/s off axis of the primary ion and is 250 m/s inside the ESC (2.4 eV). In studies at keV energies the energy deposited to produce mass $C_2H_5^+$ averaged about 1.7 eV corresponding to a velocity shift of 20 m/s inside the ESC and accompanied by a velocity spread of 300 m/s resulting from kinetic energy release.

Figure 2 displays the distribution of $C_2H_5^+$ ions resulting from collision of propane ions with helium at 100 eV lab. At this lab energy the CM collision energy is 8.3 eV. The ESC has a radius of 1740 m/s. The $C_2H_5^+$ peak maximum is at a CM scattering angle of 27 degrees and 290 m/s inside of the ESC (2.5 eV) and 700 m/s off axis of the primary ion beam. The distribution is similar to the one obtained from argon collision gas but the velocity spread parallel to the primary ion beam is broader while the velocity spread perpendicular to the primary ion beam is narrower. Distributions obtained at 13.5 eV lab with neon collision gas are also centered 850 m/s off axis of the primary ion velocity vector.

The distribution of $C_2H_4^+$ from collisions of propane with argon at 100 eV is shown in figure 3. The maximum intensity is shifted 340 m/s from the primary ion beam and is 170 m/s inside the ESC (1.6 eV). The maximum intensity is at a CM scattering angle of 2.0 degrees. At keV energies the propane ions are excited by 1.0 eV to produce $C_2H_4^+$ which is a shift in velocity of 12 m/s. At this collision energy $C_2H_4^+$ has a velocity spread of 270 m/s due to kinetic energy release. $C_2H_4^+$ is scattered through smaller angle and has less energy deposited than $C_2H_5^+$.

The angular distribution of the CID process results from the superposition of scattering from collisions and release of kinetic energy when a neutral fragment is ejected from the parent ion and the daughter ion is formed after several vibrational periods of the excited parent ion. It is difficult to separate the contribution from scattering from the contribution of energy release. From the diagrams mentioned above it is apparent that the velocity spread from energy release is less than the velocity spread caused by angular scattering for $C_2H_5^+$.

The result obtained at intermediate and high energies are consistent with studies performed at eV energies. No change in mechanism is discernable between eV and keV CID. The systems studied show significant off axis

scattering from collisions and kinetic energy release. The off axis velocity for $C_2H_5^+$ is remarkably insensitive to changes in CM collision energy. Our prediction is that any difference in CID spectra between beam and quadrupole methods are the result of different acceptance angle of these two methods. The angular and velocity distributions resulting from the CID process must be convoluted with instrumental angular and energy transmission functions to explain the difference in data collected by beam methods and by triple quadrupole instruments. Furthermore the relative abundances of the daughter ions observed should be sensitive to the acceptance angles and energy bandpass of the instrument used to observe the CID process.

ACCELERATION REGION PROCESSES

R.E. March, R.J. Hughes*,
Department of Chemistry, Trent University
Peterborough, ON, Canada K9J 7B8

*Registered at Queen's University, Kingston, ON, Canada

The method of Acceleration Region Kinetics (ARK), has been applied to investigations of uni-molecular fragmentation of nitrous oxide molecular ions, n-butylbenzene and nitrobenzene-d5[1,2]. The ARK technique is similar to that of Field Ionization Kinetics (FIK) and has the advantage that it may be used with a standard Nier-type source.

In the reaction

unimolecular dissociation occurs when m_1^{z++} has fallen through a fraction b of the accelerating potential V_0 ; the daughter ion falls through the remaining fraction $(1-b)$. When $b = 0$, m_2^{y+} is formed in the source; when $b = 1$, m_2^{y+} is formed in the 1st FFR and the apparent mass/charge ratio is given by $m^* = m_2^2 x / m_1 y^2$. For decompositions throughout the acceleration region the apparent mass-to-charge ratio, m_b^*/e , is given by

$$\frac{m_b^*}{e} = \frac{m_2}{ye} \left[\frac{m_2 x}{m_1 y} b + (1-b) \right] \quad (2)$$

The kinetic energy of the fragment when it exits the acceleration region will be:

$$KE_{m_2} = \left[\frac{m_2}{m_1} x b + y(1-b) \right] eV_0 \quad (3)$$

and the ion will be passed at an ESA setting E_b such that

$$E_b = \left[\frac{m_2 x}{m_1 y} b + (1-b) \right] E_0 \quad (4)$$

The value of b , may be calculated from equation (5):

$$b = [(1 - E_b/E_0) / (1 - m_2 x / m_1 y)] \quad (5)$$

When the process is a charge stripping or charge exchange reaction, as opposed to a decomposition, then the relevant settings of the mass spectrometer are given by:

$$m_b^* = \frac{m_2}{y} (1-b) \quad (6)$$

$$E_b = y(1-b)E_0 \quad (7)$$

A plot of m^* vs. E is referred to as an ion incidence map. Such maps are employed to investigate processes which occur throughout the acceleration region such as:

- (1) half-lives of fast decay processes not seen in conventional mass spectra [1,2]
- (2) field ionization of Rydberg states *e.g.* $Ar^{z+} \rightarrow Ar^{z+}$ by the accelerating field of about $10^4 V cm^{-1}$: A linear pressure dependence suggested that Ar^{z+} ions may be created in this manner, but the results have not been conclusive.
- (3) estimation of ion residence time in the Nier-type source of a mass spectrometer: Comparison of ARK results with those of FIK are being carried out in the hope of determining the absolute age of the ions detected. Compounds employed so far include n-butylbenzene, methyl cyclopentane and cyclohexene.
- (4) an investigation of the production of F^- from SF_6^- : The same diagrams constructed for positive ions may be employed for the study of negative ions. SF_6 has been chosen for study because of its high cross-section and because it has been studied extensively with other techniques.

Figure 1. Ion incidence map for nitromethane. The parabola is the locus of all decompositions of the parent ion m/z 61. The line segments represent acceleration region processes for the production of the ion indicated. The points of intersection are located at the terminal point of the acceleration region process: that is, where $b = 1$ and the process occurs in the first field-free region (FFR1).

Signals encountered during Ion Kinetic Energy scans may be plotted on the map and thus the mass of the product ion can be determined.

Figure 2 (below) shows a schematic representation of the acceleration region kinetics (ARK) technique. The production of daughter ions, m_2^{v+} , is measured throughout a window, Δb , which is very narrow. Kinetic data collected in this region is related to a time in the life of an ion which is earlier than that of FFR1 processes. The window is of the order of 10^{-7} s wide and the resolution is of the order of 10^{-5} s.

A COMPARISON OF INTERNAL ENERGIES OF IONS FORMED BY CHARGE INVERSION COLLISIONAL
ACTIVATION AND DIRECT EXCITATION BY COLLISIONAL ACTIVATION

Fred Strobel, D. L. Bricker, D. H. Russell
Department of Chemistry, Texas A&M University, College Station, TX 77843

Collision induced dissociation has developed as a useful analytical technique; however, for high molecular weight species, it is desirable to deposit large amounts of energy into the ion. The amount of energy deposited can be increased by using multi-collision conditions (e.g., high collision-gas pressures or long collision cells), but such methods reduce sensitivity and could lead to unwanted complications of the data (e.g. thermal rearrangements reactions, etc.). Another approach that has not been extensively evaluated is charge-inversion collisional activation. An evaluation of the mechanism of charge-inversion collisional activation is performed with emphasis on the energetics of the charge-inversion process.

All experiments were performed on a Kratos MS-50TA. Positive ions were formed by electron impact, but the negative ions were formed by dissociative electron transfer. The charge-inversion spectra were obtained by mass selecting a negative ion, colliding the ion with a neutral target atom (keV collision energy). The mass-analysis of the positive ions formed by the high energy collisions is accomplished by reversing the polarity on the second ESA and energy analyzing the resulting positive ions.

The high amount of energy deposited in the charge-inversion reaction is observed from a comparison of the positive and negative ion collision induced dissociation with the charge inversion spectra. The products of the charge inversion reaction correspond to a high degree of fragmentation of the reactant ion, for example, the most abundant ions in the charge inversion spectra of $\text{Fe}(\text{CO})_4^-$ and $\text{Cr}(\text{CO})_6^-$ are $\text{M}(\text{CO})^+$ and M^+ ($\text{M} = \text{Fe}, \text{Cr}$); however, $\text{M}(\text{CO})^{+/-}$ and $\text{M}^{+/-}$ are less than 4% of the total ion current in the collisional induced dissociation spectra of $\text{Fe}(\text{CO})_4^+$, $\text{Cr}(\text{CO})_6^+$, $\text{Fe}(\text{CO})_4^-$ or $\text{Cr}(\text{CO})_6^-$.

Other evidence for the deposition of large amounts of energy in the charge inversion reaction can be estimated by energy loss measurements. The energy loss value is calculated using equation 1;

$$\Delta E = e(V/E_0)(m_f/m_p)(E_1 - E_2)$$

where V is the ion source accelerating potential, E_0 is the potential of the electrostatic analyzer and $E_1 - E_2$ is the energy shift in electrostatic units. Figure 1 shows a plot of the energy loss accompanying charge inversion for several systems the data is presented as a function of the ratio of fragment ion mass to parent ion mass. The energy loss value correlates with the energetics of the dissociation reaction. For example, the energy loss observed for Fe^+ is greater than that observed for $\text{Fe}(\text{CO})^+$. Conversely, collision induced dissociation is accompanied by very small energy loss, and, to a first approximation, is independent of the fragment ion mass.

The excess energy used to induce the charge inversion reaction arises by multiple collisions with the target gas. Pressure studies of the charge inversion signal were consistent with multiple collisions. For example, the relative intensities of the product ion in the charge inversion spectrum of $\text{Fe}(\text{CO})_4^-$ were monitored as a function of the percent attenuation of $\text{Fe}(\text{CO})_4^-$ (pressure). A significant increase in the low m/z ions is observed. Also, the relative abundance of $\text{Fe}(\text{CO})^+$ (normalized to $\text{Fe}(\text{CO})_4^-$) increases with the percent attenuation with both helium and argon collision gases (Figure 2). Note that the charge inversion signal is very small until the main beam is attenuated by more than 10%.

In conclusion, charge inversion collisional activation deposits large amounts of energy into the ion, but the mechanism for energy deposition is multiple collisions, which can reduce sensitivity and lead to unwanted complications of the data. To our knowledge the mechanism of charge inversion has not been determined, but two plausible mechanisms are; i) electron detachment followed by collisional ionization and fragmentation of the re-ionized species, or ii) electron detachment, collision induced dissociation of the neutral fragments followed by reionization of the neutral fragments. Note that both mechanisms are multi-collision processes; therefore, both proposed mechanisms are consistent with the results presented in this paper.

COLLISION INDUCED DISSOCIATION VERSUS TARGET GAS EXCITATION : A REINVESTIGATION OF KINETIC ENERGY LOSS ACCOMPANYING ACTIVATION OF CHLOROPHYLL-a IONS.*

A.J. Alexander, R.K. Boyd and P. Thibault
National Research Council of Canada, Halifax, Nova Scotia, B3H 3Z1, CANADA.

The dissociation of precursor ions collisionally activated by keV collisions with a neutral target gas is often characterized by a substantial translational energy loss (ΔE_F) of the projectile ion (1). The extent of this energy loss was recorded by Bricker and Russell (2) for the major fragmentation pathway of chlorophyll-a ($m/z:893 \rightarrow m/z:614$) using different collision gases. They found that the translational energy losses for this fragment (ΔE_F), recorded via a mass-analyzed ion kinetic energy (MIKE) scan, progressively increased as Kr, Ar, Ne and He were successively used as targets. When these results were used to calculate the corresponding translational energy loss undergone by the precursor ion [$\Delta E_F = \Delta E_F \times 893.5/614.2$] (1), values remarkably close to the ionization energies (I.E.) of the respective target gases were obtained. This was interpreted (2) as evidence that, in the keV collision energy regime, CA of the precursor ion and excitation of the collision gas via ionization are competitive processes.

There are several reasons why experimental results of this nature are at best ambiguous and should be treated with caution. Firstly each CID MIKE peak obtained previously (2) represents a composite of fragment ions formed by unimolecular dissociations occurring throughout the length of the field-free region, together with fragment ions formed via CID processes (3). Consequently the energy loss measured as a simple displacement of the MIKE peak when gas is added to the collision cell does not represent the true value of ΔE_F . In fact the observed displacement will depend on the relative lengths of the field free region and the collision cell, on the relative ion optical collection efficiencies from these two regions, and on the degree of precursor ion attenuation (3). If provision is made to electrically float the collision cell these two components can in principle be separated (3). Secondly the values for ΔE_F were obtained (2) from single scans of the appropriate region of the MIKE spectrum with inherently poor signal to noise ratios. Thirdly, the ΔE_F value for xenon as collision gas was not reported (2) and no data were presented for any diatomic gases. In order to clarify these ambiguities it was decided to repeat these experiments with and without electrical floating of the collision cell, with multi-channel accumulation (MCA) of successive MIKE scans, and with a wider range of collision gas types.

MIKE spectra were recorded using a VG Analytical ZAB-EQ tandem mass spectrometer under the following conditions: initial translational energy of the precursor 7936.0 eV; energy width of precursor ion beam, measured at double-focus point in the absence of collision gas, 5eV at half peak height; attenuation of precursor ion ~ 50%

Figure 1 illustrates typical results obtained with the collision cell at ground potential. On addition of collision gas the peak maximum is not only shifted to a lower energy, but the resultant MIKE peak is now asymmetric. As expected (3) the shift varies with the degree of attenuation of the precursor ion; for example with helium as target gas ΔE_F was found to vary from 6eV at 15% to 15eV at 90% attenuation. If the collision cell is floated at -700 V the MIKE peak shown in Figure 1(a) splits into a number of components (labelled B, C and D) as shown in Figure 2(a) [peak A corresponds to a different fragment mass than m/z 614]. Peak B was identified as corresponding to unimolecular dissociations occurring within the floated cell. Peak C, whose shift is also a function of the float potential but not in accordance with that expected for dissociations occurring within the cell (3), is possibly due to dissociations occurring in the fringe-field between the floated cell and ground. Figures 2(b) and 2(c) show the results obtained with He and Xe respectively as collision gases. The shift in the peak maximum of the true CID component (peak B) from its unimolecular value can now be used to evaluate ΔE_F . This shift was found to be invariant to increasing collision gas pressure. The calculated values for ΔE_F obtained with Ne, Ar, Kr and Xe as collision gases were the same within experimental error. The values obtained for H_2 , D_2 and He were also indistinguishable from one another, but were appreciably larger than that obtained for the heavier gases. The present results are displayed graphically as a function of I.E. in Figure 3 and unambiguously show that there is no correlation between the translational energy loss of the precursor ion (either M^+ or MH^+) and the I.E. of the target gas. In particular both H_2 and D_2 give practically identical shifts to that obtained for He, but have considerably lower ionization energies. Also the shift obtained with Ne is closer in value to that observed with the heavier targets yet its I.E. is only 3 eV lower than that of He.

* NRCC #30275

Compared to previous work (2) this study was conducted with several instrumental advantages; a floatable collision cell, an MCA facility and a tandem quadrupole for unambiguous mass analysis. While the complete interpretation of the results summarized in Figure 3 is open to debate, the earlier interpretation (2), in terms of target gas excitation as a necessary accompaniment to CID of chlorophyll-a ions, is now seriously in doubt.

INTERNAL ENERGY UPTAKE OF SURVIVING IONS FROM KILOVOLT COLLISIONS*

Alexander A.J.¹, Boyd R.K.¹, Thibault P.¹, Tomer K.B.²

¹National Research Council of Canada, Halifax, B3H3Z1; ²Laboratory of Molecular Biophysics, NIEHS, P.O. box 12233, Research Triangle Park, NC 27709

Collisional activation (CA) of ion beams in the kilovolt energy range with target gas gives rise to a wide variety of competing reactions. A proportion of the excited projectile ions will survive the collision without dissociating during the time frame of observation ($\approx 10^{-5}$ s after collision). These survivors have experienced at least one collision which could in turn result in a substantial loss of their translational energy (ΔE). Their energy distribution as observed in the MIKE spectrum is superimposed on those precursor ions unaltered by their journey in the flight tube. These mixed energy profiles account for the shoulder observed on the low energy side of the precursor peak [1-3].

In addition to their translational energy profiles, surviving ions differ from the unaltered precursors by their internal energy content [4]. An example of such a phenomenological observation is illustrated in Figure 1 for the formation of the A_4 and B_4 fragments from CA of Leu-enkephalin impinging on He. The upper part of Figure 1 shows the main beam profile obtained on an hybrid BEqQ tandem mass spectrometer with and without collision gas. The fragment ions A_4 and B_4 resulting from the unimolecular dissociation in q (rf only collision cell) of precursor ion having selected ΔE values are shown in the lower part of Figure 1. It is observed that as ΔE is progressively increased from 0 to 20 eV, the intensity ratio of 397/425 rises from a value of 0.3 to 1.1. Similar observations were made when the same experiment was repeated on a 4 sector tandem mass spectrometer of BEEB geometry. However in the latter situation the relative increase of the 397/425 ratio as a function of ΔE was less pronounced, probably reflecting the different time frame of observation for these two instruments.

The internal energy uptake of surviving ions of different ΔE values was estimated using the intensity ratio of fragment m/z : 91 and m/z : 92 from *n*-butyl benzene obtained on a 4 sector instrument. The relative increase of this ratio with ΔE was compared with the calibrated energy "thermometer" from PEPICO experiments [5]. Thus it was estimated that precursor ions of $\Delta E=12$ eV apparently had 0.6 eV of internal energy. One possible explanation for this lack of correspondence of ΔE with internal energy is that in the usual MIKES experiment no collimation is made in the non-focussing z direction. This lack of collimation would result in the transmission of ions having a broad range of scattering angles, which in turn translates into detection of ionic species having less internal energy uptake than that calculated directly from the value of ΔE estimated from the difference in sector plate potentials. In addition, of course, some of the inelasticity must end up as kinetic energy of the target.

This was investigated by analyzing the main beam energy profile of m/z :912 CsI cluster, and of m/z : 343 from perdeutero acetyl galactose, as a function of z direction using an angle resolving slit prior to the collector. Figure 2 illustrates the distribution of the precursor beam from m/z : 912 upon CA with He projected on the y - z plane. It can be observed that as the angle-resolving slit is progressively moved away from the central ion trajectory, the energy profile becomes broader. Furthermore as the slit position approaches a value of 3 mm the mixed ion profiles composing this peak tail are resolved into two components B and C, corresponding to the unscattered and scattered species. When the same experiment was repeated with Ne or Ar as target gas two changes were immediately obvious. First the energy profile of scattered ions lay much closer to the unscattered ion distribution for any z position. In order to achieve the resolution of B and C profiles with Ne collision gas, it was necessary to move the slit further out toward 4 mm, whereas using Ar collision gas no resolution could be achieved within the limit of the instrument (z direction). Secondly, the low energy tail of scattered ions was less intense compared to the situation when He was used as target gas.

The information accumulated thus far concerning the extent of internal energy uptake of survival ions in kilovolt collisions by MIKES indicates that measurement of a ΔE value, via sector potential measurements cannot be quantitatively transposed into excitation energy of the precursor ion. In the absence of z collimation this disparity is likely to be more severe when He is used as a target since a larger distribution of scattered ion species will be transmitted for a given offset of electric sector field (apparent ΔE).

REFLECTION OF POLYATOMIC IONS UPON COLLISIONS WITH SURFACE

By: Sohrab Habibi-Goudarzi and R. Graham Cooks, Aston Laboratories, Chemistry
Department, Purdue University, West Lafayette, IN 47907.

In 1985, a BQ hybrid mass spectrometer (Fig. 1) was developed for the study of polyatomic ion/surface interactions.¹ This instrument uses a solid surface in the second field free region to induce collisional activation (CA) of the incident mass-selected parent ion. A surface as a collision partner is superior to a collision gas in many respects. For example, surface collisions deposit a larger portion of the laboratory kinetic energy in the ions as internal energy with a narrower energy distribution than those of comparable experiments using gaseous targets for collisional activation.² Furthermore, the BQ instrument includes capabilities for linked scanning the two analyzers.³ This allows reflection of ions to be studied in a single mass scan and the present study utilizes this procedure to study polyatomic ion stability upon collision (typically at 35 eV) with a stainless steel surface. The information gained leads to a better understanding of the nature of ion/surface collisions including the competition between surface-induced dissociation and neutralization.

Figure 2 illustrates the four types of experiments performed. All are identical in the first step of mass analysis, i.e. ions produced in the EI source are mass analyzed by scanning the acceleration voltage at a fixed magnetic field strength. The ions are either allowed to collide with the surface (in reflection mode) or to avoid it (in deflection mode) by varying the extraction lens potential after the surface. Before reaching the detector, the ions traverse a quadrupole mass filter either linked to the first analyzer in a neutral loss of zero scan or operated in the rf-only mode. In the Reflection Spectrum (Fig. 2a), the two analyzers are linked and only those ions which survive collision upon the surface without a change in their mass-to-charge ratio or charge state are recorded. When the ions are steered past the surface without collision, the spectrum is referred to as linked analyzer Deflection Spectrum (Fig. 2b). In contrast, when the quadrupole is operated in its rf-only mode, all ions emerging from the surface reach the detector. If collision upon the surface is permitted, the spectrum is modified by the extent of neutralization (or charge changing, in general) of an incident ion, without contribution from fragmentation, and is referred to as the Reflection and Dissociated Ions Spectrum (Fig. 2c). Otherwise, the mass spectrum is obtained which is also labeled as single mass analyzer Deflection Spectrum (Fig. 2d).

Two examples are offered in Fig. 3 and 4. Comparison of the percent relative abundances of ions in the linked analyzer deflection and reflection spectra of phenetole (Fig. 3) reveal that m/z 63 reflects particularly well. Other particularly stable ions include $C_6H_5^+$ (m/z 50) and $C_6H_7^+$ (m/z 65). These ions are less susceptible to fragmentation or neutralization and thus reflect in greater yield than other ions in the spectra. Some ions which reflect well have an even number of electrons others do not. Molecular ions and saturated hydrocarbon ions are relatively unstable in the reflection spectrum. Comparison of the reflection spectrum of phenetole with the spectrum of reflected and dissociated ions reveals that charge changing (neutralization) is the major loss process except that m/z 79 and m/z 66 dissociate readily. Results obtained for limonene (Fig. 4) show that the even-electron ion $C_{10}H_{17}^+$ (m/z 67) and the odd-electron ion $C_{10}H_{15}^+$ (m/z 68) have nearly equal abundances in the deflection spectrum but only the former even electron ion reflects. On the other hand, $C_{10}H_{13}^+$ dissociates extensively while $C_{10}H_{11}^+$ does reflect well. From these data and others, it is clear that the ease of neutralization with the surface does not parallel that of gas phase charge exchange processes although the ease of dissociation can be predicted from a knowledge of gas phase collisional activation.

EVALUATION OF PHOTON INDUCED DISSOCIATION IN A FOUR-SECTOR MASS SPECTROMETER.

S.A. Martin¹, J.A. Hill², C. Kittrell³, K. Biemann²

¹Genetics Institute, Andover, MA 01810; ²Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139; ³Rice University, Houston, TX 77005

Since the installation of the tandem mass spectrometer at M.I.T. we have acquired the collision induced dissociation (CID) mass spectra of numerous samples from a variety of compound classes in the mass range from 100-3500 daltons. During these studies parameters such as collision gas and collision energy have been varied in an effort to define the limits of this process. A major limitation is the decreased efficiency of fragmentation with increasing mass, estimated to be only a few percent at m/z 2000. This is thought to be a consequence of the increased degrees of freedom available to dissipate the energy with increasing mass, fixed maximum kinetic energy of the precursor ions (10 kV in the JEOL HX110) and the limited amounts of collision gas which can be introduced into the high vacuum region. In an attempt to overcome the problems associated with the gas collision process, we have investigated the feasibility of photon induced dissociation (PID) at 193 nm in a magnetic tandem mass spectrometer.

There have been several reports of PID of underivatized peptides using excimer lasers in ion storage devices (1,2), however, the experimental parameters necessary to determine if it would be a useful technique for tandem magnetic deflection instruments have not been defined. Therefore, the efficiency of PID, the effect of laser power on the type and extent of fragmentation and a comparison with gas collisions at the same sampling frequency were investigated on a JEOL HX110/HX110 tandem mass spectrometer equipped with a multichannel array detector (3). A collision cell was constructed that can be electrically floated to 10 kV and permits either laser or gas induced fragmentation. Preliminary experiments were performed with a model R2440 excimer laser on a two week loan from Questek, Inc. Billerica, MA. This laser has a 15 nsec pulse width, 100 Hz repetition rate and 275 mJ maximum power at the wavelength employed in these experiments, 193 nm. The laser emits a beam profile of 25x6 mm which is collimated by a cylindrical lens to a 22x0.5 mm photon beam profile at the point of intersection with the ion beam. The laser beam enters the mass spectrometer through a 14 cm diameter fused silica window located directly above the collision cell. In the interaction region the laser beam is perpendicular to the plane of the ion beam and its long axis is parallel to the ion flight path. The 193 nm line of the excimer laser was chosen because peptides absorb strongly at this wavelength and it has sufficient energy to cleave a chemical bond.

Due to the low overall sampling frequency in our initial experiment, 0.01% compared to conventional gas collisions, we were limited to recording PID MS/MS spectra of samples which produced abundant secondary ion yields in MS-1. One such example, angiotensin III produced a PID MS/MS spectrum which exhibited all the fragments that are observed in a conventional gas collision experiment, i.e. a_n and d_n , including the d_4 ion for Ile (Figure 1b). Furthermore, the overall sensitivity of the PID spectrum was significantly better than that of a CID MS/MS spectrum acquired with the same low duty cycle (Figure 1c). A plot of the relative abundance of the precursor and product ions as a function of laser power (Figure 2) showed increasing immonium and decreasing high mass ion abundance with increasing laser power and vice versa. These data indicate that PID is a viable technique. Presently modifications are being made which will increase the effective PID duty cycle from 0.01 to 5-10%. These modifications will be combined with a pulsed Cs^+ gun which will produce precursor ions only when the laser is on. This will result in an effective laser/ion beam interaction frequency of unity and permit a detailed comparison of PID versus CID MS/MS.

FIGURE 1. Comparison of the efficiency of PID versus CID MS/MS for Angiotensin III (Arg-Val-Tyr-Ile-His-Pro-Phe, M_r 930). In A-C, the precursor ions are pulsed into the collision cell at 100 Hz with a pulse width=2.2 μ sec (T_2 , Figure 4). A) Laser off, B) laser on, 6.8 mJ/pulse and C) helium collision gas. D) Conventional helium collision spectrum. The same integration time was used for the acquisition of all four MS/MS spectra.

FIGURE 2. Plot of the change in relative abundance of the precursor ion of Angiotensin III $(M+H)^+$ and several of its' product ions, a_4 and d_4 , and the immonium ions for Val (V) and Pro (P), as a function of laser power (mJ/pulse) for PID MS/MS. As the laser power increases the yield of the immonium ions increase while the $(M+H)^+$ and higher mass fragment ions decrease in relative abundance.

MEASUREMENTS OF DAUGHTER ION MASS SPECTRA IN A REFLECTING TIME-OF-FLIGHT MASS SPECTROMETER

Xuejun Tang, Werner Ens and Kenneth G. Standing
Physics Department, University of Manitoba, Winnipeg, Canada R3T 2N2

Measurements of daughter ion mass spectra arising from decomposition of a given parent ion provide useful structural information about the parent. Such measurements can be carried out on a reflecting time-of-flight mass spectrometer [1] by determining the correlation between neutral and charged daughters from decomposition of parent ions in the first leg of the flight path. This gives information about the decay paths of the parent ions.

Efficiency of the Correlated Measurement (MS/MS)

For a given decay, the number of events when both neutral and charged fragments are detected is measured by the number of counts (N_{coin}) in that peak in the correlated spectrum. The total number of daughter ions detected from this decay (N_+) is measured by the number of counts in the corresponding peak in the overall reflected spectrum. $\epsilon_n = N_{\text{coin}}/N_+$ is therefore a direct measure of the efficiency of detecting a neutral fragment when the corresponding daughter ion has been detected. Fig. 1 shows the ratio N_{coin}/N_+ as a function of m^*/m for $[M+H]^+$ and $[M+Ag]^+$ decay in GGF (m^* and m are the masses of the daughter ion and parent ion, respectively). As might be expected the efficiency decreases as the energy of the neutral fragment becomes smaller.

The total number of neutrals detected from decay of a given parent ion N_n is given by the number of counts in that peak in the neutral spectrum. The ratio of $N_{\text{coin total}}$ to the total number of neutrals detected gives the average efficiency $\epsilon_+ = N_{\text{coin total}}/N_n$ for detecting charged daughters from the decay of a given parent when the corresponding neutral fragments have been observed. Fig. 2 shows the average efficiency for detecting charged daughters as a function of secondary ion acceleration voltage for $[M+H]^+$ and $[M+Na]^+$ decay in GGF.

Recently we reported our first measurement of the efficiency of such correlated measurements [2]. This has now been considerably increased by enlarging the front aperture of the ion reflector and increasing the acceleration voltage of the secondary ion to increase the transmission and the detection probability. If we assume the efficiencies for detecting the neutral and charged daughters are independent, we may estimate the overall efficiency for detecting both charged and neutral fragments from any decay as the product $\epsilon_n \epsilon_+$. From Fig. 1 and Fig. 2, with 10kV acceleration voltage, a 25% efficiency for detecting both charged and neutral daughters from a typical decay ($m^*=m/2$) was achieved, an improvement by an order of magnitude over our previous results.

The Resolution of Daughter Ions

When the ion mirror is optimized for the parent ions, it produces a considerable improvement in their resolution. Fig. 3 shows the mass spectra of $[M+H]^+$ ions of melittin, both with and without the mirror. The improvement is then less for daughter ions, since the daughters do not spend a long enough time in the mirror to provide full compensation for their velocity spread. However, the electric field in the mirror can also be optimized for a given daughter ion (instead of the parent); under this condition the parent will pass through the mirror. For a parent of mass ~ 1000 u, unit daughter mass resolution may be obtained for all daughters by recording the spectrum in several segments. For example, Fig. 4 shows the daughter ion doublet at masses 278/279 from the $[M+H]^+$ parent ion of Leu-enkephalin with corresponding adjustments in the mirror voltage. Clearly the resolution for the daughters is greatly improved when the voltage on the ion mirror is optimized for the daughters instead of parents. Thus this technique provides satisfactory daughter ion resolution coupled with high efficiency.

Applications of the Correlation Method to Larger Peptides

The use of the correlation method to produce daughter ion mass spectra has been applied to some larger peptides, e.g. proenkephalin, LHRH, tyrothricin (a mixture of cyclic decapeptides of masses ~ 1300 u) α -neoeendorphin, substance P, α -endorphin etc. Considerable structure and sequence information can be extracted from the daughter ion spectra from metastable decay. Fig. 5 shows the daughter ion spectra of α -endorphin.

CHARGE SEPARATION AND ELECTRON CAPTURE INDUCED DISSOCIATION OF DOUBLY CHARGED PORPHYRIN IONS

Gary J. Van Berkel, Gary L. Glish, and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-8121

Electron ionization of a porphyrin forms abundant doubly charged ions (Fig. 1). The gas-phase chemistry of doubly charged porphyrins has been little studied and mass spectrometric methods of porphyrin analysis that incorporate the propensity of porphyrins to form doubly charged ions have not been developed. Reported here are preliminary results from a study of the gas-phase decompositions of doubly charged free-base and metal containing alkylporphyrins. Doubly charged porphyrins were observed to undergo four types of decomposition reactions: a) metastable ion decomposition (Fig. 2a), b) collision induced dissociation (CID, Fig. 2b), c) charge separation (Fig. 2c), and d) electron capture induced dissociation (ECID, Fig. 2d). The charge separation and ECID results are discussed here.

All spectra were acquired using a BE instrument. Ion source voltage (4.5 keV) and magnetic field were fixed to allow doubly charged ions of interest to enter the reaction region between B and E and the electric sector voltage was scanned from 0-2E so as to detect ionic products formed from metastable ion decompositions, CID, charge separation, and ECID in this region.

Charge Separation ($M_p^{2+} \rightarrow M_{d1}^+ + M_{d2}^+$). A large kinetic energy release is associated with charge separation of doubly charged porphyrins producing broad, dishd peaks. The kinetic energy release arises predominantly from the Coulombic repulsion of the fragment ions and can be used to calculate the charge separation in the transition state (1). Several different charge separation reactions can occur as witnessed by the multiple charge separation peaks observed (Fig. 2c).

Kinetic energies released were measured at FWHM of the charge separation peak, ($M-29$)⁺ arising from the reaction:

for several different porphyrins. The charge separation calculated from the kinetic energy release data is similar for all the porphyrins studied indicating that the metal has little effect on charge separation (Table 1). Since the diameter of the porphyrin macrocycle is approximately 8 Å, the charges on the transition state ion must be located on opposite sides of the molecule. Note that the charge on the stable doubly charged free-base porphyrin, as determined by molecular orbital calculations, is distributed between the meso carbons and nitrogens, a charge separation of approximately 2 Å.

ECID. ECID consists of two events: charge exchange of M^{2+} with the collision gas to form the M^+ and fragmentation of M^+ (2).

The rare gases did not charge exchange with the doubly charged porphyrins, but the collisions with the rare gases did promote, as do other target gases, collision-induced charge separation ($M^{2+} + N \rightarrow M_{d1}^+ + M_{d2}^+ + N$).

Both isobutane (IP = 11.4-11.7 eV) and ammonia (IP = 10.2 eV) charge exchanged with the doubly charged porphyrins. The charge exchange process was maximized using ammonia at a beam attenuation of 50% (Fig 2d). ECID occurs when the singly charged porphyrin is formed in an excited state (M_p^{+*}) and fragments. The only unambiguous ECID product observed is loss of CH_3 from M_p^+ .

2E Mass Spectra. M^+ formed from M^{2+} by charge exchange has a kinetic energy-to-charge ratio twice that of M^+ formed in the ion source. By using ammonia as the collision gas, setting the electric sector voltage at 2E, and scanning the magnetic sector, a 2E mass spectrum is obtained (Fig. 3). Only the doubly charged species in the mass spectrum that undergo the reaction $M^{2+} \rightarrow M^+$ are observed in the 2E mass spectrum. The 2E scan, therefore, may be of use when analyzing complex matrices for porphyrins.

Characterization of large molecules by tandem mass spectrometry requires new methods of ion dissociation to yield structurally useful fragments. Dissociation techniques capable of high internal energy deposition, or non-ergodic dissociations should be of increasing value with increasing molecular size. Collisionally activated dissociation (CAD), photodissociation, and surface induced dissociation (SID) in a Fourier transform mass spectrometer (FTMS) are compared.

CAD is the most common technique used in tandem mass spectrometry, with dissociation efficiencies approaching 100% for low mass ions in FTMS. However, when the mass of the precursor ion (m_p) is much larger than that of the target, the center of mass collision energy (E_{CM}) becomes inversely proportional to m_p , thereby reducing the available energy for internal excitation of high mass ions. In addition, the maximum kinetic energy obtainable in FTMS is inversely proportional to m_p . For an ion at mass 4700 undergoing a collision with Ar, ~0.12 eV of internal energy will be deposited (~0.25 E_{CM}) which corresponds to absorption of a single IR photon from a CO₂ laser.

Ions formed by plasma desorption and laser desorption are trapped in an elongated cell of a prototype Nicolet FTMS-2000 (1). CAD of gramicidin D (MW 1881) using pulsed Ar collision gas results in a dissociation efficiency of only a few percent (Figure 1a). Photodissociation with 193 nm deposits 6.4 eV per photon absorbed. Extensive structurally-useful fragmentation is observed for a variety of peptides up to mass 2000 with dissociation efficiencies up to 100% (Figure 1b).

For SID, ions formed by FAB are accelerated into a QQ-FTMS (2) and undergo dissociations on the front screened trapping plate of the cell. Substance P (MW 1348) underwent extensive dissociation with 48 eV collision energies (Figure 2). Few fragments above m/z 600 were observed, even for peptides up to ~3100 MW (e.g., RSBP 3056 MW) indicating substantial internal deposition as reported by Cooks (3).

Using a pair of grounded screens inside the trapping plates of a FTMS cell can increase resolution for high mass ions by up to 4x, consistent with Marshall's observations (4).

Electrospray ionization (ESI) (5), capable of producing highly protonated species from peptides up to 130,000 MW has been coupled to a modified QQ-FTMS (2). The high resolution capabilities of FTMS will make possible analysis of peptide mixtures with unprecedented accuracy. For example, our computer simulations show that with 10⁵ resolution at m/z 1000, substitution of a valine for an alanine (+C₂H₅) in bovine albumin (Ave. MW ~66075) at the 10% level could readily be distinguished (Figure 5), making this a very promising technique for monitoring mutations in peptides. Preliminary results show abundant multiply charged ions for a variety of peptides up to ~17,000 MW. Photodissociation (193 nm) of ($M + 2H$)⁺⁺ of gramicidin S (MW 1142) formed by ESI produces abundant ($M - H$)⁺ and sequence fragments (Figure 4) indicating this will be a useful technique for obtaining structural information from large molecules.

FURTHER INVESTIGATION OF THE ENERGETICS OF CHARGE REMOTE FRAGMENTATION

D.E. Giblin and M.L. Gross

Midwest Center for Mass Spectrometry
University of Nebraska, Lincoln, NE 68588-0304

INTRODUCTION

The internal energy requirements for charge-remote fragmentation have been estimated by employing several different methods. Estimates have ranged from less than 2eV^1 to greater than $10\text{eV}^{2,3}$. A theoretical treatment has yielded activation energies of 4 and 5eV for the 1,4 and 1,2 hydrogen elimination mechanisms, respectively⁴. Particularly troubling have been the difficulties in observing charge-remote fragmentation by using low kinetic energies and CA with massive targets. Because of these problems, an extended study of the charge-remote fragmentations from a model ionic species has been performed.

In all of the employed methods, the amount of kinetic energy deposited into the internal modes of the incident ions is inferred indirectly. However, the kinetic energy displacement of the daughter ionic species can be measured directly from which the kinetic energy displacement of the population of parent ionic species that fragmented to the selected daughter species can be directly calculated. From the kinetic energy loss, the internal energy uptake can be calculated assuming no internal energy uptake by the target gas and no significant scattering of the parent population⁵. This method is well suited to sector instruments and appears to be more direct than other methods. It was employed in this study.

EXPERIMENTAL

All experiments were performed on a Kratos MS-50TA (Triple Analyzer) of EBE configuration. The parent ionic species were selected by MS-I, the magnet and ESA₁. Collision gas was admitted to the second collision cell which is located between the magnet and ESA₂. Beam suppression in CA was typically 25% which results in over 85% of the collisions being single events. ESA₂ was controlled by a custom-built MID which generates sweeps of programmable width and which performs like a precision programmable voltage divider. Sweeps in energy space by ESA₂ was performed in peak-switch format with constant proportional energy widths. The final β slits were closed sufficiently to make the peak of the parent species be Gaussian in energy space. Data were collected by a Nicolet 1170 signal averager then transferred to the host Data General Nova 4X computer. The peaks were fit by Gaussians from the parameters of which were calculated the kinetic energy loss, ΔT , of the population of the parent ionic species that gave rise to the selected daughter ionic species, and the energy width and kinetic energy release, T_r , of the daughter species. From the kinetic energy loss was calculated the apparent internal energy gain, Q_a , of this specific population of parent ions by assuming no internal energy gain by the target gas and no scattering of the beam of parent ions by CA.

The model species used in this study was n-dodecyl sulfate anion (LS-) which was generated by Ar FAB of a solution of sodium n-dodecyl sulfate (SLS) in triethanolamine (TEA). This species was chosen because the spectrum of charge-remote fragmentations is cleaner than for n-alkyl carboxylate anions in that the first seven fragmentations give essentially single peaks and there is less interference from other fragmentations.

RESULTS AND DISCUSSION

Parameters relating to the energetics of fragmentation were determined for six of the first charge-remote fragmentations from n-dodecyl sulfate anion at kinetic energies of 8.0, 4.0, 2.0, and 1.4keV and with He and Ar as collision gasses. A summary of the results are presented in the graphs later in this section. There are several interesting trends in the data:

1. At a set kinetic energy of the parent ionic species and with a given collision gas, there are no large individual variations from the average of the data over the series of charge-remote losses except for methane.
2. The average values of kinetic energy loss and corresponding internal energy gain with He as collision gas are much greater than the corresponding values with Ar as collision gas.
3. With He as the collision gas, the average values of kinetic energy loss increase dramatically with decreasing kinetic energy. The corresponding values with Ar as the collision gas remain almost constant. In both cases the kinetic energy losses for methane loss start diverging from the average as the kinetic energy is lowered. In addition, the values for ethane and hexane losses decrease as kinetic energy is decreased with Ar CA.

4. At a set kinetic energy and with a given collision gas, kinetic energy release (KER) decreases as the mass of the neutral loss increases. With Ar as collision gas, the KER for a given product, except for methane loss, increases slightly with decreasing kinetic energy. But with He, the corresponding values of KER increase significantly as the kinetic energy is decreased and at kinetic energies of 2.0 and 1.4 keV, become such that energy widths of the losses are constant.

CONCLUSIONS

The divergent trends in kinetic energy loss and internal energy gain with respect to kinetic energy indicate some fundamental difference in the mechanisms of CA between He and Ar. The sense of the trend with respect to available energy in the case of He strongly indicates that excitation of He does not play a role. With He CA, the trend of KER's that ends in constant energy widths at 2.0 and 1.4 keV kinetic energies indicates that some other mechanism besides KER is dominating peak broadening. If the difference between He and Ar CA is scattering in the He case, rms values of the scattering angle, θ_s , are .21°, .34°, .54°, and .63° for kinetic energies of 8.0, 4.0, 2.0, and 1.4 keV, respectively.

The diverging values of kinetic energy loss and corresponding internal energy gain for methane loss over the average values as kinetic energy is decreased is consistent with a postulated difference in mechanism for this loss.

CHARGE-REMOTE FRAGMENTATION OF A SERIES OF HOMOCONJUGATED OCTADECADIENOIC ACIDS: A CA MS/MS STUDY

J.S. Crockett and M.L. Gross

Midwest Center for Mass Spectrometry
Dept. of Chem., Univ. of Nebraska, Lincoln, NE 68588-0304

A nearly complete series of Octadecadienoic Acids was utilized to investigate the effect of location of a 1,4-double bond moiety upon charge-remote fragmentation (CRF). The series also gave the opportunity to investigate the effectiveness of activating various ionic precursors; i.e., Lithium Cationized $[M - H + 2Li]^+$, Barium Cationized $[M - H + Ba]^+$, and Carboxylate Anion $[M - H]^-$.

OCTADECADIENOIC ACIDS

NORMAL CHARGE-REMOTE FRAGMENTATION MECHANISM

Charge-remote fragmentations have been studied in previous work involving a wide variety of compounds and different precursor ions.¹ This is the first time a continuous series has been used, allowing investigations of CRF as a function of ionic precursor and location of the double bonds.

CAD of an straight chain fatty acid gives a characteristic CRF pattern for which the 1,4-H₂ elimination mechanism has been proposed.² The methylene separated double bonds of the octadecadienoic acids interrupt the normal CRF pattern with a characteristic identifiable pattern.

EXPERIMENTAL

The acids were synthesized by William Christie and obtained from the Hormel Institute, Austin, Minn.³ Ions were desorbed from three different matrices by adding an acid (ca 1 ug) to a matrix on a copper probe tip. Matrices used were 3-NBA/LiI/GLY, Ba(OH)₂, and triethanolamine.

CAD spectra was acquired with a Kratos MS-50 triple analyzer tandem mass spectrometer (EB/E). It is equipped with a commercial Kratos FAB source, an Ion Tech saddle field FAB gun, and a Kratos DS-55 data system.

The FAB-desorbed precursor ions were produced by bombardment of sample/matrix with 7-8 keV Ar atoms followed by acceleration through an 8-kV potential. Mass-selection was achieved by using MS-I, CA with He in the collision cell followed, reducing the beam by 30%. Scanning MS-II resulted in structurally informative MIKES spectra.

RESULTS AND DISCUSSION

LITHIUM CATIONIZED

LEGEND

V ventic cleavage
A allylic cleavage
H homolytic cleavage

The lithiated species undergo facile CFR upon CA to give the most uniformly consistent spectra, containing principally CRF, resulting in reliable structural information with little dependence upon the location of the double bonds. Charge-driven neutral losses do not interfere with the CRF. Fragmentations due to competing charge-proximate, homolytic reactions occur with similar relative abundance as CRF, and are seen at the low mass end of the spectra. They do not interfere with structural identification. The lithiated precursor is the most generally applicable to structural determination.

BARIUM CATIONIZED

The bariated species undergoes facile CRF; however, the CRF appear suppressed by charge-proximate homolytic cleavages. Structural identification is still possible and the location of the double bonds has little effect upon the use of the bariated species for structural determination. In the case of the 3,6-acid, however, the CRF is complicated by the charge-driven CO_2 loss.

CARBOXYLATE ANION

CRF of the carboxylate anion is significantly affected by the location of the double bonds. Charge-driven neutral losses dominate the spectra when the double bonds are within a distance of five carbon atoms from the carboxyl group. Beyond this point, CRF is intense enough to be structurally informative. The 3,6- acid loses mainly CO_2 , the 4,7- acid loses both CO_2 and H_2O . Water loss also occurs when the double bonds are in the 5,8- and 6,9- positions interfering somewhat with CRF. As the functional group moves further down the alkyl chain, the intensity of CRF increases as does the structural information obtained from it.

STRUCTURE INFORMATION DERIVED FROM KINETICS OF DISSOCIATION REACTIONS

D. H. Russell and L. Sellers-Hann

Texas A&M University
Department of Chemistry
College Station, Texas 77843

The unimolecular chemistry of activated diene ions has been studied by a variety of gas-phase ion chemistry techniques. One of the long standing issues is the occurrence/non-occurrence of diene radical cation to cyclobutene radical cation rearrangement reactions prior to dissociation. Our studies probed this question; the method used is laser-ion beam photodissociation and dynamical data on the photodissociation reaction is obtained by using a biased activation cell.¹

The laser-ion beam photodissociation experiments were performed using a Kratos MS-50 tandem mass spectrometer and a Coherent Cr-18 argon ion CW laser and components for performing phase sensitive detection.² The laser-ion beam photodissociation apparatus has been modified by the addition of a biased activation cell. The activation cell can be biased (± 0.8 kV) with respect to the adjacent lenses and act like a symmetrical einzel lens decelerating the ions as they enter the cell and then accelerating them as they exit the cell. We recently reported on the novel use of a biased activation cell to study "prompt" versus "slow" dissociation reactions of photoexcited ions. The biased activation cell provides a means of distinguishing ions which dissociate promptly (< 50 ns within the biased activation cell) from those which are longer lived (50 ns to several microseconds and dissociate outside the biased activation cell).¹ The separation of "prompt" and "slow" dissociations can be used to estimate the rates of photofragment ion formation. For example, photodissociation rates of $> 5.6 \times 10^6$ and $5.6 - 0.29 \times 10^6$ can be specified for a 500 amu ion photodissociating within the activation cell and between the exit of the activation cell and the entrance to the second electrostatic analyzer, respectively.

The major emphasis of this paper is on the unimolecular chemistry of diene radical cations, specifically, questions related to direct dissociation versus rearrangement prior to dissociation. As an approach to the question of rearrangement, it is interesting to compare the prompt/slow ratios for the photodissociation reactions of diene radical cations. For example, the *trans,trans*-2,4-hexadiene, *cis,trans*-2,4-hexadiene and *cis,cis*-2,4-hexadiene $C_6H_{10}^{+\bullet}$ ions photodissociate to yield $C_5H_7^{+\bullet}$ and $C_4H_6^{+\bullet}$.³ For the photofragment ion the prompt/slow ratio for *trans,trans*- $C_6H_{10}^{+\bullet}$ is ca. 50/50, for *cis,trans*- $C_6H_{10}^{+\bullet}$ is ca. 60/40, and for *cis,cis*- $C_6H_{10}^{+\bullet}$ is ca. 75/25. Whereas for the photofragment ion the prompt/slow ratio for *trans,trans*- $C_6H_{10}^{+\bullet}$ is ca. 80/20 and for both *cis,trans*- $C_6H_{10}^{+\bullet}$ and *cis,cis*- $C_6H_{10}^{+\bullet}$ is $> 95/< 5$. There is also a distinct wavelength dependence for prompt/slow ratios for the loss of CH_3 from the 2,4-hexadiene isomers as shown in Figure 1 below.

For example, the *cis,trans*-C₆H₁₀⁺ shows no significant wavelength dependence, whereas the *trans,trans*-C₆H₁₀⁺ isomer shows an increase in the prompt/slow ratio with decreasing energy and the *cis,cis*-C₆H₁₀⁺ isomer shows a decrease in the prompt/slow ratio with decreasing energy. In an earlier paper these isomers were differentiated on the basis of kinetic energy release data for the photofragment ions.³ The isomer dependent kinetic energy release data were interpreted in terms of the photoexcited *trans,trans*-C₆H₁₀⁺ ions undergoing a slow rearrangement reaction prior to dissociation. The prompt/slow photodissociation ratio data for the C₆H₁₀⁺ isomers is also consistent with the interpretation of the kinetic energy release data. On the basis of the photodissociation data we propose the following model for photodissociation of diene radical cations.

Reaction 2 corresponds to dissociation of diene radical cations by a rearrangement reaction, while reaction 1 corresponds to direct dissociation. For simplicity, we show the rearrangement reaction occurring through a cyclobutene intermediate; however, dissociation through some other structural intermediate cannot be ruled out.

In general, for the diene systems studied, it was found that ions having an excited state which lies near the energy of the dissociation threshold both prompt and slow dissociation was observed. However, photoexcited dienes formed by absorption of ultra-violet radiation access excited states well above the dissociation threshold and only prompt dissociation is observed. This is consistent with our proposed model as well as field ionization kinetics work by Gross et al.⁴ which shows that diene radical cations with energies near the dissociation threshold dissociate via a rearrangement reaction while ions with higher internal energies dissociate directly. This differs from the results found for transition metal systems which were studied; these systems showed only prompt dissociation products. Also for systems which are thought to undergo photodissociation from a repulsive state, such as the propargyl, chloride and bromide,⁵ only prompt dissociation was observed.

Influence of Cationizing Metal Ions on Fragmentation in Folic Acid Derivatives

A. Daniel Jones
Facility for Advanced Instrumentation
University of California, Davis, CA 95616

Andrew J. Clifford and Nathan D. Bills
Department of Nutrition
University of California, Davis, CA 95616

Folate is an essential nutrient for humans that varies in substitution and oxidation state on its pteridine ring and in the number of γ -glutamyl residues in its peptide chain. Differences in the bioavailability of the various folates which occur in foods have been attributed in part to these structural variations, and provide an impetus for the development of mass spectrometric methods for characterization of folates in foods and determination of bioavailability using stable isotope techniques. Experiments in our laboratories previously demonstrated the potential of FAB ionization and parent ion MS/MS scanning for the analysis of the varied forms of intact folates [1].

Fast atom bombardment mass spectra of folates extracted from biological samples are frequently complicated by cationization by alkali metal cations such as Na^+ and K^+ . We have observed that this effect becomes more pronounced as the length of the polyglutamate chain increases. This effect has the potential to interfere with the identification of naturally occurring folates if alkali metal cations are not sufficiently removed from samples before analysis.

In order to establish fragmentation characteristics of metal ion cationized folates, daughter ion spectra of $[\text{M}+\text{H}]^+$, $[\text{M}+\text{Li}]^+$, $[\text{M}+\text{Na}]^+$, and $[\text{M}+\text{K}]^+$ ions of various folate derivatives were generated using constant B/E and MIKE scans. Daughter ion spectra of $[\text{M}+\text{H}]^+$ ions generated from most folate derivatives yields simple spectra characterized by: (1) loss of the polyglutamate chain, yielding various pteroyl cations; and (2) fragmentation at or adjacent to the pteridine ring. Cationization by Li^+ yields a similar set of fragments, with the metal ion retained in both daughter ions. However, as the size of the alkali metal ion is increased, numerous new kinds of

-
1. A. J. Clifford, A. D. Jones, and S. R. Missler, presented at the 34th Annual Conference on Mass Spectrometry and Allied Topics, Cincinnati, OH, June 1986, pp. 312-313.

daughter ions are observed which arise from various fragmentation pathways. Most of these new fragmentation pathways involve either the loss of small neutral fragments from the polyglutamate chain or the migration of the metal ion from the pteridine ring to the aminobenzoylglutamate portion of the molecule. The larger metal ions (Na^+ , K^+) yielded only minor amounts of either the pteroyl cation or its metallated analog.

Collisional activation experiments (CAD/MIKES) suggest that the decomposition pathways peculiar to the larger cations are facile processes that occur readily without collisional activation. The most apparent effect of the addition of collision gas (He ; $E_{\text{lab}} = 8 \text{ keV}$; 50% attenuation) was an increase in the abundance of the alkali metal cation as a daughter ion.

Figure 1. CAD/MIKE Daughter Spectra of $[\text{M}+\text{H}]^+$ ions (upper spectrum) and $[\text{M}+\text{Na}]^+$ ions (lower spectrum) obtained from tetrahydrofolic acid dimethyl ester.

CONTROLLED ENHANCEMENT OF STEREOCHEMICAL EFFECTS BY MS/MS/MS: ACCESS TO ENDOTHERMICALLY FORMED PRECURSOR IONS WITH UNIQUE DECOMPOSITIONAL PATHWAYS

Richard B. Cole, Chantal Prevost, and Jean-Claude Tabet*

Laboratoire de Chimie Organique Structurale, U.A. 455, Université Pierre et Marie Curie (Paris VI), 4 Place Jussieu, 75230 Paris Cedex 05, FRANCE

A tetraquadrupole MS/MS/MS (Nermag R30-10 modified principally by T. Blasco and S. LeMeillour) with consecutive surface-induced dissociation/ collisionally-activated decomposition (SID/CAD) capability¹ has been used to investigate decompositional behavior of bifunctional terpenes. Stereoisomeric distinction between exo (1) and endo (2) hydroxyl forms of tetracyclic terpenes (Fig. 1, MW = 334 amu) further containing a neighboring ketal group, was established using either CAD or SID. Positive CI-NH₃ MS/MS differentiation was based upon prominent loss of (NH₃ + C₂H₄O) by consecutive decomposition from (M+NH₄)⁺, or very weak C₂H₄O loss from MH⁺ (Fig. 1A). Both processes are stereospecific for the exo isomer (1), and m/z 291 is formed in each case.

To explain this stereochemical effect and the apparent contradiction (i.e. stronger decomposition to m/z 291 from the stabilized ammonium adduct), different protonated forms of 1H⁺ are postulated to exist. In the ion source, (1+NH₄)⁺ (having NH₄⁺ solvated by the ketal group (1a+NH₄)⁺) dissociate readily to form 1aH⁺, where the ketal group is protonated. Upon consecutive decompositions these 1aH⁺ ions do not yield m/z 291. On the other hand, (1c+NH₄)⁺ having NH₄⁺ solvated by the exo hydroxyl group, have much slower rates of source decomposition to 1cH⁺ (protonated hydroxyl, endothermic process), so other competitive processes such as nucleophilic substitution² preferentially take place at this site. 1cH⁺ protonated at the hydroxyl group thus represents a higher energy variety of MH⁺. Stereospecific formation of m/z 291 for the exo isomer (1) is believed to proceed via decomposition of this latter form of MH⁺. 1cH⁺ ions constitute a small fraction of the total 1H⁺, because although the daughter ion at m/z 291 is certainly significant, it still represents a very minor source process.

For the endo hydroxyl isomer (2), NH₄⁺ molecules can be solvated simultaneously by ketal and hydroxyl groups. Here, the 2aH⁺ form is likewise stabilized by this chelation process. The kinetics of decomposition of the cyclobutanol moiety from 2aH⁺ (or other forms) is apparently very sluggish compared to decomposition of the ketal group, hence, m/z 291 is not formed. M/z 291 is thus diagnostic of the exo-hydroxyl structure (1) in CAD or SID spectra of MH⁺, even though present in very low abundance. By selecting (1+NH₄)⁺ with the first quadrupole, then forming 1H⁺ via SID, production of molecules protonated at the hydroxyl group (1cH⁺ form, disfavored in the source) can be heavily promoted. Subsequent CAD of these 1cH⁺ yields m/z 291 as the base peak (Fig. 2A). This ion never appears in the corresponding MS/MS/MS spectrum of the endo hydroxyl isomer 2 (Fig. 2B).

Such MS/MS/MS experiments are thus shown to offer distinct advantages over MS/MS for accentuating stereochemical effects. Enhancement of diagnostic signals is achieved by promoting the formation of a specific structure of precursor ions. If these precursors are formed endothermically in the ion source, their source yields will be minor. Formation of the precursors may be promoted via the use of collisions to induce a selected initial structure to give the disfavored precursor. In this manner, diagnostic ions which were minor ions in the MS/MS spectrum, may become the dominating ions in the MS/MS/MS spectrum.

Collisionally Activated Dissociation of Laser Desorbed N-Alkylpyridinium Cations

C.H. Watson; A.R. Katrizky; Z. Dega-Szafran; and J.R. Eyler
University of Florida, Department of Chemistry, Gainesville, FL 32611

Appearance energies (AE) have been estimated from collisionally activated dissociation (CAD) results for laser desorbed N-substituted pyridinium cations. These AE were compared with the energy differences,

$$\Delta\Delta H_i = \Delta H(\text{Py}) + \Delta H_i(\text{R}^+) - \Delta H_i(\text{PyR}^+) \quad (1)$$

determined by AM1 calculations.

Ions formed by laser desorption were trapped in the analyzer cell of a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. The trapped ions were excited to high translational energies by application of an RF pulse and allowed to collide with argon atoms. By varying the RF amplitude the relative kinetic energy per collision and thus the degree of CAD could be changed. The maximum amount of translational energy that can be converted into internal energy is given by Equation 2,

$$\text{KE}(\text{relative}) = \mu_r g^2 / 2 \quad (2)$$

where μ_r is the reduced mass and g is the difference in the velocity of the ion and neutral. Assuming that the fragment ions are in the ground state, the relative kinetic energy represents the maximum amount of energy available for fragmentation. By plotting the percentage of fragmentation versus the relative kinetic energy and extrapolating to zero dissociation, estimates of the fragment ion appearance energies were made.

Samples were dissolved in MeOH or EtOH and deposited on a solids probe. A pulsed CO₂ laser was used to desorb the ions from the probe. An argon background pressure of 1×10^{-6} torr was maintained to serve as a collision gas. A delay of 1s before the CAD pulse allowed time for the desorbed neutrals to be removed and for collisional and radiative thermalization of the trapped ions. Calculations were performed by the AM1(1) method using the MOPAC program with complete geometry optimization. Standard bond lengths and bond angles were taken as the starting points. Planarity of the phenyl and pyridine rings, and C_{2v} symmetry of the pyridine rings were assumed, but conformations of the substituents were optimized.

Two distinct pathways for the CAD of these ions have been observed. Direct bond cleavage of the alkyl substituent produces pyridine and a carbonium ion as represented by pathway 1 in Figure 1. Many ions which by beta-elimination can yield a strain-free olefin dissociate by pathway 2 producing a pyridinium cation and an olefin.

For all N-alkylpyridinium cations observed to dissociate via pathway 1, plots of the percentage of dissociation versus the relative kinetic energy were made. Typical plots are shown in Figure 2. Determination of the x-intercept provides an upper limit for the activation barrier for dissociation. Assuming small activation barriers for simple bond cleavage, these values are estimates of the bond energies.

The $\Delta\Delta H_i$ (Equation 1, quantities calculated by AM1) values are plotted against the CAD appearance energies in Figure 3 for selected ions. Energies for R⁺ and possible tropyli and spiro isomers are shown since it is possible that the carbocation, R⁺, undergoes rearrangement during the dissociation.

Nine compounds dissociated by both pathways 1 and 2. For simple alkyl groups both the AE for olefin formation and the calculated height of the transition state (TS), $\Delta H^\ddagger$ decrease with the number of carbon atoms contained in the N-alkyl group:

AE = 92.9	72.4-66.8	61.5-51.9	52.9-43.3 kcal/mol
$\Delta H^\circ = 71.1$	55.3-47.3	45.1-38.4	33.9-29.4 kcal/mol

The alternative dissociation into $R^\bullet$ or olefin involves distinct transition states. The energy of the transition state for $R^\bullet$ formation is dominated by the possibility of reorganization into a more stable isomer. By contrast the TS for olefin formation is dominated by the size of R, and much less influenced by the primary, secondary, or tertiary nature of the substituent.

Two-Laser Infrared Multiphoton Dissociation of Gaseous Ions Studied by FTICR

Clifford H. Watson and John R. Eyler
University of Florida, Department of Chemistry
Gainesville, Florida 32611

Ions trapped in a Fourier transform ion cyclotron resonance mass spectrometer (FTICR) experienced enhanced infrared multiphoton dissociation (IRMPD) when irradiated sequentially by two carbon dioxide lasers in a unique probe/pump scheme. A pulsed laser tuned to a resonance infrared absorption band promotes ions to vibrationally excited states. Subsequent irradiation with a fixed-frequency continuous wave (cw) laser produces fragmentation. The extent of IRMPD for the dual-laser experiment was greater than that observed for either single-laser experiment.

A probe/pump experimental sequence employing both a pulsed and a cw laser is presented. The pulsed laser was tuned from 10.8 to 9.1 μm (925 to 1100 cm^{-1}) to probe the ions' resonant infrared absorption bands. The power of this probe laser was low enough such that little or no dissociation occurred. Ions with resonance absorption bands were promoted to vibrationally excited states, presumably into the vibrational quasi-continuum. A fixed-frequency cw laser pumped sufficient energy into the ions that the dissociation threshold was exceeded and dissociation occurred.

Experiments were carried out in a FTICR mass spectrometer using a 1.935 tesla superconducting magnet. Ions were made using a standard EI source. Illustrated in Figure 1 is the pump/probe experiment. The pulsed laser was reflected by a gold plated mirror into the cell through a hole in an excitation plate. The cw laser entered the cell through a hole in the trapping plate that was covered with a stainless steel mesh of ca. 90% transparency. The wavelength and power of the cw laser were kept constant at 10.61 μm and 50 W, respectively.

The vibrational cooling rate of protonated diglyme molecules experiences was measured. The amount of fragmentation was recorded as a function of the delay time between the two laser events. The amount of fragmentation is enhanced at short delay times and decreases with increasing delay time. At a pressure of 5×10^{-8} torr the initial energy from the pulsed laser had dissipated after about 400 ms, and no enhancement was observed at longer delays.

The amount of "enhanced" IRMPD was measured as a function of the probe laser output energy. These experiments examined the feasibility of using other types of probe lasers that have modest to low energy output for photodissociation studies. For most samples studied to date, enhanced IRMPD was observed until the probe laser's pulse energy was reduced to about 50 mJ.

Previous single laser(1) studies have shown that the IRMPD spectrum of C_3F_6^+ correlates with that of the neutral IR absorption spectrum. Similar results were obtained using the 2-laser probe/pump approach. Shown in Figure 2 is the 2-laser IRMPD spectrum obtained by tuning the probe laser at a constant output energy of 250 mJ/pulse. However, when the output was reduced to 100 mJ/pulse no IRMPD was observed for C_3F_6^+ (see Figure 3) unless the pump laser was present.

A strong correlation was also observed between the neutral IR absorption spectrum and IRMPD spectrum of chloroethane. These two spectra are shown in Figure 10. The width of the P and R branches appears narrow in the IRMPD spectrum, this results from the limited number of lines available from the CO_2 laser.

Tunable wavelength sources that by themselves cannot produce photodissociation can be used in combination with a more powerful pump source to provide useful information. Further studies are planned that will exploit irradiation of ions in other regions of the infrared spectrum.

DETERMINATION OF INTERNAL ENERGY AND ENERGY
DISSIPATION RATES IN N-BUTYLBENZENE IONS
BY COMPETITIVE PHOTODISSOCIATION

GUY T. UECHI AND ROBERT C. DUNBAR, CHEMISTRY DEPARTMENT,
CASE WESTERN RESERVE UNIVERSITY, CLEVELAND, OH 44106.

THE COMPETITIVE PHOTODISSOCIATION OF N-BUTYLBENZENE IONS INTO FRAGMENTS AT m/e 91 AND 92 IS WELL KNOWN AS A CALIBRATED AND RELIABLE THERMOMETRIC METHOD FOR MEASURING THE ION INTERNAL ENERGY AT THE MOMENT OF PHOTON IMPACT(1). USING THIS METHOD THE RELAXATION OF INITIALLY ENERGETIC IONS RESULTING FROM ELECTRON IMPACT WAS FOLLOWED AT DIFFERENT PRESSURES.

N-BUTYLBENZENE IONS PRODUCED BY ELECTRON IMPACT CONTAINED AN AVERAGE OF 0.55-0.60 eV OF INTERNAL ENERGY. AT LOW PRESSURES ($1-3 \times 10^{-8}$ TORR) APPROXIMATELY 0.3eV WAS LOST AT A RATE OF $1.35 - 1.5 \text{ s}^{-1}$. SINCE THE ION-NEUTRAL COLLISION RATES WERE LOWER THAN THESE RELAXATION RATES, INFRARED RADIATIVE COOLING MUST HAVE DOMINATED OVER COLLISIONAL COOLING. IN CONTRAST, THE RELAXATION RATE AT THE HIGHER PRESSURE ($2-4 \times 10^{-7}$ TORR) WAS COMPARABLE TO THE ION-NEUTRAL COLLISION RATE. ENERGY LOSS AT THIS HIGHER PRESSURE WAS PRIMARILY BY COLLISIONAL QUENCHING.

THE MONITORING OF THE RATIO OF N-BUTYLBENZENE ION'S PHOTOFRAGMENTS, m/e 91 AND 92, HAS PROVENTO BE A CONVENIENT METHOD TO PROBE THE INTERNAL ENERGY OF THE PARENT ION. DYNAMICAL PROCESSES SUCH AS RADIATIVE AND COLLISIONAL COOLING OF INTERNAL ENERGY HAVE BEEN STUDIED USING THIS POWERFUL THERMOMETRIC TOOL.

TIME RESOLVED PHOTODISSOCIATION OF THIOPHENOL IONS IN AN ICP MASS SPECTROMETER
JIM FAULK AND R. C. DUNBAR; CASE WESTERN RESERVE UNIVERSITY; CLEVELAND, OHIO
44107

Objectives:

Photofragmentation of thiophenol cation into cyclopentadiene cation and CS requires an extensive rearrangement (See reaction 1). This process is therefore a likely candidate for a slow fragmentation. In this study we were interested in:

- 1) Measuring the rate of this photofragmentation at 308nm and
- 2) Comparing it with the rate predicted by RRKM theory.

Introduction:

A time resolved study of the photofragmentation of thiophenol cation was carried out at 308nm. The fragmentation rate was compared to the rate predicted from RRKM theory. Two models were considered; a "somewhat tight" transition state and a "very loose" transition state. The "somewhat tight" transition state is the loosest we considered plausible in view of the severity of the rearrangement required for fragmentation. The very loose transition state was arbitrarily chosen to give agreement with experiment, in order to determine the extent that the transition state had to be loosened to yield the observed rate.

RRKM Calculations:

The RRKM calculations were carried out using the equation

$$k=c(W(E-E_0)^n/p(E))$$

where $c=3 \times 10^{10} \text{ cm/s}$, E = total internal energy (photon plus thermal) of the energized parent ion, E_0 = energy of activation, $p(E)$ = density of states of the parent at E and $W(E-E_0)^n$ = number of states of the activated complex between E_0 and E .

The table compares the parent ion vibrational frequencies with those of the two transition states.

Experimental:

All rate measurements were done on an icr using capacitance bridge detection (non-FTICR). The light source was the 308nm line of an excimer laser. The pulse sequence is shown in figure 1. The fragmentation was monitored by following the appearance of the fragment ion with time.

As pointed out in reference 1 the time resolved appearance curves of the photofragment must be fitted using the following equation:

$$S=C\{\Delta+(1/k)e^{-k\tau}(e^{-k\Delta}-1)\}$$

where S is the fragment ion signal strength, Δ is the length of the effective Rf excite pulse, k is the fragmentation rate, τ is the time from the laser pulse to the beginning of the Rf excite pulse and C is a constant adjusted to make S equal to the long delay time fragment ion signal.

This equation predicts that if $1/k$ is comparable to Δ there will be a noticeable zero time ($\tau=0$) fragment signal as was observed on all of the time resolved plots. All plots were satisfactorily fitted by this equation.

Results:

The photofragmentation rate was found to be about $1.0 \times 10^5 \text{ s}^{-1}$ (see figure 2), 200 times faster than predicted by the "somewhat tight" transition state RRKM model. It was possible to increase the RRKM rate enough to agree with the experimental rate using an unreasonably loose transition state (compare the first and second columns in the table).

Discussion:

It seems that this process requires tightening (rather than loosening) of the molecular geometry in going from the energized parent ion to the activated complex. The somewhat tight transition state used here, which is similar to the energized parent, is already a looser transition state than seems reasonable and the "very loose" transition state seems unrealistic. Therefore we will discuss and rule out two possible reasons for the observed rate being much faster than the rate calculated by the more realistic "somewhat tight" transition state.

I. Hot ions with a total internal energy greater than that assumed in the RRKM calculation will fragment with a correspondingly faster rate. Through a series of cooling experiments

we have shown that excess internal energy of the ions was not the cause of the unexpectedly fast fragmentation observed here. We have shown that after thorough thermalization thiophenol ions (with around 0.2 eV of thermal energy) still fragment with a rate of about $1 \times 10^5 \text{ s}^{-1}$ nearly 200 times faster than the calculated rate.

II. Satisfactory agreement between the experimental rate and that predicted by RRKM theory can be achieved by setting the activation energy for this process at 2.66 eV. However we were able to show that the photodissociation threshold is at least 0.05 eV higher than this and accurate Photoionization AE measurements place this threshold between 3.35 eV and 3.65 eV. In addition heat of formation values yield a thermochemical threshold of 3.2 eV.

We therefore conclude that the unexpectedly fast observed fragmentation rate can not be accounted for by postulating hot parent ions or a dissociation threshold that is too low. A reasonable interpretation of these results requires further study.

Fragmentation rate for thermalized ions 380 s⁻¹ 1x10⁵ s⁻¹

FRAGMENTATION MECHANISMS FOR HIGHLY FUNCTIONALIZED IONS:
THE FAB MASS SPECTRA OF SOME CARDIAC GLYCOSIDES REVISITED

Karen Light, Gary Schultz and John Allison, Department of Chemistry,
Michigan State University, East Lansing, Michigan 48824

When electron ionization (EI) was the dominant ionization method in mass spectrometry, and analyte molecular weights were below 1000, mass spectral interpretation was frequently straightforward. Fragmentation mechanisms were established (1) which were extremely useful in understanding the relationship of fragment m/z values and intensities to the structure of the analyte molecule. Desorption/ionization methods have taken us to a situation where much larger, highly functionalized molecules can be studied, however the focus has not been on establishing fragmentation mechanisms for these large molecules. When working with small molecules, many mechanisms are determined through labeling experiments, which are much more difficult to perform for larger molecules such as saccharides and peptides. We evaluate here the use of high resolution MS and MS/MS for providing insights into the mechanisms leading to fragment ions formed in the FAB analysis of cardiac glycosides, and focus on the molecule digoxin, $C_{41}H_{64}O_{14}$.

The compound is protonated in the FAB analysis, using a glycerol matrix. The MH^+ ion, at m/z 781, forms a number of fragment ions due to cleavage of the three glycosidic linkages in the molecule (figure 1). We will use as an abbreviation (2) for digoxin, $A-O-S_1-O-S_2-O-S_3-OH$. We quickly found that nominal mass information on the fragment ions is frequently insufficient for tentative assignments, and used high resolution results on all fragment ions as the starting point in the project. It was determined that most fragment ions contain the aglycone moiety (A), although some, such as the ion current at m/z 391, represent two species - one containing the saccharide chain and one containing the aglycone, with assignments of $C_{23}H_{35}O_5^+$ ($[AOH]H^+$) and $C_{18}H_{31}O_9^+$ ($[HOS_3OS_2OS_1-H]H^+$).

Consider as an example, a major fragment ion that is observed at m/z 651. It corresponds to the $AOS_1OS_2O^-$ part of the molecule, plus 2 H's in the form $[AOS_1OS_2OH]H^+$. We considered a number of mechanisms by which this fragment may be formed. The simplest mechanism is charge-initiated fragmentation (CIF) which follows protonation of the glycosidic oxygen between S_2 and S_3 with accompanying H shift from the departing neutral. The H-shift could follow a 1,2 or 1,3-elimination mechanism, which would yield the same ionic fragment, presumably with the initial site of protonation also being the site of protonation in the product. We also consider a remote-site (RS) mechanism, in which protonation of the aglycone occurs, and a 1,2 or 1,3-elimination about the glycosidic linkage in question follows. To investigate the structure of this ion, a B/E linked scan was performed on m/z 651, on a JEOL HX-110 double-focusing instrument. The resulting spectrum is shown in Figure 2. If the CIF mechanism is operative, and the site of protonation in m/z 651 is a terminal OH group, we would expect H_2O loss to dominate in the linked-scan spectrum, however this is not the case. The ion fragments in much the same way as does the protonated digoxin molecule - possibly suggesting a RS mechanism. Linked-scan data for the fragment ions are very informative, and show that multiple water losses, which are frequently observed, may be due predominantly to the hydroxy groups on the aglycone ring, rather than those on the sugars. The results suggest that both the CIF and the RS mechanisms may be operative. The combination of high resolution data, and MS/MS analysis of fragment ions formed by FAB can provide some insights into the fragmentation mechanisms of large molecules (when fragment ions are observed in the FAB mass spectrum), however labeling studies (or possibly MS/MS/MS) are still required to sort out the many details that control the fragmentation of protonated, highly functionalized molecules such as cardiac glycosides.

Figure 1. FAB mass spectrum of digoxin in glycerol

Figure 2. B/E linked scan of the digoxin fragment ion at m/z 651. The successive loss of H_2O from m/z 651 (e.g. at m/z 633, 615) is not as prevalent as the cleavage of the glycosidic bonds (e.g. at m/z 521, 391).

LASER ABLATION MASS SPECTRA OF HIGH
MOLECULAR WEIGHT POLYMERS DETERMINED
BY FOURIER TRANSFORM MASS SPECTROMETRY

J. T. Brenna and W. R. Creasy
IBM Technology Laboratory, D/T43, P.O. Box 8003,
Endicott, New York 13760

Laser microprobe mass spectrometry (LAMMS) is one of the more promising methods for identification of polymeric or organic particulates on surfaces. Almost a decade ago, TOF-based LAMMS was first applied to polymer analysis. However, the observation of extensive rearrangement products and the limited selectivity of TOF spectrometers militate against the usefulness of the technique. Last year, three groups (including ourselves) reported design and construction of the first FTMS-LAMMS instruments (1 - 3). High mass resolution and multi-stage MS capability of FTMS are expected to be invaluable in studies of complex rearrangement products produced by laser ablation. We report here a survey of industrially important polymers analyzed in the broadband mode of FTMS. The goals of this work are to determine: 1) the extent to which FTMS-LAMMS (spot size $10 < \mu\text{m}$) can be used to identify polymer particles on surfaces; 2) if differences exist between LAMMS spectra from TOF and FTMS analyzers; 3) trends in the observed ion distributions which may yield insight into formation mechanisms and interpretation of unknowns.

Mass resolution sufficient to achieve exact mass measurement was not possible with polymers as analyzed in this study. This contrasts with our previous experience with laser ablation of metals in which mass resolution of $> 4 \times 10^5$ was obtained at $m/e = 206$. Recent experiments indicate the insulating property of the polymers dramatically shorten the transient in our configuration, and high mass resolution studies are currently being pursued. Nevertheless, the spectra indicate a number of trends in FTMS-LAMMS polymer analysis.

Positive ion spectra: 1) FTMS spectra usually show drastic differences from literature TOF spectra. FTMS spectra are usually higher in mass and show more rearrangement products. 2) A number of FTMS spectra exhibit odd mass ions series not observed in TOF spectra. We *speculate* on the origin of these peaks: It is known that the laser atomizes a substantial proportion of the ablated material. In the 3 T magnetic field of the FTMS, protons (and ions with exchangeable protons) will be confined at the ab-

Amino Acid Analysis by DCI MS/MS

Procedure: Amino acid residues obtained from acid hydrolysis are reacted with PITC to form PTH-derivatives.

Most PTH-amino acids yield a prominent 136⁺ ion under MS/MS conditions. By acquiring a DCI parent ion spectrum only species that dissociate to produce the 136⁺ fragment are observed, permitting identification of the MW of the PTH-AA's. PTH-arginine and PTC-lysine do not yield intense 136⁺ by MS/MS but they may be screened for by searching for parents of 174⁺ and 306⁺, respectively. After the molecular weights have been determined, a daughter ion mass spectrum is obtained from each component. The resulting spectra are compared against our PTH-AA library for positive identification.

Conclusion Peptides produced by micro-organisms pose special problems for sequence determination. These peptides may contain unusual or novel amino acids whose chirality may be D or L, erythro or threo. The identity of these unusual amino acids and their stereo-chemistry can be determined by GC-MS. Alternately, for rapid amino acid analysis, the PTH derivative of the hydrolysate can be examined by DCI MS/MS. The presence of D-amino acids also limits peptide susceptibility to enzymatic cleavage. Mild acid hydrolysis is useful for producing fragment peptides when MS/MS and enzymatic digests fail. Also Edman degradation followed by FAB-MS and CI MS/MS is an extremely valuable tool for sequence determination of peptides with a free N-terminus.

FOURIER TRANSFORM MASS SPECTRA OF POLYBUTADIENES AND POLYISOPRENES

A. Kasem Chowdhury and Charles L. Wilkins

Department of Chemistry

University of California, Riverside, Riverside, CA 92521

Introduction. Although laser desorption Fourier transform mass spectrometry (LD-FTMS) has emerged as an alternative soft ionization method for analysis of non-volatile polymer samples, very few non-polar polymer samples have been analyzed to date. The majority of samples examined thus far have been polymer samples containing oxygen and nitrogen. Here, we report the first characterization of polybutadienes and polyisoprenes using LD-FTMS.

Experimental. All mass spectra were obtained with a Nicolet FTMS-2000 mass spectrometer equipped with a 7.0 tesla superconducting solenoid magnet and a CO₂ laser. Polybutadienes and polyisoprenes were obtained from Polysciences, Inc. Samples were loaded onto a probe tip either as a pure compound or dissolved in dichloromethane. Addition of a few drops of gold oxide/methanol solution appears to assist ionization of polymer samples. For thermal desorption studies, water was used as the CI reagent to obtain thermal desorption CI (TD-CI) spectra. The polymer samples were thermally desorbed at 75-150 °C. Water was ionized by a 10-us (for negative CI 100-ms) beam of 50 eV (for negative CI 6.75 eV) electrons with filament emission current of approximately 10 uA. The ions were trapped in the cell for about 5 seconds, prior to observation, to allow ion-molecule reactions with the desorbed polymers.

Results and Discussion. LD-FTMS spectra were obtained for the following polymers; polybutadiene-1000; polybutadiene-1350 (OH terminated); polybutadiene-1300 (phenyl terminated) and polyisoprene -3280. Figure 1 shows mass spectra of polybutadiene-1350 and polyisoprene-3280. The major peaks in the spectra are those arising from potassium attachment to the individual oligomers differing by 54 amu for polybutadiene and 68 amu for polyisoprene. Although no significant fragmentation is observed for the polybutadienes, polyisoprene shows small secondary envelope corresponding to loss of two methyl groups. Figure 2 shows TD-CI mass spectra of polybutadiene-1350 (OH terminated). The thermal desorption CI methods produce a series of low mass ions differing by 54 amu corresponding to losses of $(n \times 54 + H_2)$

and $(n \times 54 + 57)$ for positive and negative CI, respectively. The loss of mass 57 in addition to the loss of $n \times 54$ in the negative CI spectrum appears to be a terminal $(CH_3)_3C$ group. Thus, TD-CI method can provide complimentary information for analysis of polymers. This study demonstrates that certain non-polar polymers can be analyzed using the FTMS technique.

LASER DESORPTION FT/ICR MASS SPECTRA OF POLYAMIC ACIDS

W. D. Weber
IBM Corporation
D/12W High Performance Product Assurance
Hopewell Junction, New York 12533

INTRODUCTION

Polyimides have gained increased attention in recent years due to their excellent thermal stability and property retention following high temperature processing (1). Because of the intractable nature and high thermal stability of polyimides, direct analysis of their structure by mass spectrometric methods is difficult. Recent descriptions of laser desorption mass spectra obtained from polyimides are not encouraging as the spectra were dominated by carbon clusters and only small, structurally insignificant, organic ions were observed (2). Polyamic acids are common precursors to polyimides and are generically poly(ortho-carboxylic acid)amides. Previous work on polyamides (3) suggests that polyamic acids would yield analytically meaningful spectra using laser desorption mass spectrometry. If successful, the approach would provide identification of the constituent monomers in the resin.

EXPERIMENTAL

Laser desorption mass spectra were obtained using a dual-cell Nicolet FTMS 2000 spectrometer interfaced with a Tachisto 215G carbon dioxide laser (10.6 μm). The spectra were obtained using standard pulse sequences. The trapping potential was + 1.0 V. The excitation band width was 800 KHz and a sweep rate of 800 Hz was used. When analyzer side detection was performed, an ion transfer time of 400 μs was used. The transients from single laser pulses were digitized at 64K, zero filled twice, and transformed using three-term Blackman-Harris apodization. Accurate mass measurements were made using calibration tables obtained from laser desorption spectra of a mixture of monomeric polyimide model compounds as an internal or external calibrant.

Polyamic acids were either synthesized by standard methods (4) or were purchased from suppliers. Four different polyamic acids were studied. Two different methods were used to prepare samples for analysis. In the first method, the viscous polyamic acid solutions were precipitated in methanol using a Waring blender. The precipitate was collected and vacuum dried at ambient temperature to yield a powder which was applied directly to the probe tip as a smear. In the second method, the polyamic acid solution was diluted 100:1 in NMP solvent and the diluted solution applied to the laser target using a microliter syringe following by drying in vacuum for 2 hours at 60 C.

RESULTS AND DISCUSSION.

Polyamic acids can be viewed as polymeric phthalate half amides. and their positive ion LD spectra follow a pattern that is very similar to the patterns observed from the fragmentation of phthalate derivatives. Figure 1 shows a source side, positive ion spectrum obtained from a polyamic acid derived from 3,3',4,4'-benzophenone tetracarboxylic acid dianhydride (BTDA), 1,4-oxydianiline (ODA), and 1,3-phenylene diamine (mPDA). All of the information required to determine the monomer composition of the polymer is present in the spectrum. For example, the ions at m/e 108, 200, and 323 (Figure 1) correspond to the molecular ion of mPDA (in a mass doublet with an ODA fragment), the molecular ion of ODA, and the protonated pseudomolecular ion of BTDA. The higher mass ions at m/e 504, 696, and 990 correspond to polymer repeat units and are formed by a process involving both N and O acyl bond cleavages and a series of dehydrations. This process results in a series of amine-anhydride terminal ions corresponding to BTDA-ODA (504 amu), ODA(BTDA)ODA (696 amu), and ODA(BTDA)ODA(BTDA) (990 amu) combinations. Ions representing more than two repeat units were not observed despite numerous attempts involving varied laser power, pulse sequence modifications, and cationization with alkali metal salts. The spectra from the other polyamic acids studied gave spectra following the same pattern as the BTDA-ODA-mPDA polymer. The only difference in source vs. analyzer side spectra was that the source spectra showed higher abundances of ions in the 500 to 1000 amu range.

The accurate mass data obtained from Figure 1 are shown in Table I and are averages from ten consecutive laser pulses with internal calibrant. The values measured were in good agreement with those calculated from the postulated structures. The accurate mass measurements were reproducible using the external calibration method. For example, ten repetitive measurements of the ODA molecular ion showed: calculated for $C_{12}H_{12}N_2O=200.0944$ amu; measured mean=200.0938 amu and standard deviation=0.0012 amu. As expected, internal calibration gave a somewhat better result with mean=200.0948 amu and standard deviation=0.00064 amu.

SUMMARY

Laser desorption FT/ICR spectra of polyamic acids provide structural information on the polymers and allow monomer identification. Polymer fragment ions of up to two repeat units are routinely observed. Mass accuracy with internal calibrant was routinely less than 5 ppm.

Table I

Accurate Mass Data For BTDA-ODA-MPD Polyamic Acid

Ion/Charge	Measured Mass amu	Calculated Mass amu	Error ppm
MPDA M^+	108.0684	108.0681	2.8
MPDA $+H^+$	108.0782	108.0782	1.8
ODA M^+	200.0948	200.0944	2.0
ODA $-CO_2H^+$	108.0437	108.0444	0.3
BTDA $+H^+$	323.0178	323.0186	2.5
BTDA M^+	322.0115	322.0118	1.2

IDENTIFICATION OF POLYMER SYSTEMS BY MASS SPECTROMETRY

Mark Chace and Marina Plat,
IBM Corporation, Rt 52, Hopewell Jct., NY 12533

Identification of the component monomers of a polymer system can be achieved by mass spectral analysis after hydrolytic cleavage of the polyimide into its monomers. Hydrolytic cleavage (1,2,3) of the polyimide can be carried out in aqueous hydrazine or ammonium hydroxide. Cleavage of a polyimide by hydrazine will produce diamine and hydrazide components (4). Cleavage by ammonium hydroxide will produce diamine and tetraacid components.

This study involved the use of direct inlet probe (DIP) FTMS and GCMS for the analysis of hydrolysis products. DIP-FTMS allowed direct analysis of all hydrolytic species resulting from hydrazinolysis and NH_4OH hydrolysis without additional sample preparation. Due to their low volatility, hydrazides were not detectable by GCMS. Chemical derivatization of tetraacids for enhanced volatility was necessary for detection by GCMS.

HYDRAZINOLYSIS

Hydrazide standards were prepared from two common dianhydrides, Pyromellitic dianhydride (PMDA) and Benzophenone dicarboxylic dianhydride (BTDA). Reaction of the dianhydride powder was completed in 40% aqueous hydrazine at 85°C for 12 hours. The hydrazide and diamine components in the hydrolysis medium were analyzed directly using heated DIP-FTMS. The sample was heated in the DIP to 400°C. The PMDA bishydrazide showed a molecular ion at $M=246\text{amu}$ and fragment ions at 189amu ($M-\text{N}_2\text{H}_2$, CO) and 160amu ($M-\text{N}_2\text{H}_2$, 2CO), see Fig. 1. The reaction of BTDA with hydrazine produced two components: BTDA bishydrazide, $M=350\text{amu}$ and BTDA bishydrazide-hydrazone, $M=364\text{amu}$. The BTDA bishydrazide spectra (Fig. 2) showed a large molecular ion at 350amu and fragment ions at 189 ($M-\text{C}_8\text{H}_5\text{O}_3\text{N}_2$) and 160amu ($M-189$). The BTDA bishydrazide-hydrazone showed a relatively small molecular ion at 363amu ($M-\text{H}$) and a large fragment ion at 336amu ($M-\text{N}_2$).

A polymer of unknown composition was hydrolyzed in aqueous hydrazine. The same procedure used in the preparation of the hydrazide standards was used in the hydrolysis of the unknown. Probe FTMS analysis of the hydrolyzate showed the presence of ODA, PMDA and BTDA in the unknown. (see Fig. 3).

HYDROLYSIS WITH AMMONIUM HYDROXIDE

Methyl ester and trimethylsilyl (TMS) ester derivatives were prepared from the tetraacids of PMDA and BTDA. GCMS detected the tetramethyl ester of PMDA (Fig. 4) but not of the larger BTDA. TMS derivatization further increased the volatility of the tetraacids. TMS esters of both PMDA and BTDA were detectable by GCMS. The TMS esters were prepared by reacting the tetraacids with hexamethyldisilazane (HMDS) in a solvent medium of HMDS/pyridine (1/4). Figure 5 shows the spectrum of PMDA tetra(TMS) ester, with molecular ion of $M=542\text{amu}$ and fragment ions at 527 ($M-\text{CH}_3$), 425 ($M-\text{TMS ester}$), and 73amu (TMS). BTDA tetra(TMS) ester (Fig. 6) exhibits a molecular ion of $M=646\text{amu}$ and fragment ions at 631 ($M-\text{CH}_3$) and 573amu ($M-\text{TMS}$, OTMS).

1,4-Oxidianiline (ODA) and 1,3-bis(aminophenoxy)benzene (APB), two commonly used amines, were readily detected using both probe FTMS and GCMS techniques. ODA produced a molecular ion of $M=200\text{amu}$ and a large fragment ion of 108amu . APB produced a molecular ion of $M=292\text{amu}$ and a fragment ion of 183amu .

GCMS SPECTRUM OF TETRAMETHYL ESTER OF PMDA

GCMS SPECTRUM OF TMS ESTER OF BTDA

CONCLUSIONS:

Positive identification of the monomeric components of a polyimide system can be successfully achieved using either GC/MS or probe FTMS. Hydrolytic and hydrazinolysis products of polyimide cleavage can be analyzed directly using heated solids probe MS. Hydrazinolysis products could not be analyzed by GCMS due to low volatility. Diamine components of hydrolytic cleavage are easily detected by GCMS. Tetraacid components of hydrolytic cleavage require additional derivatization, preferably silylation, to be detected by GCMS.

EI AND CI SFC/MS OF ISOCYANATE PREPOLYMERS

A. M. Cary, Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Isocyanate prepolymers are very difficult to analyze by mass spectrometry. Their lack of volatility prevents their analysis by GC/MS, and their reactivity in the presence of free hydrogen precludes their analysis by conventional thermospray liquid chromatography/mass spectrometry. Other types of ionization for non-polar LC methods are also problematic. Supercritical fluid chromatography / mass spectrometry (SFC/MS) provides a very good method to separate and analyze these compounds quickly and easily. Both electron ionization (EI) and chemical ionization (CI) information can be obtained by capillary column SFC/MS. A sample of 4,4'-diisocyanatodiphenylmethane was analyzed by both EI and CI capillary SFC/MS. From the EI results, it is possible to identify the three components of the sample as the 4,4'- and 2,4'- positional isomers of the diisocyanate prepolymer and one polymerization moiety. Methane-CI SFC/MS corroborates the EI result, but is an order of magnitude more sensitive for these compounds. Three additional peaks found in the CI chromatogram represent another positional isomer of the polymerization product, the next expected polymerization product, and a methanol reaction product. These results show that SFC/MS is an excellent method for understanding the exact nature of contaminants in polymer starting material of this type, which are very difficult to analyze by other methods.

Methods

A sample of 4,4'-diisocyanatodiphenylmethane was analyzed by capillary SFC/MS on a Lee Scientific Model 602 supercritical fluid chromatograph interfaced to a Finnigan MAT SSQ™ 70 single quadrupole mass spectrometer.

Chromatographic Conditions:

Injector:	Valco timed split with 2-m retention gap
Column:	SB-Biphenyl-30, 50 μ m
Supercritical Fluid:	CO ₂
Pressure Program:	100 to 300 atm at 10 atm min ⁻¹
Temperature:	100°C
Restrictor Conditions:	Frit restrictor at 325°C Guthrie restrictor at 250°C

The sample was analyzed under both EI and methane-CI mass spectrometer conditions. There is some evidence that under CO₂ SFC conditions, EI is, in fact, CO₂ charge-transfer ionization. However, spectra yielded under these conditions are very similar or identical to classical EI spectra and are library-searchable using standard library-searching algorithms and the NBS (NIST) library of mass spectra.

Results

The three peaks shown in the EI results correspond to two positional isomers of the monomer and one polymerization moiety. The molecular ion is predominant in all the spectra and is the base peak in both monomer spectra. The primary peak is most likely the nominal 4,4'-diisocyanatodiphenylmethane. Its primary fragment ion is m/z 208, which corresponds to the loss of an isocyanate group (i.e., 42 u). The smaller monomer peak is the 2,4'-positional isomer. The loss of 29 u results from the *ortho* effect in which CHO is lost through rearrangement. In any case, m/z 221 and m/z 208 are present in both spectra and differ only in their relative abundances. The third peak is m/z 381 from the polymerization product, 3,4-di(4'-isocyanatotolyl)phenylisocyanate.

The CI chromatogram shows the three major peaks, and the spectra corroborate the EI results by showing the M+H ions expected for each of the molecular ions found in the EI spectra. It is interesting to note that the sensitivity of the analysis by CI is about an order of magnitude better than EI, which is probably due to the increased ionization efficiency of methane CI as compared to CO₂ charge transfer. Also, three additional small peaks are found. One is the second expected polymerization product, with a molecular weight of 512 u, as shown by the M+H ion at m/z 513. A second small peak, showing a molecular weight of 282 u, represents the urethane formed in reaction with methanol, which can probably be found in trace amounts in the methylene chloride used as the solvent in this analysis. A third very small peak represents the 2,4'- isomer of the di(isocyanatotolyl)phenylisocyanate polymerization product.

Photo- and Thermal Degradations of Iodonium Salts:
'Complications' within Secondary Ion Mass Spectrometry and
Fast Atom Bombardment

Helen H. Schurz, Kenneth L. Busch, Department of Chemistry,
Indiana University, Bloomington, IN 47405

Previous work with iodonium salts has shown that liquid secondary ion mass spectrometry (SIMS) and fast atom bombardment (FAB) produce good quality mass spectra for iodonium salts, containing abundant signals for the intact cation and some degree of structurally informative fragmentation. Diaryliodonium salts are used extensively as photocatalysts of cationic polymerizations. Upon irradiation with ultraviolet light, they form strong Bronsted acids that initiate cationic polymerizations, used most often in the cross-linking of polymers. The presence of certain ions in the spectra suggest that some amount of photodegradation of the salts may be occurring within the mass spectrometer. This study is concerned with determining whether the ions seen in the mass spectra of these salts are related to their thermal and photodegradations or if these reactions are completely unique to the mass spectrometer.

The ion and atom sources in FAB and SIMS are good sources of light in the visible and ultraviolet wavelength regions. This would suggest that photoinduced reactions could occur within the mass spectrometer to form the products seen in thermal and photodegradations. Therefore, thermal- and photo- reactions were performed outside the mass spectrometer, their products analysed and compared to the liquid SIMS spectra of the salts in glycerol. Both reactions were performed using 0.01M solutions of diphenyliodonium chloride in acetonitrile or diglyme. For the photodegradations, the solutions were irradiated with ultraviolet light for 1-3 hours, and then analysed. The thermal reactions were also performed on 0.01M solutions of the salt, but these solutions were refluxed for 1-3 hours, and then analysed.

Ions formed from loss of iodine from the intact cations, and the product iodobenzene, were detected in the liquid SIMS and FAB mass spectra of the salts, and in the FAB mass spectra and GC/MS analysis of the reaction mixtures. Polymerization products were seen in the FAB mass spectra of the photo- and thermal experiments, in addition to the regular mass spectrum of the iodonium salt. The secondary ion yield for iodonium salts is very high, and only a short time is required for measurement of the mass spectrum. If the monomer is present along with the iodonium salt in the sputtered solution, the formation of polymerization products is not expected to be a "complication" in the interpretation of the mass spectra. With longer irradiation times in the source of the mass spectrometer, a similar reaction to that observed in the external irradiation experiments may occur. Experiments with extended irradiation/sputtering times are underway.

Ions that were detected in the FAB mass spectra and the GC/MS analysis of the reaction mixtures differed with ionization method and reaction. In the thermal and photodegradations of diphenyliodonium chloride in acetonitrile, the FAB spectra indicate a tropylium ion which is not seen in the EI spectra. Additionally, ions corresponding to polymerization products are seen in FAB, the highest molecular weight corresponding to a polymer of seven monomer units ($m/z = 289$). The main difference between the thermal and photodegradations is in the intensity of the ions that are related to polymeric species. This indicates that the photolyzed sample polymerizes to a greater extent than the thermal sample.

In the EI mass spectra of these reactions, the more volatile species chlorobenzene and iodobenzene are seen along with diphenyliodonium and biphenyl, though they were not observed with FAB.

When the same reactions were performed with diglyme, only FAB spectra were recorded because the diglyme was too polar for separation by GC. The products seen were iodobenzene (small relative abundance), diphenyliodonium and polymerized diglyme for both the photo and thermal reactions. The photo reaction, however, produced higher molecular weight products.

Paul Vouros, Northeastern University, Boston, Massachusetts 02115

Gary L. Hagnauer, Army Material Technology Laboratories, Watertown, Massachusetts 02172.

The curing of epoxy resins with amines to create high performance composites with high heat resistance is of considerable commercial interest. In order to understand the properties and behavior of these materials, a fundamental knowledge of their chemistry is required. This overall understanding of the bulk properties is facilitated by the identification and characterization of the many intermediates which are involved in the polymerization process. Since, however, the most often used epoxy resins are polyfunctional, such as N,N,N',N'-tetraglycidyl-4-4'-diamino diphenylmethane (TGDDM) and they are cured with polyfunctional primary amines, the final product and its intermediates are difficult to characterize. As a means of simplifying the problem a model system, diglycidylaniline (DGA) and aminodiphenyl sulfone (ADS), has been used in identifying the key polymerization processes. Moreover, because the structure of the first intermediate (1:1 DGA/ADS) will define all further reactions, the structural identity of this product is of considerable interest.

It is known that the addition of the DGA to the ADS occurs *via* the opening of the epoxy ring to create a secondary amine and free hydroxy. However, the relatively high reactivity of the second glycidyl group and its close proximity to both the amine and the hydroxy functionalities allows for several intramolecular reactions to occur. In order to determine the correct structure of this product the material was isolated and subsequently identified using linked scans fast atom bombardment mass spectrometry. By performing linked scans on the major fragment ions, the structural relationship between the ions was determined which made structure identification easier and more confident. It has been shown that although the possibility exists for several intramolecular reactions, only one of the epoxies initially reacts.

In addition to the DGA/ADS system, linked scans were used to determine the structure of an impurity formed during the synthesis of another polymer starting material, 1,1'-(methylene-di-4,1-phenylene) bismaleimide (APO-BMI). The linked scans of both the compound of interest, as well as the impurity are presented in Figures 1a and 1b respectively.

Many of these peaks were not seen in the normal FAB spectra because of the high abundance of background peaks.

A wealth of information may be obtained by following the metastable transitions which a particular molecule undergoes in the first field free region of a double focusing mass spectrometer. The added selectivity of the linked scans allows for the determination of low intensity fragmentations which would normally be lost within the background chemical noise. These fragmentations, which are normally higher energy processes, help identify and characterize the molecular structure.

Figure 1 Linked scans of protonated molecular ions of (a) APO-BMI (m/z 437) and (b) impurity (m/z 455).

THE CHARACTERISATION OF AROMATIC POLYMERS BY FIELD DESORPTION MASS SPECTROMETRY

K Rollins, J H Scrivens, M Taylor, ICI Wilton Materials Research Centre
Cleveland, England

H Major, R H Bateman, V G Analytical Ltd, Manchester, England

INTRODUCTION

The importance of non-polar synthetic molecules of >1000 daltons has significantly increased in recent years with the use of sophisticated formulations in the general chemical and polymer fields and with the advent of low molecular weight (5-20,000 daltons) aromatic polymers used in high performance applications such as composite manufacture.

We have reevaluated FD techniques for the characterisation of these molecules and have found that this approach affords significant advantages over pyrolysis, laser desorption and high temperature probe techniques previously used.

DEMULSIFIERS

Among a range of complex chemical formulations we have studied using FD are a range of products manufactured by ethoxylating and/or propoxylating alkyl phenol formaldehyde resins. These materials, which are extremely difficult to characterise, are used as demulsifiers in the oil industry. Molecular weight distribution, both of the resin and the product, and degree of ethoxylation/propoxylation are key parameters in determining the end properties of the product.

Fig 1 shows the FD spectra of two typical products together with their GPC traces. RA 00/50 is an ethoxylated octylphenol formaldehyde resin and RC 15E/05 is an ethoxylated and propoxylated butyl phenol formaldehyde resin. The spectra indicate, at a glance, whether the sample is ethoxylated, propoxylated or both and gives excellent molecular weight distribution information. Closer inspection of the spectra indicate the nature of the resin employed.

AROMATIC OLIGOMERS

Fig 2 shows the FD spectra of two oligomeric systems A and B which are both based on the system $\text{ClOSO}_2(\text{OSOSO}_2)_n\text{OCl}$ (where O indicates a para substituted benzene ring). The first point to notice is the abundant multiply charged ions in the lower part of the spectrum. The spectra show that sample B has a higher molecular weight distribution than sample A indicating that the polymerisation has gone further. Of even more interest however is the presence in the spectrum of sample B of ions to the left of the major oligomeric ions. These correspond to molecules in which the end group is different. The differences indicate that the substitution is F for Cl and OH for Cl. The distributions for these mixed end group species can also be measured giving important information on kinetics and reactivity. Note that the identification of OH and F end groups requires a resolution of two daltons.

AROMATIC POLYMER

Modern aromatic polymer systems such as aryl ethers, ketones, sulphides and sulphones have a molecular weight range of ~5-25,000 daltons. In the past mass spectrometry could only contribute to the characterisation of these materials after chemical or thermal degradation. This approach has only limited utility. Developments in ionisation technique, mass range and sensitivity of mass spectrometric instrumentation was required in order for these systems to be studied intact. The combination of FD with high performance double focussing instruments has made this a reality. Figure 3 shows the FD spectrum of an aromatic polymer of the structure indicated. This is typical of a wide range of polymers studied where ions up to 10,000 daltons can be easily seen.

CONCLUSIONS

Field desorption ionisation coupled with high mass range double focussing mass spectrometers has been shown to be a powerful approach to the characterisation of non polar molecules of >1000 daltons mass range. Providing information on structure and molecular weight distribution difficult to obtain by other methods.

FIGURE 2

THE CHARACTERISATION OF SYNTHETIC LUBRICANT FORMULATIONS BY FIELD DESORPTION MASS SPECTROMETRY

K Rollins, M Taylor, J H Scrivens, A Robertson, ICI Wilton Materials Research Centre, Wilton, Cleveland, TS6 8JE, England

H Major, VG Analytical Ltd., Manchester, England.

The analysis of complex mixtures in difficult matrices is a recurring requirement for the industrial mass spectrometry laboratory. This provides a considerable challenge to the mass spectroscopist since such samples can often contain compounds of widely differing polarity, thermal lability and molecular weight. A recent example of this type of work in our laboratory has been the analysis of commercial synthetic lubricant samples. These formulations typically consist of up to three major components; a synthetic or natural oil, a polyolefin and a synthetic ester.

The initial approach to this problem was the analysis of the lubricant formulations by conventional GC-MS and direct insertion probe methods. However, the combined problems of overwhelming hydrocarbon background signal which results in extreme difficulty in the extraction of useable information coupled with the involatility of the increasingly complex high molecular weight esters used make the use of both of these techniques in this area inappropriate. For these reasons, the techniques of field desorption (FD) and field ionisation (FI) were evaluated as possible solutions.

The FD/FI spectra were obtained using a VG Analytical ZAB-2SE mass spectrometer of reverse geometry and the standard combined VG FAB/FD/FI source. 13 μ m FD emitters were prepared using the high temperature indene FD-emitter activation process of Rabrenovic et al (1).

Three examples of the utility of the FD-MS technique over a range of three different types of mixtures are presented here. The first example, shown in Figure 1, is the FD spectrum of a synthetic oil-based lubricant of molecular weight distribution 300 to 600. Figure 2 shows a second example in which the oil base has been supplemented by the addition of a polyalphadecene additive as shown by the peaks appearing at a spacing of 140 daltons. The final example shown in Figure 3 is a good illustration of a lubricants package comprising a synthetic oil base of molecular weight distribution 300 to 500, again the polyalphadecene additive (peaks at M/Z 421, 561, 701, 841 and 979) and proprietary esters at M/Z 424 and 1110. A further point worth noting from the spectrum is the distribution of peaks at M/Z 1110 $\pm$ 14 daltons which provides information on the alkyl chain length distribution of the feedstock acids/alcohols used in the preparation of these esters. This again provides a convenient method for ester characterisation.

The use of FD/FI techniques clearly provides an elegant approach to the characterisation of complex mixtures. The ability to investigate a wide range of compound types of varying polarity and thermal stability all within a single mass spectrum is an extremely attractive feature. The installation of a four sector tandem MS-MS system of BEBE geometry (the VG Analytical ZAB-T) in late 1989 will be used to extend the present work to the use of FD-MS-MS is the characterisation of synthetic lubricants.

MASS SPECTRAL CHARACTERIZATION OF COMPOUNDS FORMED DURING HIGH TEMPERATURE OXIDATION OF STYRENE BASED POLYMERS USING THERMAL CHROMATOGRAPHY

Chris Sutton and John E. Zumberge, Ruska Laboratories, Inc., Houston, Texas 77063

Three styrene based polymers, polystyrene, poly[4-chlorostyrene], and poly[4-t-butylstyrene] were thermally decomposed by heating to 600°C in both helium and air in a Ruska Laboratories' Thermal Chromatograph-Mass Spectrometer (TC-MS). In this turn-key heating/GC/MS instrument, the identification and detection of compounds eluting from a capillary GC column was accomplished by using a Hewlett-Packard 5970 MSD mass spectrometer equipped with a 59940 HP-UX data system.

Different experiments were performed in order to assess the dependance of relative amounts of oxidation upon various experimental parameters. The polymers were heated at either 5°C/min or 30°C/min in either helium or air from 30°C to 600°C. In the oxidation experiments the effect of flow rate of air past the heated polymer was studied as well. Thermal degradation compounds were trapped in a cold trap at -80°C. They were desorbed by heating the trap to 340°C at 30°C/minute and were subsequently cryogenically focused on the head of a 30m x 0.32mm DB-5 capillary column at -45°C. The GC column was heated from -45 to 305°C at 5°C/min. Simultaneously with the initiation of GC column temperature programming, the Hewlett-Packard MSD was turned on. It scanned a 34 to 450 amu mass range once every 1.35 seconds.

For each polymer, the major thermal decomposition product formed by heating in helium was the monomer: styrene, 4-chlorostyrene, and 4-t-butylstyrene (Figure 1, for example). The most abundant oxygenated thermal decomposition product formed by heating polystyrene in air was benzaldehyde. Other oxygenated compounds formed included phenol, benzene acetaldehyde, 1-phenylethanone, phenylpropenal isomers, and benzoic acid (Figure 2). The 4-chloro and 4-t-butyl analogs of these compounds were formed by heating poly[4-chlorostyrene] and poly[4-t-butylstyrene] in air.

THERMAL DEGRADATION OF POLYSTYRENE BEAD IN HELIUM

Figure 1

THERMAL DEGRADATION OF POLYSTYRENE THIN LAYER IN AIR

Figure 2

One way in which the relative degree of oxidative thermal degradation can be assessed is by the ratio of the aldehyde to the corresponding styrene based monomer (Table 1). For one set of experimental conditions, this ratio is 3.83 for polystyrene, 8.01 for poly[4-chlorostyrene], and 1.53 for poly[4-t-butylstyrene]. Note that the benzaldehyde to styrene ratio of 19.3 in Table 1 may be anomalously high because of loss of styrene to benzaldehyde caused by inefficient trapping in that experiment. Other

parameters such as the ratios of benzoic acid to benzaldehyde, 4-chlorobenzoic acid to 4-chlorobenzaldehyde, and 4-t-butylbenzoic acid to 4-t-butylbenzaldehyde also indicate oxidation. Interestingly, the oxidation of 4-chlorostyrene was accompanied by the formation of significant amounts of hydrochloric acid. Further experiments indicated that the most important experimental parameter affecting the relative amount of oxidation was the heating rate from 30 to 600°C: slower heating rates led to more oxidation. The surface to volume ratio of the heated polymer and the flow rate of air through the porous, fused quartz crucible appear to be of less importance. Finally, the susceptibility of the styrene based polymer to oxidation depended upon the nature of the substituent group on the benzene ring. An oxidation index was formulated by dividing the ratio of aldehyde to monomer for thin layer data at a 5°C/minute heating rate by the same ratio for thin layer data at a 30°C/minute heating rate for each polymer. Larger values of this index indicate increased susceptibility to oxidation. Based upon this index, poly[4-chlorostyrene] appears to be more susceptible to oxidation than polystyrene which, in turn, appears more susceptible than poly[4-t-butylstyrene]. In this respect the oxidation index correlates well with the Hammett substituent constant, sigma.

TABLE 1
ALDEHYDE TO MONOMER RATIOS INDICATE OXIDATIVE THERMAL DEGRADATION OF SUBSTITUTED POLYSTYRENES

EXPERIMENT	POLYSTYRENE	POLY[4 CHLOROSTYRENE]	POLY[4 t BUTYLSTYRENE]		
	BENZALDEHYDE ¹ STYRENE ²	4-CHLOROBENZALDEHYDE ³ 4-CHLOROSTYRENE ⁴	4-t-BUTYLBENZALDEHYDE ⁵ 4 t BUTYLSTYRENE ⁶		
Helium 30°C/min	0.0	0.0	0.0		
Air, Bead 30°C/min Air = 30 ml/min	0.78	1.60	1.12		
Air, Thin Layer 30°C/min Air = 30 ml/min	0.72	0.69	0.68		
Air, Bead 5°C/min Air = 30 ml/min	19.3	6.50	1.63		
Air, Thin Layer 5°C/min Air = 30 ml/min	3.83	8.01	1.53		
Air, Bead 30°C/min Air = 4 ml/min	0.73	1.45	0.98		
Air, Thin Layer 30°C/min Air = 4 ml/min	0.86	0.74	0.76		
1. m/z = 106	2. m/z = 104	3. m/z = 139	4. m/z = 138	5. m/z = 147	6. m/z = 145

Although this study focused on low molecular weight thermal decomposition products, various dimers and trimers were also identified along with corresponding oxygenated derivatives formed by heating the polymers in air.

Mass Spectral Study of the Thermal Behavior of Polymers of Oxalic Acid

Stephen Weininger, Worcester Polytechnic Institute, Worcester, MA 01609
and

Walter Yeomans, US Army Natick RD&E Center, Natick, MA 01760

This project involves the design of polymers that decompose cleanly to gaseous products. One class of polymer that appears promising in this regard is the unsaturated aliphatic polyoxalates, which may be expected to decompose to carbon dioxide and conjugated polyenes. In order to test the concept, a series of polyoxalate esters was prepared by transesterifying diethyl oxalate with the following C4 alcohols: 1,4-butanediol, *cis*- and *trans*-2-butene-1,4-diol, and 2-butyne-1,4-diol. The structures of the resulting polymers (1-4) are as follows:

The polymers were characterized by IR and NMR spectroscopy. The latter technique showed that the degree of polymerization was generally low for each product; the highest DP (~ 32) achieved with polymer 4. Thermal behavior of the four products was investigated by means of TGA, DSC, and EI- and CIMS.

TGA showed that polymers 1-3 decomposed quite cleanly, leaving residues ≤ 10 percent at 450°C. Polymer 4 left a residue of 20-30 percent at that temperature. DSC results were consistent with our initial hypothesis: while the saturated polymer 1 decomposed endothermically as expected, polymers 2-4 decomposed exothermically. This result agrees with formation of stable fragments by a simple bond cleavage mechanism.

In order to investigate the decomposition mechanisms in detail, MS was used for product identification. The literature contains no report on the MS of polyoxalates and few on simple oxalate esters. The latter are "very unstable upon electron impact." [1] For this reason, both EI- and CIMS (methane reagent gas) were applied. The former was useful for identifying low molecular weight fragments, the latter for detecting oligomeric products. Samples were decomposed in the direct insertion probe of a Finnigan 4500 mass spectrometer while the temperature was raised from 50 to 350°C. The probe was held at several intermediate temperatures (~ 140, 200, 250, 300) for periods up to 1 minute with rapid change between temperatures.

Three major processes were identified for the decomposition of 1. At temperatures up to 140°C, the main reaction is further polymerization, indicated by production of the alcohol end groups, ethanol and butanediol (see Table). A temperature increase leads to appearance of small linear oligomers, also a result of further transesterification. At temperatures above 300°C, depolymerization through formation of cyclic oligomers becomes important. [2]

Polymers 2 and 3 also undergo transesterification and evolve alcohols and short chain linear oligomers below 300°C. Unlike 1, however, 2 and 3 lose alcohols by heterolytic cleavage of the labile allylic and propargylic O-CH₂ bonds. This reaction produces HOOC-COOR end groups, evidenced by the detection of protonated oxalic acid (*m/z* 91) and of their thermal products, fragments with formyl end groups, HCOOR. Above 300°C 2 and 3, like 1, depolymerize to cyclic oligomers, but this process becomes secondary to homolytic fragmentation to CO₂ and 1,3-butadiene, as suggested by DSC. Both 2 and 3 produce very similar spectra, suggesting similar thermal fragmentation paths.

THERMAL PRODUCTS

Polymer	$T < 125^{\circ}\text{C}$	$100^{\circ}\text{C} < T < 300^{\circ}\text{C}$	$T > 300^{\circ}\text{C}$
1	$\text{HO}(\text{CH}_2)_4\text{OH}$ EtOH	$\text{HO}(\text{CH}_2)_4\text{OOCOR}$ $\text{EtOCCOO}(\text{CH}_2)_4\text{OR}$	$[-\text{O}(\text{CH}_2)_4\text{OCCO-}]_n$
2,3	$\text{HOCH}_2\text{CH:CHCH}_2\text{OH}$ EtOH	$\text{EtOCCOOCH}_2\text{CH:CHCH}_2\text{OR}$ $\text{HOCCOOCH}_2\text{CH:CHCH}_2\text{OR}$ $\text{HCOOCH}_2\text{CH:CHCH}_2\text{OR}$	$\text{CH}_2\text{:CHCH:CH}_2$ $[-\text{OCH}_2\text{CH:CHCH}_2\text{OCCO-}]_n$
4	$\text{HOCH}_2\text{C:CCH}_2\text{OH}$ EtOH	$\text{HOCH}_2\text{C:CCH}_2\text{OCCOOR}$ $\text{HOCCOOCH}_2\text{C:CCH}_2\text{OR}$ $\text{HCOOCH}_2\text{C:CCH}_2\text{OR}$	$\text{CH}_2\text{:C:C:CH}_2$ $\text{HOCCOOCH}_2\text{C:CCH}_2\text{OR}$

Polymer 4 continues the pattern of transesterification and alcohol loss at low temperatures, and fragments to butatriene at high temperatures. Formation of cyclic oligomers is restricted by conformational considerations and no compounds larger than dimers were detected. Cross-linking of the triple bonds at elevated temperatures probably explains the large residue.

DEGRADATION OF POLY[BIS(PHENOXY)PHOSPHAZENE] POLYMERS

Shawn J. Maynard, Thomas R. Sharp and James F. Haw
Department of Chemistry, Texas A&M University
College Station, Texas 77843 U.S.A.

Poly(organophosphazenes) (**1**) are made by the reaction of poly(dichlorophosphazene) (**2**) with alkoxides (**3**), shown below in Scheme 1, where OR is an alkoxy or an aryloxy group^{1,2}. They are elastomers or film-forming thermoplastics, and have superior physical and mechanical properties. These polymers are currently being used where physical flexibility or chemical durability are needed in extreme temperature regimes³. As a result of the high technology applications of poly(organophosphazenes), thermal and hydrolytic degradation of these materials has been, and continues to be of interest⁴. One of the main conclusions drawn by several studies is that the degradation of poly(organophosphazenes) is greatly affected by "weak links", as shown below. To date, however, a systematic study of the effect that weak links have on the thermal or hydrolytic degradation of poly(organophosphazenes) has not been done. This study focuses on the effects that P-Cl weak link sites have on the thermal and hydrolytic degradation of poly[bis(phenoxy)phosphazene] (PBPP). A series of polymers that have varying concentrations of P-Cl weak link sites were prepared and subjected to several degradation conditions⁵. This report will discuss only one of these degradation conditions -- dynamic degradation.

Compounds: Three samples of PBPP were prepared and studied in detail, and were designated based on their chlorine contents: PBPP-0.00 contained less than 0.005% (by weight) chlorine, while PBPP-2.40 and PBPP-9.90 contained 2.40% and 9.90% chlorine, respectively. The chlorine content in the latter two polymers corresponds to one [N=P(Cl)(OPh)] unit for every six [N=P(OPh)₂] units in PBPP-2.40 and one [N=P(Cl)(OPh)] unit for every [N=P(OPh)₂] unit in PBPP-9.90. All evidence is consistent with the distribution of chlorine along the backbones of the polymers being random.

Dynamic Degradation Procedure: Mass spectral analyses were performed on a VG Analytical 70-S mass spectrometer⁶ using 70 eV electron impact ionization. Samples of PBPP-0.00, PBPP-2.40, PBPP-9.90, or model compounds were introduced by direct insertion probe and heated from ambient temperature to ca. 480°C at ca. 26°C/min. Mass spectra of volatilized materials were concomitantly acquired by repetitive scanning.

Dynamic degradation of PBPP samples. Mass spectrometry was used to identify the degradation products evolved during dynamic degradation of these samples. Figure 1 shows the total ion current (TIC) profiles as a function of probe temperature. These curves are similar to differential thermogravimetric curves, in that their maxima characterize the temperature at which maximum depolymerization of the polymers occurs under these experimental conditions. Figure 2 shows representative mass spectra corresponding to the maxima of the TIC profiles in Figure 1. Identification of products was supported by comparison with the mass spectra of authentic samples. The presence of structurally significant fragment ions, such as [M-OPh]⁺ and M²⁺, that evolved concomitantly with their respective molecular ions were used to support identification^{7,8}. Chlorine isotope patterns were used to identify chlorine-containing products.

Figure 1:

The TIC profile in Figure 1a shows that depolymerization of PBPP-0.00 was negligible between 25–480°C. Traces of phenol (m/z 94) and $[\text{NP}(\text{OPh})_2]_3$ (M^+ , m/z 693, and M^{2+} , m/z 346.5) were evolved from the sample at 200°C and 480°C, respectively. Traces of monochlorotrimer were also observed at 145°C.

Unlike PBPP-0.00, large amounts of volatile degradation products were evolved from PBPP-2.40, which began to degrade at 375°C (Figure 1b). The species that evolved (Figure 2b) were identified as $[\text{NP}(\text{OPh})_2]_3$ (m/z 693), $[(\text{NP})_3\text{Cl}(\text{OPh})_5]$ (m/z 635), $[(\text{NP})_3(\text{Cl})_2(\text{OPh})_4]$ (m/z 577), $[(\text{NP})_4\text{Cl}(\text{OPh})_7]$ (m/z 866), and $[(\text{NP})_4(\text{Cl})_2(\text{OPh})_6]$ (m/z 808). The corresponding M^{2+} were observed at m/z 346.5, m/z 317.5, m/z 462, m/z 433, and m/z 404, respectively.

Likewise, PBPP-9.90 evolved large amounts of volatile degradation products at 350°C (Figure 1c). The species that evolved (Figure 2c) were identified as $[\text{NP}(\text{OPh})_2]_3$ (m/z 693), $[(\text{NP})_3\text{Cl}(\text{OPh})_5]$ (m/z 635), $[(\text{NP})_3(\text{Cl})_2(\text{OPh})_4]$ (m/z 577), $[(\text{NP})_4\text{Cl}(\text{OPh})_7]$ (m/z 866), $[(\text{NP})_4(\text{Cl})_2(\text{OPh})_6]$ (m/z 808), and $[(\text{NP})_4(\text{Cl})_3(\text{OPh})_5]$ (m/z 750). The corresponding M^{2+} were found at m/z 346.5, m/z 317.5, m/z 259.5, m/z 433, m/z 288.5, and m/z 375.

Figure 2:

Traces of monochlorotrimer observed during the dynamic degradation of PBPP-0.00 show that mass spectrometry is uniquely able to identify the presence of residual chlorine by identification of cyclic trimer phosphazene compounds that contain chlorine, even at this very low concentration. The observation of monochlorotrimer indicates that the phosphorus-nitrogen bond from the P-Cl weak link site undergoes a heterolytic bond cleavage to form monochlorotrimer by cyclization depolymerization (Scheme 2). However, there was not an increased amount of trimer or tetramer observed when monochloro trimer was examined. Therefore, depolymerization by cyclization was not significant for PBPP-0.00. This indicates that it is important to identify and quantify the residual chlorine content in a phosphazene polymer prior to characterizing its thermal behavior, in order to obtain an accurate evaluation of its thermal stability. Allcock et al. observed chlorobenzene produced from degradation of PBPP and suggested it to be a sensitive test for identifying residual chlorine. In this study, where PBPP was intentionally prepared with residual chlorine, no chlorobenzene was detected under these conditions.

THERMAL STABILITY OF ETFE COPOLYMER SYSTEMS *, John J. Morelli, Charles G. Fry, Clarence J. Wolf, Michael A. Grayson, and Arthur C. Lind, McDonnell Douglas Research Laboratories, St. Louis, MO, 63166.

This report focuses on evolved gas mass spectrometric (EGAMS) analysis of an irradiated (X) poly(ethylene tetrafluoroethylene) (ETFE) insulation and neat unirradiated ETFE resin. ¹³C-NMR and IR data are presented to complement the EGAMS findings and allow a more complete understanding of chemical changes occurring within the resin during thermal aging in air. This combination of techniques allowed both evolved gases and bulk polymer constituents to be characterized.

Figure 1 is typical of the total ion current (TIC) profile obtained from ETFE and X-ETFE systems before and after nine days of thermal aging in air at 200°C. The major change observed between the evolution profiles of aged and unaged systems is in the region of scans 15 to 45 of Figure 1 (corresponding to 200 and 350°C). The EGAMS spectra obtained in this temperature interval from the unaged systems indicate that the materials evolved are low-molecular-weight oligomers of ETFE. Figure 2 is an example of the spectra obtained. Although the spectrum is a mixture of compounds, major ions can be rationalized by comparison with reference spectra of tetradecafluorodecane (I) and octafluorodecane (II). Spectra of I and II indicate m/z 69, 77, 127, 177, and 197 are ions associated with fragmentation from the CF₃ terminus, whereas m/z 79 characterizes fragmentation from the CH₃ terminus.

I

II

The following series of ions were observed below pyrolysis temperatures in EGAMS spectra of ETFE systems: (a) 69 + n128, 77 + n128, 127 + n128, 177 + n128 due to fragmentation from the CF₃ terminus; (b) 79 + n128 due to fragmentation from the CH₃ terminus; (c) 147 + n128, m/z 147 is seen in both fluorinated decane spectra. The spectrum in Figure 2 and the reference spectra of I and II indicate fragmentation preferentially involves the bond between consecutive fluorinated carbons. We assume that ions which do not fit the above series but can be rationalized as displaced by 28 mass units indicate that an extra ethylene unit is present in the fragment. Preliminary data indicate that such ions are direct evidence of consecutive ethylene units in an otherwise alternating chain of ethylene and tetrafluoroethylene units. Similarly, ions displaced by 50 or 100 from these series indicate extra tetrafluoroethylene units. For example, m/z 205 is included in series (a); therefore, this signal is not attributed to be m/z 177 + 28. Alternatively, m/z 227 and m/z 297 are not members of series (a), (b), or (c); thus, these ions are assigned to m/z 177 + 50 and m/z 197 + 100, respectively. In general, series (d) is assigned to ions characteristic of consecutive ethylene or tetrafluoroethylene units.

An additional species was detected in the unaged X-ETFE wire insulation between 200°C and 350°C and was identified as triallyl isocyanurate (TAC; III). This species was not detected during EGAMS analysis of the aged wire, suggesting that it was lost during thermal aging.

Figure 3 shows the solid-state ¹³C cross-polarization/magic-angle-spinning (CP/MAS) NMR spectra of unaged and thermally aged wire insulation. Resonances from tetrafluoroethylene (3) and ethylene (5) units, and TAC resonances (1, 2, and 4) were observed in the unaged wire. The "s" contributions are spinning sidebands, that is, artifacts due to the sample spinning used to maximize spectral resolution from solid-state materials. In the NMR spectrum of the thermally aged insulation, the allyl moiety resonances, 2 and 4, of TAC are missing. Together, the NMR and EGAMS data indicate TAC is present in unaged wire as two separate species. We conclude that these forms are "free" TAC and crosslinked TAC. During thermal aging, "free" TAC is lost. In addition, a new resonance (6) is observed by NMR after thermally aging insulation and neat ETFE resin and indicates the polymer is undergoing crosslinking reactions during thermal aging.

Figure 4 shows the IR spectra obtained from unaged and thermally aged insulation between 1800 cm⁻¹ and 1550 cm⁻¹ and confirms that two carbonyl species are present (1700 cm⁻¹ and 1740 cm⁻¹). IR spectral examination also shows the preferential loss of one species after thermal aging of the wire.

The pyrolysis mass spectra of all systems obtained in the temperature region above 400°C show the ETFE ion series (a) - (d) described above and many low-intensity ions as yet unidentified. The wire insulation also evolved antimony oxide and antimony fluoride at pyrolysis.

LIQUID CARBON DIOXIDE VS. SOLVENT EXTRACTION
OF ORGANIC POLYMER ADDITIVES
FOR MASS SPECTRAL ANALYSIS

M. L. Miller, Monsanto Chemical Co.
Akron, Ohio 44313

The analysis of polymer additives is an important part of product formulation or failure analysis. Traditionally, organic additives in rubber formulations have been analyzed by characterization of isolated extracts from solvent extraction techniques. A common method involves the use of Soxhlet-type apparatus, where the additives are exposed to boiling solvent for long periods of time and are diluted by a large volume of solvent. Typically, organic polymer additives are used at a level of less than 1%. Consequently, the loss of analyte to reaction, degradation, and volatilization during extraction or sample concentration makes the task of analysis much more difficult. Additionally, degradation of the polymer and the volume of solvents involved can introduce artifacts. Uncured compounded rubber presents an additional complication in the analysis of samples because the reactive curatives are temperature sensitive. This paper presents a comparison of liquid carbon dioxide extraction versus soxhlet-type solvent extraction of organic polymer additives for mass spectral analysis. The advantages of liquid carbon dioxide extraction are the low temperature to which the additives are exposed and that the analytes are obtained as a solvent free residue. Mass spectrometry is a highly sensitive and proven technique for the identification of organic additives in polymers (1).

Experimental: The liquid carbon dioxide extractions were carried out in a J&W high pressure soxhlet extractor for 3 hours using dry ice as a source of carbon dioxide. The solvent extractions were carried out in a Soxtec extraction apparatus using 50 ml of acetonitrile as solvent for a period of one hour and were concentrated under nitrogen flow with heat. Both types of extraction were performed on uncured and cured rubber samples consisting of a white stock and a black stock based on synthetic polyisoprene. One gram samples in thin sheets were extracted. Field desorption mass spectrometry was carried out by dipping the carbon emitters in an extract solution at a concentration of 20 mg/ml.

Results/Discussions: The extracts were run by FD/MS since it has been demonstrated this technique gives the most information in the least amount of time (2). The white stock sample contained the following organic additives: mercaptobenzothiazole disulfide (MBTS); tetramethylthiuram monosulfide (TMTM); 4,4'-thio-bis-(2-methyl-6-t-butyl phenol) (TMBP); and tris(3,4-di-t-butyl-4-hydroxybenzyl) isocyanurate (BHBI). The black stock sample had the following organic additives: t-butylamine-2-benzothiazylsulfenamide (TBBS), N-(cyclohexylthio) phthalimide (CTP) and N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD). Molecular ions for the curatives, TBBS and CTP were observed at 238 and 261 amu in the uncured black stock extracts by liquid carbon dioxide and solvent extraction. However, molecular ions for the curatives, TMTM and MBTS were observed (208 and 332 amu) only in the liquid carbon dioxide extract of the uncured white stock. Rheological curves of the black and white stock samples indicate the white stock is vulcanized in half the time of the black stock. This indicates the white stock sample is too reactive for soxhlet-type extraction, but the

mild conditions of liquid carbon dioxide extraction isolates intact curatives. The antidegradant molecular ions of 6PPD, TMBP, and BHBI were observed at 268, 358, and 783 in cured and uncured samples by both extraction techniques. Ion intensities of all the additives were similar in the mass spectra of the liquid carbon dioxide and acetonitrile extracts even though in every case the liquid carbon dioxide extract weights were lower than the equivalent acetonitrile sample. This suggests the liquid carbon dioxide extraction efficiency is comparable to the acetonitrile extraction for the range of polarities and molecular weights of organic additives in this study.

**STEPWISE PYROLYSIS OF POLYMERIC MATERIAL
BY ON-LINE PYROLYSIS/GC/MS**

Henry L. Chung, Denise S. Moore, and John C. Aldridge

R. J. Reynolds Tobacco Company
Bowman Gray Technical Center
Winston-Salem, NC 27102

Pyrolysis (PY) is the thermal dissociation of material into simpler fragments. Pyrolysis under controlled conditions can be used to obtain characteristic fragmentation of non-volatile materials into volatile components. Pyrolysis, followed by GC/MS, is a particularly powerful tool for the separation and identification of polymeric materials.

An on-line PY/GC/MS system has been constructed and modified from commercially available instruments. A Chemical Data Systems (CDS) Pyroprobe Model 122 was coupled to a Hewlett-Packard (HP) 5890 Gas Chromatograph/5970 Mass Selective Detector (GC/MS) system. A four-way ball valve was installed between the inlet and the outlet of the GC interface of the Pyroprobe, so that the GC carrier gas could either sweep or by-pass the interface after the pyrolytic process. A small amount of sample was placed in a quartz tube. The quartz tube was inserted into a platinum coil probe. The temperature of the probe was set at different temperatures. The same sample was pyrolyzed for 10 seconds at each temperature. The temperature of the probe chamber was 200°C. Helium was used as the carrier gas. The flow rate was 15 ml/min over the pyrolytic zone. After the pyrolytic process, the volatile pyrolysis products were transferred directly into the GC injector and were analyzed by GC/MS. A 60-m DB-1701 fused silica capillary column was used for GC separation of the pyrolysis products. The GC oven temperature was set at 35°C, held for 5 minutes and then programmed to 220°C at 3°C/min. The GC/MS interface was an open-split interface at 250°C. The temperature of the ion source was 200°C. The mass spectrometer was operated in the EI mode at 70 eV energy. The mass spectral scan range was from 29 to 500 amu. The GC/MS system was interfaced to an HP 1000 computer with the RTE-A series data system. During the course of such successive Pyroprobe treatments, the number of the pyrolysis products detected was seen to increase with increasing temperatures up to a maximum, after which the number decreased with each successive treatment until only a few or no further pyrolysis products could be detected. In the example studied, the temperature of the probe was set at 400°C, 500°C, 550°C, 600°C, 650°C, 750°C, 850°C, and 950°C, respectively. The maximum number of pyrolysis products occurred at about 550°C with only a few components being seen above 950°C. Mass spectra of the pyrolysis products revealed the presence of derivatives of furan, 2-cyclopenten-1-one, furanone and phenol. Since such products are components of pyrolyzed cellulose, it is thus shown that the stepwise pyrolysis technique as performed by the described system can satisfactorily assist in the identification of pyrolysis products and give a full profile of the polymeric materials.

BULK POLYMER ANALYSIS USING LASER IONIZATION MASS SPECTROMETRY (LIMS) AND
PATTERN RECOGNITION TECHNIQUES

Robert W. Odom and Filippo Radicati di Brozolo, Charles Evans & Associates,
301 Chesapeake Drive, Redwood City, CA 94063, USA

and

Peter B. Harrington and Kent J. Voorhees, Depts. of Chemistry and
Geochemistry, Colorado School of Mines, Golden, CO 80401.

Laser ionization mass spectrometry (LIMS) is a microanalytical materials analysis technique which employs a focused, high power density pulsed laser irradiation and time-of-flight mass spectrometry (TOF-MS) for the chemical analysis of a wide range of solid materials. The LIMS technique is capable of performing both elemental or inorganic microanalysis as well as organic microanalysis. This paper describes continuing research performed in our laboratories in which pattern recognition processes are employed to classify and identify complex LIMS mass spectra produced from organic polymers.

The present study had two main objectives:

1. Determine how well principal component analysis/discriminant analysis (PCDA) routines can distinguish mass spectra produced from chemically similar polymers and
2. Evaluate whether partial least squares (PLS) techniques[1] can quantitatively relate physical testing data with mass spectra.

These evaluation were performed on an epoxy system comprised of various stoichiometries of the 4, 4'-diaminodiphenyl sulfone (DDS) hardener to the tetraglycidyl 4,4'-diaminodiphenylmethane (TGDDM) resin. The DDS/TGDDM epoxy resin is one of the most important bonding matrices utilized for carbon fiber materials in the aviation industry and its physical properties are strongly dependent on the DDS/TGDDM stoichiometries[2]. Thus, the ability to predict the stoichiometry and hence the physical properties of this important epoxy system *in situ* on the microanalytical scale typical carbon fibers could represent a unique method for certifying the integrity of these reinforced components.

Previous studies on this epoxy system demonstrated that the most unique LIMS mass spectra of the different compositions were produced in positive ion analyses at relatively low laser irradiance ($\sim 10^6 \text{ W/cm}^2$). Thirty positive ion mass spectra were acquired from thirty distinct locations on each sample and the data was processed using the RESOLVETM principal component analysis/discriminant analysis software which has been previously described[3]. Twenty-nine principal components described >94% of the raw data and cross validation of the canonical variates produced in the linear discriminant analysis yielded a cross validation accuracy of ~ 60%. Thus, the PCDA analysis could accurately describe 60% of this data which is considered reasonably good considering the similarities in the composition of the samples. Figure 1 is canonical variate score plot obtained in this analysis in which each letter in the plot represents an individual mass spectrum and the different letters represent different hardener to resin ratios. With the exception of the 1.5 (Sample E) data, this score plot illustrates a nearly linear variation of score value and sample stoichiometry. Thus, this type of component score plot can be used to predict the stoichiometry of an unknown sample.

This data was also analyzed using a PLS routine. The correlations investigated in this analysis were between sample stoichiometry, mechanical properties (tensile strength and peak strain) and the LIMS mass spectra. Figure 2 is a plot of the calculated relationship between the mechanical properties and the LIMS data obtained in the PLS analysis. The 0.2 stoichiometry (C Sample) is not included in this plot because there was no mechanical data for this stoichiometry. The variation in the LIMS data indicates the reproducibility of the raw data in the PLS analysis. This data does illustrate an almost linear relationship between the mechanical data and the LIMS mass specibility of the raw data in the PLS analysis. This data does illustrate an almost linear relationship between the mechanical data and the LIMS mass spectra (sample stoichiometry) indicating that the LIMS technique in conjunction with these data analysis procedures can provide useful information on this materials' mechanical properties at the microanalytical dimensions.

Study of Redox Properties of Poly-3-methylthiophene Films by
Cf-252 Plasma Desorption Mass Spectrometry

J. Ai and R. D. Macfarlane

Department of Chemistry, Texas A&M University, College Station, TX 77843

Poly-3-methylthiophene (PMeT) films are stable in both the oxidized and reduced forms. The oxidation of PMeT films is accompanied by negatively charged counter ions diffusing into the film to balance the charge of polymer chains. If the film is reduced, counter ions are expelled from the film. These processes can be reversibly accomplished in an electrochemical cell. The oxidation of the film introduces electronic states in between the band gap known as bipolarons, which contribute the conductivity of the polymer. In this study, we made thin PMeT films for Cf-252 Plasma Desorption Mass Spectrometry (CF-252 PDMS) studies. The desorbed counter ions were detected as a function of oxidation potential in the cycling processes either from the oxidized state to the reduced state or vice versa. Electronic states are formed in between the band gap due to oxidation and can be studied by UV-Vis spectrophotometry.

Figure 1(a) shows the intensity of the counter ion CF_3SO_3^- from PMeT films which were held at different potentials as the film was reduced in the electrochemical cell. The counter ion intensity was very high for the oxidized state (1.00 V vs. Ag/AgCl). As the potential decreased, the counter ion intensity remained at a fairly constant value and then dropped to a much lower intensity from 0.4 V to 0.20 V. At this stage, the PMeT film was reduced. We repeated the same measurement as PMeT films were cycled from the reduced state to the oxidized state. The mass spectra are shown in Figure 1(b). The intensity of CF_3SO_3^- peak increased rapidly as the potentials went from 0.4 V to 0.6 V. The PMeT film was oxidized.

Fig. 1 Mass spectra of PMeT, CF_3SO_3^- is the counter ion. The intensity of the counter ion changes as the potential held the for the PMeT film varies (Ag/AgCl as the reference). (a) the PMeT is cycled from the oxidized state to the reduced state. (b) The film is cycled from the reduced state to the oxidized state.

Figure 2 shows the UV-Vis absorption spectra of PMeT films held at different potentials. The intense absorption band for the reduced PMeT film at 400nm is the band gap transition for PMeT. As the film is oxidized, a new absorption band appears at about 800nm which is a transition from the valance band to the bipolaron states. The intensity of this peak increases gradually as the PMeT film is oxidized. There is no big difference in absorption

spectra whether the PMeT film is cycled from the oxidized state to the reduced state or vice versa.

From mass spectra of the PMeT film (Figure 1), we can see that the potential range at which the counter ion intensity changes depends on the cycling processes. If the PMeT is cycled from a higher potential (oxidized) to a lower one (reduced), the intensity drop is in the 0.4 V to 0.2 V range. If the film is cycled from the reduced state to the oxidized state, the intensity increase occurs in the 0.4 V to 0.6 V range. There is no such difference in UV-Vis absorption spectra. Compared with the cyclic voltammogram (Figure 3), the potential range corresponding to the change of counter ion intensity in mass spectra is seen as two peaks on the cyclic voltammogram. One of these appears at 0.6 V as the film is cycled from the reduced state to oxidized state. Another is at about 0.25 V when the film is cycled from the oxidized state to the reduced state. The diffusion of counter ions into or out of the PMeT film involves kinetic factors not seen from the UV-Vis absorption spectra which mainly reflect oxidation levels. The following mechanism is suggested to explain the phenomenon. The reduction of the PMeT film occurs layer by layer starting with the layer closest to the Au electrode substrate. As counter ions are being expelled into the solution during the reduction, the counter ion concentration is kept almost constant at the surface layer where the 252 Cf-PDMS is most sensitive until the whole film is reduced. That is why a fairly constant intensity of counter ion peaks is observed as the film is reduced. In the re-oxidation process, counter ions diffuse to the inner layers first and the surface layer is filled last. After the whole film is filled with counter ions, a constant intensity of counter ion peak will be observed.

WATCHING REACTIONS WITH K⁺IDS:

William J. Simonsick, Jr., Maryann Fulginiti;
E. I. du Pont de Nemours & Co, Ltd., Philadelphia, PA 19146

Many of today's architecturally designed high performance polymers are synthesized using oligomeric building blocks which possess molecular weights of less than 1000 Dalton (Da). The chemical microstructure of these oligomers is critical to the final properties of the high performance polymer. We have used the molecular weight data furnished by potassium ionization of desorbed species (K⁺IDS) to characterize several oligomers. Based upon the molecular weight data and a knowledge of starting materials, we have identified and quantified multifunctional oligomers synthesized by group-transfer polymerization (GTP). Furthermore, K⁺IDS analysis can also be used to identify differences in product distributions resulting from catalyst changes or in the polymerization conditions.

The K⁺IDS technique uses rapid heating to desorb large intact oligomers (>1500 Da). Once in the gas phase, ions are generated by potassium attachment. The K⁺IDS mass spectrum consists of [M]K⁺ for each desorbed molecular species, hence a molecular weight snapshot of the sample is produced. The picture takes only ten minutes to develop. All experiments were performed on a Finnigan 4615B quadrupole GC/MS system operated in the electron impact mode. No equipment modification or capital investment was necessary to perform K⁺IDS.

Figure 1 is the K⁺IDS MS of the GTP reaction targeted at the synthesis of a glycidyl methacrylate (GMA) building block. The reaction sequence is given below. Initially, we compared the reaction products from a batch versus a continuous feed polymerization. The K⁺IDS data showed no significant differences in the products. However, we did not expect the ions seen in Figure 1. The expected ions are 425 Da (degree of polymerization (dp) = 2), 567 Da (dp = 3), and 709 Da (dp = 4). The 142 Da spacing results from the GMA repeat unit. We observe a lower intensity envelope corresponding to the expected ions, but the major ions are 383 Da, 525 Da, and 667 Da. These ions are 42 Da less than the expected products. A transesterification by a methoxy (-OCH₃) (m/z = 31 Da) for a glycidyl group (-OCH₂CH(O)CH₂) (m/z = 73 Da) could account for the -42 Da mass change. To test this hypothesis, a batch reaction was quenched with CD₃OD. If transesterification occurred, a shift of four Da would be expected in the CD₃OD quenched transesterified GMA oligomers. Our results support the hypothesis because an increase in four Da was seen in the base ion envelope. This results from the incorporation of both the deuterium and the -OCD₃. Furthermore, we found more than one transesterification had occurred on some of the oligomeric GMA chains. For example, the 551 Da ion seen in Figure 1 was shifted 6 Da higher in mass to 557 Da in the CD₃OD quenched reaction. This results from incorporation of two -OCD₃ groups. We observed as many as three transesterifications on some GMA chains.

The loss of the epoxide functionalities can be detrimental to product performance. K⁺IDS provides a quick and simple method to monitor this loss because a functionality change results in a change in molecular weight. Furthermore, using the molecular weight data afforded by K⁺IDS we have been able to characterize the specific structures of GTP oligomers functionalized with nitro, amine, or diol groups. Finally, the total time necessary to obtain this information was under 10 minutes which included sample preparation.

PYROLYSIS GAS CHROMATOGRAPHY MASS SPECTROMETRY
OF POLYARYLACETYLENE RESINS

M. P. Easton and D. Gilmartin

The Aerospace Corp.

P.O. Box 92957, MS: M2/248

Los Angeles, CA 90009

ABSTRACT

Polyarylacetylene (PAA) resins are being considered as matrix precursors in the fabrication of carbon (C-C) composites and for use as spacecraft structural materials. These resins leave 82-86% carbon residue when pyrolyzed to 1000°C. Resins presently in use have much lower char yields. PAA resins are prepared by the polymerization of diethynylbenzene using a Ni catalyst which favors cyclotrimerization. The polymer structure contains mainly polyphenylene units; acetylinic, benzylic and ethylbenzylic end groups; and possibly olefinic units due to linear polymerization. Thermogravimetric analysis shows that the resins lose weight in two steps at about 600 and 750°C. Pyrolysis Gas Chromatography Mass Spectrometry (Py-GC-MS) was performed to determine the thermal decomposition products and to characterize the chemical structure. The cured resins analyzed were prepared from meta diethynylbenzene (DEB) or a 60/40 ratio of meta to para DEB. Phenylacetylene (PA) was added as a chain terminator to some of the resins. Ethylethynylbenzene a 5% wt impurity in DEB also acts as a chain terminator. Py-GC-MS was obtained at 400, 600, 700, 800, and 1000°C. The Py-GC-MS analysis shows that above 700°C the main product is hydrogen. Below this temperature a number of aromatic hydrocarbons are detected. The differences observed in the pyrograms of the different cured resins can be correlated to the polymer structure.

PHOTOIONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY OF ORGANIC COMPOUNDS FROM MANTLE MINERALS

Tracy N. Tingle and Christopher H. Becker
Molecular Physics Laboratory, SRI International
Menlo Park, California 94025

Sensitive detection of abiotic organic molecules in geological samples has been achieved using thermal desorption combined with surface analysis by laser ionization (SALI), which uses nonselective photoionization combined with reflecting time-of-flight mass spectrometry. Photoionization was accomplished by single-photon ionization with 118 nm light (10.5 eV) generated coherently by tripling the third harmonic of a pulsed Nd:YAG laser; this method has recently shown attomole sensitivity when combined with pulsed stimulated desorption (1).

Figure 1. Temperature-integrated thermal-desorption mass spectra; a, blank heater (lower) and tumble-polished olivine from San Carlos with no cracks or inclusions; b, interior fragment cleaved from San Carlos olivine with microcracks; c, interior portions from two separate Hualalai olivine porphyroblasts. Prominent mass peaks are indicated. Mass assignments discussed in text.

Volcanoes bring samples of the Earth's mantle to the surface in which olivine, $(\text{MgFe})_2\text{SiO}_4$, is the most abundant mineral. Carbon x-ray microscopy and x-ray photoelectron spectroscopy have revealed that 1-10 nm thick carbonaceous films exist on many microcrack surfaces in mantle samples (2,3). Thermal desorption SALI yielded more detailed chemical information on these films.

We sampled interior portions of large single crystals of olivine and other silicates from rock samples by fracture in the laboratory and then immediately introduced them into the ultrahigh vacuum chamber for analysis. Spectra were accumulated during 200-2000 pulses of the 10 Hz laser as a function of sample temperature which was ramped over the range 25-750°C. Representative temperature-integrated thermal-desorption mass spectra are shown in Fig. 1 for olivine from two different localities, San Carlos, Arizona, and Hualalai, Hawaii. Significant variation among samples from the same locality has also been observed (3). Peaks observed in these spectra have been assigned to NH_3 , an alkene series [butene, $m/z = 42, +n \times (14 \text{ amu})$], and some relatively simple aromatic compounds (e.g., benzene, toluene, phenol, cresol, benzaldehyde, benzoic acid, and thiophene). Alkyl radicals are probably responsible for some masses, such as $m/z = 43$ and 55. The observed volatile compounds were released primarily above 300°C, and hence probably were pyrolysis products. For these temperature-integrated thermal desorption spectra, the sensitivity for a given mass is estimated to be 40 ppb for samples weighing ~5 mg.

To assess the extent of laboratory contamination, crack-free specimens were similarly analyzed; these showed negligible organic molecular ion signals. Field or environmental contamination also has been eliminated. We determined that the microcracks on which the organics occur have been apparently sealed; analysis of crystals immersed in solvents doped with a tagging molecule showed no evidence of penetration. The organic-bearing microcracks were produced during eruption. Catalytic activity of freshly exposed silicate surfaces for condensation reactions of partially reduced

**Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL**

species found in volcanic gases, such as CO and H₂, has been proposed as the origin of the organic films (2,3).

In summary, nonselective photoionization TOF mass spectrometry of thermally desorbed species originating mostly above 300°C from fractured olivine crystals has shown the presence of various abiotic organic compounds consistent with pyrolysis of known very thin carbonaceous films on microcracks. Contamination could be ruled out, and from the petrography of the cracks where these films occur it is concluded that these films represent the products of condensation reactions of reduced volcanic gases on fresh-fractured silicate surfaces produced during eruption.

HYDROCARBON-TYPE ANALYSIS BY FIELD IONIZATION
MASS SPECTROMETRY

By E. J. Gallegos
Chevron Research Company, Richmond, California 94802-0627

This work proposes and demonstrates a field ionization mass spectrometric, FIMS, method of analysis designed specifically to replace the six-component group-type matrix calculation method now being run on our CEC 103 mass spectrometer in the electron impact mass spectrometric, EIMS, mode. This analytical method is for hydrocarbons in the C_6 to C_{14} molecular weight range. The FIMS method adds molecular weight information to the analysis. It also evaluates the contribution from all the molecular ions, unlike the electron impact matrix calculation method which selects specific fragment ions and ignores others.

A VG ZAB mass spectrometer was used to generate the data presented here. A resolution $M/\Delta M$ of 2500 was used to separate the $Z=+2$ from the $Z=12$, etc.

A special open FI source was designed for the ZAB to minimize as much as possible fragmentation of the molecules through contact with hot surfaces. A schematic diagram of this source is shown in Figure 1.

The vapor from the batch inlet sees only the emitter prior to ionization. The emitter is pulse heated between acquisition scans to clean and activate the emitter. The extractor plate is heated to about 250°C.

The structural candidates for each Z category are shown in Figure 2. The sensitivities determined for the various categories are shown in Figure 3. A typical output from the FIMS method is shown in Table I. The statistics on a standard sample for FIMS and EIMS are shown in Table II.

THE ON-LINE DETERMINATION OF WATER BY MASS SPECTROMETRY

R. W. Crawford, T. T. Coburn and A. Alcaraz
Lawrence Livermore National Laboratory
Livermore, CA 94550

Our triple quadrupole mass spectrometer is used to monitor 62 species on-line while pyrolyzing fossil fuel samples. One of the major oxygen-containing species evolved is water, and it is important to determine it accurately with the same temporal resolution as all other species. In addition, we must determine the amount released or created, not just the concentration. We have succeeded in determining the water by mass spectrometry.

One of the most difficult tasks was developing a reliable method of standardization. A series of four bubblers were used; the first two contain water and the last two are water saturated with NaCl. Argon passes through the bubblers at from 100 to 200 cc/min. The first two bubblers bring the water content to above 50% humidity. The last two bubblers drop the humidity to ~25%, the exact partial pressure depending upon the temperature. This method has been checked by comparison with the integrated water evolution from $\text{BaCl}_2 \cdot 2(\text{H}_2\text{O})$. It was also verified by decomposing propane over hot copper oxide, calibrating for CO_2 , and using stoichiometry to know the water content.

The samples and standards were introduced through a two stage pressure drop, a pumped capillary followed by an orifice into the TQMS source. All lines that see water vapor were heated to ~140°C.

Water vapor reduces the overall sensitivity of the mass spectrometer. Research to date suggests that the water is chemically modifying critical lens elements in the source. This is a critical problem in these experiments. The intensity from the argon, used as a precisely flow controlled sweep gas through the pyrolysis zone, must be determined accurately. The argon signal is used to modify the signal from determined species in order to convert concentration into flow. As can be seen in Figure 1, the argon signal recovered very slowly after a large (50% of the gas) water peak.

Our experience suggested that the repeller was the single most contamination sensitive source element. We applied a thick, electro-plated coating of gold on the repeller. As can be seen in Figure 2, the argon intensity recovered rapidly, after a water peak as concentrated as that in Figure 1. This improvement is not degraded by repeated exposure of the repeller to fossil fuel pyrolysis products.

Figure 3 shows an analysis in which water standards (O) were introduced at intervals throughout the run to verify the calibration with time. Although some variations in the standard can be seen, due mostly to increased background because of the large amount of water evolving from the sample, no serious drift is encountered. Figure 4 shows three runs on the same oil shale but at different heating rates, 1, 4 and 10°C/minute. A major shift in the temperature of maximum evolution is seen for the water coming from the mineral Analcime (one of the minerals in the Green River Formation oil shale), moving from ~280°C at 1°C/m to ~350°C at 10°C/m.

Work performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under contract W-7405-ENG-48.

NAPHTHENIC ACIDS IN PETROLEUM BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY
T. P. Fan, Shell Development Bellaire Research Center, Houston, Texas 77025

The naphthenic acids in the crudes are considered a class of biological markers. Their potential use in source correlation and as indicator of biodegradation have been reported previously (1). The presence of naphthenic acids may also cause corrosion problems and fish toxicity in the waste water at refineries. Detailed structural characterization of these acids has been difficult due to the high complexity of the mixture. This report describes a method using ion exchange column chromatography and FAB analysis. This provides a group type distribution of the acids and was found useful for geochemical correlation purposes.

The resin fraction in the crude oil was first isolated, followed by ion exchange column separation of the resin into fractions of different acidity. The FAB analyses were first dissolved in toluene (approximately 1:5) and analyzed in a TEA matrix (triethanol amine). The analyses were performed in negative ion mode at 8 kV acceleration voltage with a Xe atom beam at 1 mAmp ion current and 9 kV kinetic energy.

Negative ion FAB spectrum of a naphthenic acid standard from Eastman Kodak (Fig. 1) shows only intense deprotonated molecular ions of the general formula $R-COO^-$ from each acid component. The mass assignment is straightforward by calculating the corresponding molecular weight. The peak intensities are used to calculate their relative distributions.

Due to the complicated nature of the naphthenic acid mixtures, the acid components were classified into groups according to Z number. The general formula $C_nH_{2n+2}O_2$ is used to represent carboxylic acids where Z is equal to 0 for all saturated paraffinic acids. For every additional ring or double bond in the molecule, the Z number decreases by 2 due to the loss of 2 hydrogens. Thus a decrease in Z number indicates an increase in number of rings or unsaturation in a molecule.

The negative ion FAB spectrum of an acidic fraction from a Louisiana oil is shown in Fig. 2. High molecular weight naphthenic acids up to 700 amu were observed. Heavy acids have been reported in California crudes (1). The carbon number distribution of three Z groups, -2, -6, and -10 are plotted in Fig. 3. The shift in the curve maximum toward higher carbon number with decreasing Z number can be explained by the fact that a pentacyclic molecule requires a minimum number of carbons (Z = -10) greater than that for a tricyclic (Z = -6) or a monocyclic (Z = -2) molecule.

Fig. 4 compares the normalized acid type distributions (based on C12 - C32) obtained from FAB and CI(2) for two California crudes. The agreement between the two methods is excellent considering the techniques are completely different in nature. Reproducibility of the FAB analysis is within 10%.

Figs. 5 - 7 are the FAB spectra of 3 naphthenic acid extracts from California (Fig. 5) and Montana (Fig. 6, 7) respectively. The distribution of acids are similar between samples from the same source, but are significantly different between those from different sources. These can also be clearly observed in the acid group type distribution plot (Fig. 8). The greatest difference among different sources was observed in the distribution of saturated carboxylic acids, which is considered closely related to the degree of oil maturity (1).

The method described here provided a relatively simple routine procedure in characterizing the complicated naphthenic acids in petroleum based on their group types. The results demonstrated the potential in using the naphthenic acid distribution for geochemical source correlations. More data sets will be collected in the future.

DEVELOPMENT OF ITD BASED GC/MS TECHNIQUES FOR RAPID PROFILING OF
MICROBIAL CELL WALL LIPIDS

Koli Taghizadeh, Henk L.C. Meuzelaar* and Herbert J. Hatcher
Idaho National Engineering Laboratory, EG&G, Idaho Falls, ID 83403
*Ctr. Micro Analysis & Reaction Chemistry, Univ. of Utah, SLC, UT 84112

The objective of this study was to develop and compare mass spectrometric techniques suitable for classifying twenty five microbial strains isolated from hydrocarbon rich fossil deposits (viz. oil shales, tar sands, oil seeps and gilsonite) in the Green River region of Wyoming, Utah and Colorado. Three different mass spectrometric methods were compared.

- (1) GC/MS analysis of fatty acid methyl esters (FAMES) of microbial cell walls using a standard saponification, derivatization and extraction (SDE) method [1].
- (2) GC/MS analysis of FAMES obtained by rapid, pyrolytic on-line derivatization (OLD) of whole bacterial cell walls using tetramethyl ammonium hydroxide [2].
- (3) Direct Curie-point pyrolysis MS (Py-MS) analysis of whole bacterial cells.

Typical FAME chromatograms prepared by the SDE and OLD techniques are shown in Figures 1 and 2, respectively. All chromatogram peak areas were integrated. Each data set was then subjected to factor analysis (followed by discriminant rotation of the Py-MS data).

Multivariate analysis (Figures 3,4 and 5) revealed three main clusters: two Gram positive and one Gram negative cluster. The first cluster of Gram positive organisms is identified as the *Nocardia*/*Arthrobacter* group on the basis of comparisons with several reference strains (not shown) and the presence of straight chain fatty acids and tuberculostearic acid (TSA). The second set of gram positive bacteria designated as "coryneforms" are characterized mainly by strong iso- and anteiso fatty acid signals. The third cluster (Gram negative bacteria) is characterized by hydroxy fatty acids. Unfortunately, this class of compounds is missed by the OLD method [2]. Furthermore, the Gram negative group is characterized by unsaturated and cyclic fatty acids.

The Py-MS data provide information about sugar, protein and nucleic acid components in addition to some of the fatty acid patterns of microbial cell walls. The Gram positive bacteria in this study show the highest sugar content, whereas the Gram negative bacteria exhibit higher protein signals.

In order to combine the data obtained by all three methods into a single data set, canonical correlation analysis was performed. Three "significant" canonical variate functions were obtained with canonical correlation coefficients > 0.9 , as shown in Figure 6. The Gram negative organisms appear to start separating into small subgroups (e.g., *Pseudomonas*, *Aeromonas*, *Acinetobacter* and *Flavobacterium*).

In conclusion, similar clustering trends were obtained by all three methods, thus providing stable "natural" clusters. The SDE and OLD methods produce similar FAME profiles with the exception of the hydroxy fatty acids which are destroyed by the OLD method. The Py-MS data set shares more than 30% of its total variance with 50-70% of the OLD and SDE data sets, respectively. Although Py-MS provides much less detailed data on cell wall lipids, useful additional information is obtained on biopolymeric components (viz., proteins, polysaccharides, and nucleic acids).

^W LASER PYROLYSIS MASS SPECTROMETRY OF SINGLE LEVITATED COAL PARTICLES

Wally Maswadeh, Kenneth A. Roberts, William H. McClennen

Henk L.C. Meuzelaar and Neil S. Arnold

Center for Micro Analysis & Reaction Chemistry, Univ. of Utah
Salt Lake City, Utah 84112

A laser pyrolysis mass spectrometry experiment was designed to study the devolatilization behavior of individual coal particles at high heating rates (10^4 - 10^6 K/s), characteristic of pulverized coal combustion reactors. The experimental set-up (Fig. 1) consists of an electrostatic particle levitation cell, also known as an "electrodynamic balance" [1], a 50 W cw CO₂ laser and a Finnigan-MAT ITMS system.

The particle levitation cell was constructed by modifying a regular ion trap electrode assembly in such a way as to provide line-of-sight access to the center of the cell for the CO₂ laser beam as well as for visual observation by means of a stereo microscope. Typical cell operating parameters for levitating a 120 μ m dia. Spherocharb particle are: ring electrode 3000 V (60 Hz ac), upper end-cap +100 V dc, lower end-cap -100 V dc.

The CO₂ laser (Apollo 3050 OEM) is capable of electronic pulsed beam operation. The 8 mm dia. beam is split equally into 2 opposing beams focussed at the center of the levitation cell (beam waist ca. 400 μ m, power density ca. 4-10 MW/m²), as a co-linear parfocal HeNe laser beam permits positioning the levitated particle in the optical and electrical center of the cell. Two IR detectors measure the integrated pulse and time-resolved pulse energy (Fig. 2).

A heated transfer line column (2m x .18 mm DB5) equipped with a special air sampling inlet [2] enables intermittent sampling of volatiles from the center of the levitation cell into the ITMS vacuum system. Feasibility studies were performed on 120-150 μ m Spherocharb particles impregnated with ng amounts of an alkylnaphthalenes mixture and heated with a single 10 ms CO₂ laser pulse. As shown in Fig. 3, ample signal intensities were obtained with the first laser pulse to permit the recording of "transfer line" GC/MS profiles. By contrast, the second laser pulse produced <10% of the volatiles observed from the first pulse, thereby demonstrating nearly complete devolatilization of the impregnated particle by a single laser pulse. Fig. 4 shows the repeatability between experiments with separate particles.

Finally, a series of experiments was performed with actual coal particles in the 100-130 μ m size range, prepared by careful sieving of two coals from the Argonne National Laboratory Premium Coal Sample bank, namely a Pittsburgh #8 seam (Illinois) coal and a Blind Canyon seam (Utah) coal of comparable rank. TIC profiles for both coals are illustrated in Fig. 5, whereas Figs. 6a and b show selected ion chromatograms representing C₁- and C₂- alkyl phenols. From previous studies of Pitt. #8 coal using time-resolved Curie-point pyrolysis [3], pyrolysis temperatures necessary to produce these phenolic building blocks at heating rates of 10^5 K/sec are estimated to be ca. 900 K. Of course, kinetic parameters obtained at the much lower heating rates of the Curie-point pyrolysis MS experiment (approx. 10^2 K/s) may only be extrapolated to the laser pyrolysis experiment if the underlying reaction mechanisms are comparable. Evidence supporting this assumption is presented in Figs. 6c and d showing similar C₁ and C₂-alkyl phenol profiles for the Pitt. #8 coal obtained by Curie-point pyrolysis GC/MS [4] using a 15 m fused silica capillary with temperature programming.

ACKNOWLEDGEMENTS

Financial support was provided by the Advanced Combustion Engineering Res. Ctr. (funded by NSF, DOE, the State of Utah, and 23 industrial participants).

THE USE OF A HYBRID MASS SPECTROMETER IN DETERMINING BIOMARKER COMPOUNDS
IN CRUDE OIL EXTRACTS.

WEIR, O. AND WOOD, D.

VG TRITECH LTD, CREWE RD., WYTHENSHAW, MANCHESTER, ENGLAND

Introduction

The study of "biological marker" compounds in crude oil extracts is now an established method used by Petroleum Explorationists in identifying genetic relationships between various oils and in aiding oil-to-oil and oil-to-source rock correlations.

Polycyclic hydrocarbons such as steranes and triterpanes have been found to be the most useful biomarkers for such studies and their use for the assessment of environment of deposition, maturation, migration and alteration of crude oils is widely documented.

"Typing" of crude oils and source rock extracts is normally carried out by GC/MS, usually with a quadrupole mass spectrometer operated in a unit mass resolution mode. Unfortunately, when monitoring in a selected ion recording mode (SIR), the responses observed are often complicated by other components in the sample. Indeed operating a sector instrument at higher resolving powers is not always a solution as the interfering components may have the same elemental formula. MS/MS analysis solves the analytical problem by greatly enhancing the specificity, even for components with the same elemental formula.

This work illustrates the use of both high and low collision energy environments for this analysis.

Experimental

All the analyses were carried out using a VG Tritech TRIBRID mass spectrometer, whole oil samples were injected in 0.1 μ l aliquots in the split mode onto a 25m bonded phase OV-1 fused silica capillary column (50:1 split). The HP5890A GC was programmed from 60 C to 160 C at 6 C/min, then to 300 C at 3 C/min, holding for 20 minutes. The reactions monitored were from the molecular ions of the steranes and triterpanes to the common fragments for each class of compounds, m/z 217 and 191 respectively. These are shown in table 1. The TRIBRID has the capability of monitoring these reactions both in a "high energy" environment in its first field free region (see figure 1.) or low energy decomposition in an RF only collision quadrupole at low energy.

The TRIBRID offers several advantages for this work, in particular the use of an air-core magnet allows rapid, reliable switching of the parent ion mass. No complicated calibration of the mass scale is necessary for the experiment set-up.

Table 1. Reactions monitored

m/z	compound	m/z	compound	m/z	compound
372	C27 steranes	370	C27 triterpanes	426	C31 triterpanes
386	C28 steranes	384	C28 triterpanes	440	C32 triterpanes
400	C29 steranes	398	C29 triterpanes	454	C33 triterpanes
414	C30 steranes	412	C30 triterpanes	468	C34 triterpanes
				482	C35 triterpanes

Figure 1. The TRIBRID EBEEQQ geometry. The instrument has three collision cells for MS/MS analyses. (analysers are in black)

The quadrupole cell experiments are set up by tuning with FC43 at m/z 219 - 131 fragment. The Cell 1. does not require any tuning or set up other than the standard source/analyser tune for EI data.

Results

Figure 2. shows the result for the C27 to C30 steranes in each cell. In general the Cell 1 and Cell 3 results are equivalent, although there is perhaps less evidence of the "hump" in the quadrupole case. The relative response of the later eluting isomers is higher in the Cell 1 traces, probably due to the rate constants being different in the two time scales from ion formation. Both experiments clearly isolate the components of interest from the enormous quantities of normal alkanes present in the sample. The absolute responses for the two methods are approximately five times greater in favour of the Cell 3 results. Triterpane results are similar to the steranes, with the exception that an interference seen from the methyl loss from the next eluting homologue is largely unseen in the Quad case (due to the higher parent ion resolution). This is not a practical problem in the Cell 1. results as the GC separation eliminates any direct conflict in response.

Conclusion

The methods of multiple reaction monitoring in either cell yield dramatic selectivity enhancement over other MS separation techniques. The quadrupole method has an advantage in terms of parent ion resolution and absolute sensitivity, however the Cell 1 experiment gives useful results and has the advantage of being available on a standard double focussing instrument as well as being extremely easy to set up.

THERMAL SLICING AS A TOOL TO STUDY THE THERMAL DECOMPOSITION OF COALS & KEROGEN

John E. Zumberge, and Chris Sutton, Ruska Laboratories, Inc.
Houston, Texas 77063

It is important to investigate the kinetics of petroleum generation (or kerogen degradation) to improve exploration success. Because of the variety of organic inputs and subsequent disparate burial (temperature) histories of petroleum source rocks, it is desirable to determine kinetic parameters of individual samples from the basin of interest. Furthermore, since kerogen/coals are heterogeneous random polymers, thermal degradation (pyrolysis) techniques can be used to study their various macromolecular structures.

A thermal slice is defined as a temperature interval bounded by a specified lower and upper temperature. With a Ruska Laboratories Thermal Chromatograph-Mass Spectrometer (TC-MS), the temperature range over which a substance thermally decomposes can be subdivided into any number of thermal slices. The relative abundance of thermal decomposition products as a function of thermal slice has been determined using mass spectrometry for two end member geopolymers: the Monterey Shale (sulfur rich kerogen) and a low rank coal (oxygen rich/hydrogen poor organic matter). Both samples were first analyzed using linear temperature programmed heating ($30^{\circ}\text{C}/\text{min}$) directly coupled to a flame ionization detector. The results indicate the decomposition temperature range for the coal and Monterey Shale, and the samples were divided into six thermal slices (as shown in Figure 1) for subsequent TC-MS analysis.

Figure 1. Linear temperature programmed-FID response curves for coal and Monterey Shale.

Distributions (relative abundance as a function of six thermal slices between 360°C and 590°C) of selected individual pyrolyzates (e.g., 2-methylthiophene, phenol, toluene, p + m-xylene, n-octane, 1-octene, n-octadecane, and 1-octadecene) were constructed to compare the thermal degradation behavior. The modes of distributions for heteroatomic molecules and aromatic hydrocarbons occurred about 40°C

lower in the sulfur rich shale than for the coal (see Figure 2). The modes of the distributions of alkanes and alkenes occurred at approximately similar temperatures between the two samples, although 1-alkenes formed in greater abundances at higher temperatures than n-alkanes in the Monterey. The total concentrations for each compound in with respect to the quantity of total pyrolyzable kerogen (P2) are also shown in Figure 2. Calculated activation energies of geopolymer thermal decomposition for individual compounds quantify the observed variations (Table 1). For example, activation energies of 17.9 and 17.2 kcal/mole for 2-methylthiophene and phenol, respectively, from the Monterey Shale are significantly lower than those calculated for the coal (30.0 and 27.6 kcal/mole, respectively). Also, 1-alkene activation energies are slightly higher than corresponding n-alkane activation energies in both samples.

Figure 2. Thermal decomposition product distribution differences between Monterey Shale and Coal over the temperature range 360° to 690°C.

TABLE I
ESTIMATED ACTIVATION ENERGIES
(kcal/mole)

	2-methylthiophene	phenol	toluene	p,m-xylene	n-octane	1-octene	n-octadecane
MONTEREY	17.9	17.2	19.6	16.3	32.1	37.7	26.7
COAL	30.0	27.6	25.3	27.4	42.7	45.2	32.7

MASS-SPECTROMETRIC ANALYSIS OF HIGH-BOILING WAXES SEPARATED
FROM SLUDGE FORMED DURING STORAGE OF CRUDE OIL IN
UNDERGROUND RESERVOIRS

Underground storage of crude oil in salt caverns may result in the formation of a layer of sludge at the brine/oil interface. This sludge is known to consist of inorganic sediment, water, and organic substances (1,2). As part of an investigation into the nature of the organics, waxes from the 850-1050° F, 1050-1250° F, and >1250° F distillates of three different cavern sludges have been isolated and partially characterized. The separation procedure is described in the literature (3). The present discussion is limited to results obtained from a wax isolated from the >1250° F distillate of the sludge recovered from one cavern designated as cavern "B".

Among other techniques, gas chromatography, nuclear magnetic resonance, and mass spectrometry were used to characterize the sludge waxes from all three caverns. Experimental conditions and results for the GC and NMR experiments are given elsewhere (3). Waxes separated from the 850-1050° F and 1050-1250° F distillates were found to consist mostly of paraffins and cycloparaffins (3).

Two methods were used to obtain mass spectra of the >1250° F wax from cavern "B". Initially, field desorption was selected for ion formation based on gas-chromatographic results showing a predominance of aliphatic hydrocarbons in waxes from the lower-boiling distillates. However, the unexpected identification by nominal mass PD/MS of long-chain alkylbenzenes in the >1250° F wax led to further experiments in which 70 eV electron impact was used for ion formation and high resolution (20,000 resolving power) for mass separation. The latter conditions were selected to enhance molecular-ion intensities of aromatic compounds and allow their elemental compositions to be identified. To further facilitate identification of aromatics in the wax, the electron-impact spectra were recorded, not on the wax itself, but on an aromatics fraction separated from it (3).

All mass-spectra were obtained on a Kratos MS-50 mass spectrometer. To record the electron-impact spectra, samples were introduced by probe microdistillation (PMD/MS) over a temperature range from ambient to 600° C. The apparatus and technique are described in the literature (4). Electron-impact data were processed with programs described previously (5,6).

The field desorption mass spectrum of the wax separated from the >1250° F distillate showed prominent peaks in a range extending from m/z 694 to m/z 1128. Based on nominal mass Z series, these peaks were identified as alkylbenzenes. The most prominent member of the series was found at m/z 834, corresponding to C(60)H(114). Other significant compound types

identified included paraffins and cycloparaffins, as shown by peaks extending from m/z 646 to m/z 870 and from m/z 714 to m/z 868, respectively.

The electron-impact spectra recorded for the aromatics fraction showed that the sample distilled over a probe temperature range from approximately 300 to 600° C. Processing of high resolution PMD/MS data produced elimination curves for molecular ions and corresponding numerical results, including areas under the curves. The latter results provided a semi-quantitative analysis of the fraction. In addition to finding the anticipated alkylbenzenes (-6 H) in the fraction, lesser quantities of -8 H and -10 H compound types were found. Homologues of alkylbenzenes were identified in a molecular mass range extending from m/z 708 to m/z 1086. The most prominent member was found at m/z 834, in agreement with results from the FD/MS data recorded for the whole >1250° F wax.

In addition to the aromatic hydrocarbons found in the fraction, benzothiophenes (-10 S) were identified in significant quantity. The most prominent member of this series was found at m/z 834, corresponding to C(58)H(106)S. Owing to very similar volatilities and the same nominal masses, homologues of alkylbenzenes and benzothiophenes were identified in overlapping molecular mass ranges. For these reasons, the latter compounds were not detected in the FD/MS spectrum of the whole wax.

In conclusion, wax separated from the >1250° F distillate of cavern "B" sludge was found to be comprised largely of alkylbenzenes. However, other compound types were present in significant quantities. These included other aromatic hydrocarbons, paraffins, cycloparaffins, and benzothiophenes. In the absence of further information, the relative contributions of these different compound types toward sludge formation is not known.

FREE RADICAL AND REDOX CHEMISTRY IN SUPERCRITICAL FLUIDS

by
S. V. Olesik, W. Larkins, and L. Pekay
Department of Chemistry
The Ohio State University
Columbus, Ohio 43210

Coal is this country's most abundant resource. The burning of coal is also a major pollution concern. The acid rain in Canada is often contributed to sulfur dioxide emission from the burning of coal by the United States. As other energy sources are depleted, coal will be needed not only as a fuel, but also as a feedstock for the production of chemicals. Consequently, efficient desulfurization of the coal matrix will also become important.

In this study new methods of coal desulfurization are being developed using supercritical fluids as solvents and in some cases reactants. Two different types of reaction processes are under study. One reaction process involves the selective solvation (bond scissioning) of carbon sulfur bonds by the action of supercritical fluids. The other reaction process involves the dissolution of reagents in supercritical fluids that selectively oxidize organo-sulfur bonds.

Several advantages are expected from the use of supercritical solvents. For example, mild thermal conditions should be possible, which should provide minimal loss of heat content. High desulfurization yield should be possible due to the low viscosity of supercritical fluids. Also, the supercritical solvent should be easily recycled.

To carefully monitor the progress of the reaction-processes, an instrumental interface was developed that allows parallel detection by a sulfur detector and a high mass quadrupole mass spectrometer. The details of the instrumental set-up were illustrated in this presentation.

Also, the initial results on the study of the solvation of oxidants in a supercritical fluid mixture were presented. It was shown that ionic species will dissolve in supercritical mixtures at temperatures below 100°C. The use of UV-Vis spectroscopy for determining the solubility of inorganic ions failed. The inorganic ions were found soluble in specific supercritical fluid mixtures, but the electronic transitions of the inorganic ions were not at energies similar to those found in liquids. SFC-ICP analysis of the solutions demonstrated conclusively that the inorganic oxidants were dissolved in the fluids. Future work will involve the mass spectral monitoring of these chemical reactions.

ADDUCTS OF d^5 AND d^{10} TRANSITION METAL CATIONS WITH ALKANES :
AB INITIO AND EXPERIMENTAL STUDIES

Claude Beaugrand,

Nermag, 49 quai du Halage, 92500 Rueil-Malmaison, France

Gaston Berthier, Michèle Suard,

Ecole Polytechnique, DCMT, 91128 Palaiseau Cedex, France

Abdelouahid Dahrouch, Hélène Mestdagh and Christian Rolando,

Ecole Normale Supérieure, 24 rue Lhomond, 75231 Paris Cedex 05, France

Gaseous transition metal cations, bare or bearing ligands, have been shown to be extremely reactive with various hydrocarbons; for example group 8 metal cations are able to cleave CH and CC bonds (1). We have demonstrated that Cr, Mn, Cu and Zn (d^5 and d^{10}) cations, which are reported to be unreactive under monocollision conditions, lead mainly to $M(\text{alkane})_n^+$ complexes ($n = 1, 2$) under multicollision conditions encountered in tandem quadrupole instruments.

These compounds are very interesting since similar association complexes are in all cases the first intermediates formed in alkane-metal ion reactions. Elucidation of their structure is a key to understand alkane activation either in the gas phase or in the condensed phase.

Using our MS/MS/MS multiquadrupole triple analyzer instrument, various $\text{Cu}(\text{alkane})_n^+$ complexes have been prepared and their structure determined by collisionally activated dissociation (CAD). Alkane loss was the only fragmentation observed, suggesting that the alkane molecule remains as a whole in the complex. Use of a mixture of cyclopentane and deuterated cyclohexane allowed to confirm that the metal ion does not insert into CH bonds, even reversibly : no deuterium exchange was detected in the reaction products, nor in the CAD spectrum of the mixed complex $\text{Cu}(\text{C}_5\text{H}_{10})(\text{C}_6\text{D}_{12})^+$, which is cleaved to $\text{CuC}_5\text{H}_{10}^+$, $\text{CuC}_6\text{D}_{12}^+$ and Cu^+ exclusively.

However, the formation of these adducts cannot be fully understood in terms of electrostatic ion-induced dipole interactions, since K^+ , Ca^+ and Na^+ (which has the same ionic radius as Cu^+) do not react under the same conditions.

Using ion confinement in the collision cell, ligand exchange reactions could be brought to thermodynamic equilibrium, in order to know the influence of alkane structure on adduct stability. For example,

study of the reaction of Cu^+ with a cyclohexane-cyclopentane mixture led to the following equilibrium constants :

Adducts with linear alkanes (pentane, hexane) were observed to be more stable than their cyclic counterparts.

Confinement of copper ion with cyclohexane up to 40 ms allowed complete conversion of Cu^+ and CuCy^+ to CuCy_2^+ . No complex bearing more than two ligands was detected under those conditions.

The rate of association of copper ion with cyclohexane was found to be proportional to cyclohexane pressure, indicating that collisional stabilization of the adduct is not a rate-determining step. The corresponding rate constant ($4.3 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$) is very close to the value reported for Cu^+ -ethane association under fast flow reactor conditions (2).

Concurrently, ab initio calculations have been performed on the simplest of these adducts, CuCH_4^+ , using an MP4 method. The bond energy obtained in this way is 52 kJ mol^{-1} (0.54 eV, 12.5 kcal mol^{-1}). The lowest energy structure corresponds to a Cu-C distance of 2.20 Å : the copper is close to two H atoms but is not located in the corresponding H-C-H plane; other structures with only slightly higher energy but more symmetrical were also obtained. In all cases C-H distances remain nearly the same as in the isolated methane molecule, but there is a noticeable distortion of the bond angles, and substantial charge delocalization : the charge on the copper atom is reduced to 0.77 electron unit.

The ethane complex CuC_2H_6^+ , studied in the case of a linear Cu--C-C geometry, gave a similar bond energy (50 kJ mol^{-1}).

The 4s orbitals of the copper ion were found nearly unpopulated : the bonding process essentially involves interaction between occupied orbitals of methane and fully occupied d orbitals of copper. Similar calculations on NaCH_4^+ , using the same geometry as in the optimal CuCH_4^+ configuration, actually led to a repulsive interaction. This might explain why formation of such adducts requires transition metal ions.

GAS-PHASE ION-MOLECULE REACTION OF Cu^+ AND C_7H_8 ISOMERS: A CA MS/MS STUDY.

D.K. MacMillan, R.N. Hayes, and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0362.

We are interested in exploring the ability of Cu^+ to initiate a valence isomerization of quadricyclane (Q). The gas-phase valence isomerization of Q to norbornadiene (NBD) in the presence of Fe^+ has been demonstrated.¹ The Collisionally Activated (CA) mass spectra of the Fe^+ -NBD and Fe^+ -Q adducts are identical. Because Cu^+ exhibits reactivity similar to that of Fe^+ with alkenes,² we wished to determine whether Cu^+ would convert Q to NBD, or alternatively, differentiate the two isomers. The CA mass spectra of the adducts of Cu^+ with two other C_7H_8 isomers, toluene (T) and cycloheptatriene (CHT), are also presented.

Unlike the CA MS/MS spectra of Fe^+ -Q and Fe^+ -NBD, the CA MS/MS spectra of the Cu^+ -Q and Cu^+ -NBD adducts (Fig. 1) exhibit some similarities, but are distinct. For both Cu^+ adducts, the loss of C_2H_2 predominates, forming an abundant CuC_5H_6^+ ion of m/z 129. Other fragment ions common to both adducts are ions of m/z 63 (Cu^+), m/z 89 (CuC_2H_2^+), and m/z 154 (CuC_7H_7^+). Significant differences are also observed. Cu^+ -NBD loses C_2H_3 , whereas Cu^+ -Q does not. Cu^+ -NBD dissociates to form an ion of m/z 92 (NBD^+), but Cu^+ -Q loses CuH to give an ion of m/z 91 (C_7H_7^+).

The CA MS/MS spectra of the Cu^+ adducts with T and CHT (Fig. 1) suggest that the structures are similar to each other but differ from those of the Q and NBD adducts. The Cu^+ -T spectrum shows two major peaks, m/z 154 and m/z 91, corresponding to the losses of H and CuH , respectively. The Cu^+ -CHT loses CuH to a greater extent than it loses H. Both adducts dissociate to yield ions of m/z 63 and m/z 65 (C_5H_5^+). Cu^+ -CHT also shows successive H losses more abundantly than does Cu^+ -T. Neither, however, show an abundant loss of C_2H_2 observed for the Cu^+ -Q and Cu^+ -NBD adducts.

CA MS/MS/MS spectra were used to further probe the structure of the CuC_5H_6^+ ions. Spectra of the CuC_5H_6^+ ions formed from Cu^+ -Q or Cu^+ -NBD are compared to the CA MS/MS spectrum of the CuC_5H_6^+ ion prepared independently by a reaction between Cu^+ and cyclopentadiene (Fig. 2). The CA MS/MS/MS spectrum of CuC_5H_6^+ from Cu^+ -Q is nearly identical to the CA MS/MS spectrum of the model CuC_5H_6^+ . The most significant fragmentations are the losses of H and C_5H_6 . CuC_5H_6^+ from Cu^+ -NBD similarly exhibits an abundant loss of H. In addition, Cu^+ -NBD loses C_5H_5 to give an ion of m/z 64 (CuH^+). The data suggest that both CuC_5H_6^+ species whether formed by direct condensation or upon fragmentation of the Cu^+ -Q adduct exist as the (cyclopentadiene)copper ion complex, whereas that ion formed from Cu^+ -NBD, exists as a (cyclopentadienyl)(hydrido)copper ion species.

The FTMS data indicate that Cu^+ is the reactive species, rather than C_7H_8^+ ; viz, Cu^+ disappears as the adduct forms (see Fig. 3). A similar result is obtained for Cu^+ -NBD. Additional support for this conclusion is provided by double resonance experiments. Moreover, both systems react with first order kinetics, but Cu^+ reacts more rapidly with NBD than with Q.

The base peak for the NBD adduct in the FTMS spectrum is an ion of m/z 91 (C_7H_7^+), whereas the ion of m/z 63 (Cu^+) is the major species observed for the Q system. Cu^+ -NBD does not exhibit loss of C_2H_3 , as it does upon CA. The Cu^+ -NBD species adds NBD to form the dimer, $\text{Cu}(\text{NBD})_2^+$ (m/z 247). We did not observe formation of a dimer in the Cu^+ -Q system at reaction times up to 2.110 secs.

The principal form of the Cu^+ -Q adduct is a (cyclopentadiene)(acetylene)copper ion complex produced by a metal-assisted valence isomerization. The rearrangement may be initiated by Cu^+ insertion into a C-C bond, as illustrated in Scheme 1.

Cu^+ catalyzes a retro Diels-Alder rearrangement of NBD to form a (cyclopentadiene)(acetylene)copper ion moiety that is able to reversibly transfer H from the cyclopentadiene unit to the metal center (Scheme 2). Cu^+ -Q, however, does not execute this last step. A similar reaction scheme has been proposed for the reaction of Fe^+ with both Q and NBD.

The Cu^+ -NBD adduct has other minor structural components. One form is a loosely-associated complex that dissociates upon CA to give the C_7H_8^+ fragment. Another adduct structure may involve C-H insertion, followed by rearrangement to a (tropylium)(hydrido)copper ion complex. This species also appears to be a minor contributor to the Cu^+ -Q structure.

LIGAND FLUXIONALITY AND METAL-METAL BOND FORMATION FOR $\text{Fe}(^{13}\text{CO})^+$ REACTING WITH $\text{Fe}(\text{CO})_5$

E. L. Kerley and D. H. Russell

Department of Chemistry
Texas A&M University
College Station, TX 77843

An FT-ICR two-section cell can be used in a mode such that two different neutral reagents are separated in the differentially pumped regions of the cell. This allows one to compartmentalize reactions performed in the FT-ICR by selecting the location at which a reaction is allowed to occur. For example, $\text{Fe}(^{13}\text{CO})^+$ (m/z 85) can be synthesized by the procedure outlined in Figure 1. $\text{Fe}(\text{CO})_5$ is admitted (ca. 2×10^{-7} torr, static) to one region of the cell and ionized to form $\text{Fe}(\text{CO})^+$ (m/z 84) (Figure 1A). $\text{Fe}(\text{CO})^+$ ions are transferred to the second region of the cell (Figure 1B) which contains ^{13}CO (ca. 5×10^{-7} torr, static). Unwanted ions are ejected from the cell at this point by rf sweeps^{1,2} such that only $\text{Fe}(\text{CO})^+$ remained. The isolated $\text{Fe}(\text{CO})^+$

ions are then allowed to ligand exchange with ^{13}CO to give $\text{Fe}(^{13}\text{CO})^+$ (Figure 1B). Finally, the newly formed $\text{Fe}(^{13}\text{CO})^+$ ions are moved to Region 1 of the cell where subsequent reaction studies are performed without complication from ligand exchange with ^{13}CO (Figure 1C). The transfer of $\text{Fe}(^{13}\text{CO})^+$ from Region 2 to Region 1 was performed under conditions such that residual $\text{Fe}(\text{CO})^+$ was not transferred.³ Such selective isolation of ML_n^+ species allows studies of gas phase reactions of specific $\text{ML}_n^{+/-}$ species without the complication of interfering ions.

The reactions of $\text{Fe}(^{13}\text{CO})^+$ with $\text{Fe}(\text{CO})_5$ to form labeled and unlabeled $\text{Fe}_2(\text{CO})_6^+$ and $\text{Fe}_2(\text{CO})_4^+$ can be studied under the conditions of static admission of $\text{Fe}(\text{CO})_5$ to Region 1. A temporal reaction plot of the normalized ion intensities for this reaction system is found in Figure 2. $\text{Fe}_2(^{13}\text{CO})_6^+$ is the dominant product by a significant margin. In fact, $\text{Fe}(^{13}\text{CO})^+$ forms the labeled $\text{Fe}_2(\text{CO})_6^+$ isomer at about four times the rate of formation of the unlabeled isomer. Assuming that the transition state contains six carbonyls, statistical (fluxional) formation of $\text{Fe}_2(\text{CO})_6^+$ should result in only about 17% labeled product. The dominance of the labeled isomer indicates that, for this reaction, $\text{Fe}_2(\text{CO})_6^+$ is approximately 22 times as likely to retain a labeled carbonyl ligand than an unlabeled one.

In the formation of $\text{Fe}_2(\text{CO})_4^+$ isomers, a somewhat different picture emerges. The labeled version of this species is formed only 1.5 times as fast as the unlabeled version indicating only a ninefold preference for the labeled carbonyl.

One explanation for the observed reactivity for these species is that the formation of $\text{Fe}_2(\text{CO})_6^+$ begins by facial attack by the iron of $\text{Fe}(^{13}\text{CO})^+$ on three carbonyl oxygens of the neutral effectively "locking" the facial carbonyl ligands in place and increasing the Fe- ^{13}C bond strength via enhanced backbonding. In order to increase orbital overlap by increasing molecular symmetry, an unlabeled, "unlocked" carbonyl is lost. Likewise, formation

Figure 1. *In situ* synthesis of $\text{Fe}(^{13}\text{CO})^+$ for study of its Fe-Fe bond formation reactions: (A) formation of $\text{Fe}(\text{CO})^+$, (B) formation of $\text{Fe}(^{13}\text{CO})^+$, (C) isolation of $\text{Fe}(^{13}\text{CO})^+$.

of $\text{Fe}_2(\text{CO})_4^+$ isomers could result from edge attack resulting in only two locked carbonyls. For this model, decreased backbonding results in increased lability for the labeled CO. Yet, the drive for increased symmetry still dominates the reaction as indicated by the preference to lose two (presumably unlocked) carbonyls. For both $\text{Fe}_2(\text{CO})_6^+$ and $\text{Fe}_2(\text{CO})_4^+$, the intermediate should quickly rearrange to form an Fe-Fe bonded species.

LIGAND EXCHANGE REACTIONS OF IONIC TRANSITION METAL CARBONYL CLUSTERS:
REACTIONS FOR $\text{Cr}_2(\text{CO})_y^+$ AND $\text{Fe}_2(\text{CO})_y^+$

L. Sellers-Hann and D. H. Russell

Texas A&M University
Department of Chemistry
College Station, Texas 77843

Ligand substitution reactions have been used extensively to probe the reactivity and chemical properties of organometallic species. Such studies provide information on the coordination saturation/unsaturation of the reaction species, i.e., before coordination of the substrate can occur, a vacant site must be available in the coordination sphere of the neutral. In our laboratory, we are using ligand exchange reactions to probe the reactivity/coordinations unsaturation relationship of ionic cluster fragments of transition metal carbonyls formed by ion molecule reactions. The chemistry of $\text{Cr}_2(\text{CO})_y^+$ ($y = 4-6$) and $\text{Fe}_2(\text{CO})_y^+$ ($y = 3-4$) ions have been studied by using a variety of neutral ligands.

The probe reactions investigated include thermoneutral reactions, e.g., substitution of ^{13}CO for ^{12}CO , and exothermic reactions, e.g., substitution of O_2 for CO . Ligand exchange reactions with ^{13}CO provide insight about ligand lability, e.g., $\text{Cr}_2(\text{CO})_4^+$ readily exchanges all four ^{12}CO ligands, whereas $\text{Cr}_2(\text{CO})_6^+$ does not exchange any ^{12}CO ligands. The relative rate of ligand exchange for $\text{Cr}_2(\text{CO})_y^+$ increases with increasing electron deficiency, e.g., relative reactivity of $\text{Cr}_2(\text{CO})_4^+ > \text{Cr}_2(\text{CO})_5^+ > \text{Cr}_2(\text{CO})_6^+$. Similar differences in ligand lability are observed for $\text{Fe}_2(\text{CO})_3^+$ and $\text{Fe}_2(\text{CO})_4^+$. For example, $\text{Fe}_2(\text{CO})_3^+$ reacts with ^{13}CO to exchange only two ^{12}CO ligands and $\text{Fe}_2(\text{CO})_4^+$ reacts to exchange all four ^{12}CO ligands. The ligand exchange reactions of $\text{Fe}_2(\text{CO})_3^+$ with ^{13}CO indicated that two of the CO ligands of $\text{Fe}_2(\text{CO})_3^+$ are equivalent.

The relative reactivity of the ionic clusters is dependent upon the electron deficiency and the nucleophilicity of the ligand. For example, as the electron deficiency increases (i.e. larger unsaturation) the relative reactivity of the ligand exchange reactions increases. That is, for ligands which are hard bases and produce a large electron density on the metal center, (e.g., NH_3) the rate of the ligand exchange reaction increases. However, for a softer ligand (e.g., CO) which can accept some of the electron density back from the metal center is observed to have a smaller rate of reactivity.

Overall the ligand exchange reactions for the $\text{Cr}_2(\text{CO})_y^+$ and $\text{Fe}_2(\text{CO})_y^+$ systems are similar. For example, most of the ligand exchange reactions observed proceed via the following general reaction.

Although the ligand exchange reactions for the iron and chromium systems have many similarities there are some significant differences observed as well. For example, the chromium dimers undergo metal-metal cleavage with certain ligands.

It is not clear why metal-metal cleavage occurs but it is probably due to the binding interaction of the ligand with the dimer. In other words, as the ligand interacts with the Cr dimer ions the dimer undergoes a coordination rearrangement to produce the metal-metal cleavage product. The occurrence of metal-metal cleavage is observed to be dependent upon the electron deficiency as well as the nucleophilicity of the ligands. For example, the product ions which arise by metal-metal cleavage are most dominant for low electron deficiencies, (e.g. $\text{Cr}_2(\text{CO})_6^+ > \text{Cr}_2(\text{CO})_5^+ >$

$\text{Cr}_2(\text{CO})_4^+$). Also, metal-metal cleavage product ions are most dominant for different ligands, (e.g. $\text{NH}_3 > \text{C}_6\text{H}_6 \approx \text{C}_4\text{H}_6 \approx \text{CH}_3\text{OH} > \text{O}_2$). Therefore, it appears that ligand addition to $\text{Cr}_2(\text{CO})_6^+$ corresponds to oxidative addition, reducing the metal-metal bond order.

In addition, different reactions are observed for the $\text{Fe}_2(\text{CO})_y^+$ ions. The ligand exchange reactions of $\text{Fe}_2(\text{CO})_3^+$ are unusual because only 30-40% of the ions react and the remaining 60-70% are unreactive. Freiser observed that only a fraction of the $\text{Co}_2(\text{NO})^+$ ions react with O_2 and suggested that the unreactive ions are of the form $\text{Co}_2(\text{N})(\text{O})^+$; a form where the NO ligand has undergone dissociation. We have no reason to suspect that ligand dissociation occurs for $\text{Fe}_2(\text{CO})_3^+$, e.g., collision induced dissociation yields Fe_2^+ , no Fe_2C^+ or Fe_2O^+ ions are observed. Consequently, we suggest that the reaction between $\text{Fe}_2(\text{CO})_3^+$ and L is subject to a small activation barrier and the reactive fraction developed from the vibrationally excited ion population.

Also, for the ligand exchange reaction between $\text{Fe}_2(\text{CO})_3^+$ and methanol an ion molecule product corresponding to $\text{Fe}_2(\text{CO})_3\text{H}^+$ is observed. This type of ion molecule product is only observed for ligand exchange reactions between $\text{Fe}_2(\text{CO})_3^+$ and alcohols (e.g. methanol and ethanol) and is not observed for any other ionic transition metal cluster or ligand. We tentatively assign the $\text{Fe}_2(\text{CO})_3\text{H}^+$ ion as a formyl ion of the form $\text{Fe}_2(\text{CO})_2(\text{CHO})^+$.

Several example temporal plots are shown below to give an idea of the chemistry observed for both the iron and chromium systems.

DYNAMICS AND THERMODYNAMICS OF LASER ABLATED METAL IONS BY HIGH PRESSURE MASS SPECTROMETRY

E. Bouchard, T. B. McMahon and J. W. Hepburn

Department of Chemistry, University of Waterloo

Waterloo, Ontario, Canada, N2L 3G1

High Pressure Mass Spectrometry studies were conducted on laser generated metal ions. Two metals were investigated thus far: copper and aluminium.

Both metal ions were ablated with an excimer laser (XeCl @ 5mJ/pulse) in a bath gas pressure of 5 torr. The ions were thermalized and then allowed to react with some ligand of interest. Extensive studies of clustering of CO on Cu⁺ have been carried out. Using a time resolved data acquisition system, we were able to observe the ions for ≈ 3 ms and see equilibrium between the following species:

However, a pressure study showed that the kinetics were not first order. While this may be suggestive of electronically excited states, since we are operating at threshold for ion formation, this seems unlikely. A more probable explanation is that surface effects are important in laser ablation. With copper, we are not able to use nitrogen as a bath gas. Ammonia evolves when we strike the target with the laser. All experiments were conducted in argon. If argon does not quench efficiently the transition state, we would expect this kind of pressure dependence.

Aluminium was studied in the same fashion. Nitrogen was used as the bath gas and CH₃COCH₃ as the ligand. We were not able to measure the binding energy for the first acetone attachment as it is larger than 30 kcal mol⁻¹. However, we have no difficulty measuring the enthalpy and entropy changes involved in the second ligand attachment. A typical time profile is shown in figure 1. A temperature study allowed us to construct a van't Hoff plot shown in figure 2. The enthalpy change is -29.9 kcal mol⁻¹ and the entropy change is -45 e.u. These changes are both quite large. This is suggestive of the structure shown in figure 3 where the second acetone molecule binds to the first acetone and not directly to the aluminium ion.

We are currently building a new apparatus that will extend our mass, pressure and temperature range. Thus far, the rich chemistry exhibited by these metal ions has been a problem but as we learn more, we hope to exploit it!

ION-MOLECULE CHEMISTRY OF METHYL CYCLOPENTADIENYL CHROMIUM DI-NITROSYL

Melvin B. Comisarow and Shu-Ping Chen

Department of Chemistry, University of British Columbia, Vancouver, B. C., Canada V6T 1Y6

The gas phase condensation chemistry of many organometallic compounds has been investigated by Fourier transform ion cyclotron resonance (FT-ICR) spectroscopy (1, 2). The first demonstration of the utility of FT-ICR for such studies concerned the ion-molecule condensation chemistry of some η^5 -cyclopentadienyl (Cp) organometallic carbonyls(1). However, most of these FT-ICR investigations have been on organometallic carbonyls(2). For both the carbonyls and Cp-carbonyls, the condensation reactions give products in which the integrity of the CO ligand is maintained. In contrast, the ion-molecule condensation chemistry of $\text{CpCr}(\text{CO})_2\text{NO}$ shows many products (1) in which the NO ligand breaks up. In this work we report an investigation of the gas phase ion-molecule chemistry of $\text{CpCr}(\text{NO})_2\text{CH}_3$. This is the first η^5 -Cp, alkyl organometallic compound we have investigated.

Our investigations were carried out on a home-built FT-ICR spectrometer operating at 1.9 Tesla. Ion-molecule reaction pathways were confirmed by FT-ICR double resonance(3), and the results are compared with those of the deuterated compound $\text{CpCr}(\text{NO})_2\text{CD}_3$.

Electron impact ionization (25 eV electrons) on $\text{CpCr}(\text{NO})_2\text{CH}_3$ gives the following ions: $\text{CpCr}(\text{NO})_2\text{CH}_3^+$; Cr^+ , CpCr^+ , CpCrNO^+ , CpCrNOCH_3^+ , and $\text{CpCr}(\text{NO})_2^+$, $\text{C}_6\text{H}_8\text{N}^+$, $\text{C}_6\text{H}_6\text{Cr}^+$ and CpCrO^+ . When these ions are allowed to react with the parent neutral, and followed to fifth kinetic order, many ion-molecule reactions were identified. The following reaction sequences which are derived from Cr^+ are typical:

The typical reaction forming highly oxygenated species, for example, is as follow:

In addition to the extensive positive ion chemistry of $\text{CpCr}(\text{NO})_2\text{CH}_3$, negative fragment ions from the parent neutral also undergo condensation. Also, the following electron transfer reaction occurs:

As was true for the condensation chemistry of $\text{CpCr}(\text{CO})_2\text{NO}$ (1), many of the product ions are highly oxygenated. The structures of these ions can be postulated by analogy to the $(\text{CpCrO})_n$ clusters studied by Bottomley (4).

THE PROPER CONSTRUCTION OF EQUILIBRIUM "LADDER" SCALES

Daniel N. Sorensen and John E. Bartmess

Dept. of Chemistry, Univ. of Tennessee, Knoxville TN 37996-1600

Dozens of equilibrium affinity scales have thus far appeared in the literature. Creation/ordering of such scales from the original equilibria is tedious. Selection of absolute ΔG 's from the experimental values has been somewhat arbitrary. We have written a program that creates the scale, orders the individual members into an ascending/descending form, gives the best fit of the absolute ΔG 's for each member, and graphs the scale.

For example, from the equilibrium measurements for seven bases a-g:

B ₁ :	a	c	e	a	c	f	h	e
B ₂ :	b	d	g	c	f	g	c	f
ΔG :	0.2	0.1	0.4	0.4	0.5	0.2	0.2	0.2

a 7*7 square skew symmetric matrix is generated:

a	b	c	d	e	f	g	
0	0.2	0.3	xx	xx	xx	xx	where xx = not measured
-.2	0	0.2	xx	xx	xx	xx	
-.3	-.2	0	0.1	xx	0.5	xx	
xx	xx	-.1	0	xx	xx	xx	
xx	xx	xx	xx	0	0.2	0.4	
xx	xx	-.5	xx	-.2	0	0.2	
xx	xx	xx	xx	-.4	-.2	0	

Typically, mostly near diagonal elements are available, due to the limited range of equilibria accessible by the methods. We discard "pendant" values (those linked only to one other base, such as d) and then separate the main matrix into submatrices along the "fusions". These are bases, such as c, in the ladder where no equilibrium arrow crosses a base. The submatrices optimize faster than the whole (ca. $n^{2.9}$ in speed). We average each row and column meeting at an xx to obtain a trial guess for the value of xx. Repeated iteration of this averaging fills the matrix to a constant set of values. The top row is then copied as a monotonically increasing edge vector (x) of absolute ΔG 's, corresponding to the affinity scale. Our actual function that serves as the measure of minimization is an rms function of the difference in the derived values on this edge vector less the measure equilibrium value. A simplex method of optimization is slower than the iterative method, but of slightly better convergence.

Several weighting schemes were considered. The implicit error function in a simple average assumes a constant error in ΔG , say 0.1 kcal/mol, regardless of the size of ΔG . This favors paths with the least number of equilibria, thus often larger ΔG values are favored. A Gaussian weighting function $a \cdot \exp(b \cdot \Delta G^2)$ favors smaller ΔG values in the averaging. We use $a=0.1$, $b=.1733$ to obtain for typical ICR equilibria:

ΔG :	0.0	1.0	2.0	3.0	4.0
$\pm$:	0.10	0.12	0.20	0.48	1.5

It is found that the best scale construction consists of one with few pendants, and fusions at regular intervals, to allow maximal checking of data. Cases in the literature are observed where one additional measurement would considerably reduce the uncertainty in the ladder values. Techniques for detecting data which do not fit well with the rest of the scale are included, to aid in detection of errors in data. The program is available from the authors.

THE STRUCTURE OF THE (M-H) ANIONS OF THE CH_3NO_2 ISOMERS OF
NITROMETHANE AND METHYL NITRITE

Deborah A. Thomas, John E. Bloor and John E. Bartmess
Dept. of Chemistry, Univ. of Tennessee, Knoxville TN 37996-1600

Methyl nitrite, MeONO , is commonly used as a source of methoxide ion in CIMS and ion/molecule reaction studies. Reaction of methoxide with MeONO yields 60^- , the (M-H) ion. This ion can be represented as $\text{O}=\text{NOCH}_2^-$, a dipole stabilized anion.¹ Based on estimated acidities, however, it seemed unlikely to us that this ion could be formed by methoxide. The 60^- could also be the more stable $\text{CH}_2=\text{NO}_2^-$, the (M-H) ion of nitromethane, MeNO_2 .

The (M-H) anions of MeONO and MeNO_2 , formed in the CI source of a ZAB EQ mass spectrometer, fragment differently under CID conditions. The ion from MeNO_2 gives fragments at 59 daltons and 42 daltons, while the ion from MeONO gives three fragment ions at 59 daltons, 58 daltons and 42 daltons. The peak at 58 daltons can be used to identify the different structures. This ion must contain the elements CNO_2^- ; however, the atom connectivity must be $^-\text{OCN}=\text{O}$ since both the CNO_2^- and $^-\text{CON}=\text{O}$ structures are not stable. MIKES was not successful on the 60^- ion from neopentyl nitrite because of its low abundance.

From equilibrium gas phase acidities, the ΔH_{acid} of MeNO_2 is 356 ± 2 kcal/mole. The ΔH_{acid} of MeONO from bracketing experiments (current work) in the ICR is 368 ± 4 kcal/mole, between benzyl alcohol and acetoxime. Neither of the 60^- ions undergo facile deuterium exchange with various ROD, but the (M-H) from MeONO did show small amounts of deuterium exchange with PhCH_2OD which has an acidity close to that of the conjugate acid of 60^- . The ions from MeNO_2 and MeONO do not react with N_2O , CS_2 , OCS or CO_2 . The (M-H) anion of MeNO_2 reacts with dimethyldisulfide (MeSSMe) to produce a characteristic anion at 106 daltons,² while the 60^- anions of MeONO and neopentyl nitrite do not produce 106⁻ under the same conditions.

Ab initio calculations (6-31+G//6-31+G) indicate that $\text{CH}_2=\text{NO}_2^-$, from MeNO_2 , is ca. 51 kcal/mol more stable than $^-\text{CH}_2\text{ONO}$, but comparable in stability to $^-\text{OCH}_2\text{NO}$, another isomer. MeONO is calculated to have an acidity of 405 kcal/mol, 25 kcal less acidic than methanol. HOCH_2NO is at 365 kcal/mol, close to the bracketed value. This calculated acidity agrees with that obtained from experimental HOCH_2X acidities correlated with a linear free energy relationship: the σ_{TP} equation indicates that the nitroso alcohol should be slightly less acidic than $\text{CF}_3\text{CH}_2\text{OH}$ at 362 kcal/mol.

We thus believe that while $^-\text{CH}_2\text{ONO}$ may be formed in a complex on deprotonation by methoxide, it must rearrange to an isomer before the complex separates to methanol and 60^- . The ion is not $\text{CH}_2=\text{NO}_2^-$, based on reactivity with MeSSMe and on acidity measurements. The $^-\text{OCH}_2\text{NO}$ form is consistent with experimental reactivity and calculations. Another possibility is the anion of formyl hydroxamic acid, $^-\text{OCH}=\text{NOH}$, which is calculated to be of comparable basicity to $^-\text{OCH}_2\text{NO}$. We favor the latter alkoxide ion, however, because the hydroxamate should undergo rapid deuterium exchange of a single hydrogen with ROD, which is not observed.

THERMOCHEMISTRY FOR REACTIVE NEUTRAL SPECIES FROM APPEARANCE
ENERGY MEASUREMENTS IN A FLOWING AFTERGLOW-TRIPLE QUADRUPOLE
INSTRUMENT.

Jose A. Paulino, Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette, IN 47907.

Introduction:

Collision induced dissociation (CID) methods have been used to estimate thermochemical properties for reactive neutral species in a flowing afterglow-triple quadrupole instrument¹. The heats of formation of reactive organic intermediates such as enols, ylides, benzyne, and carbenes can be calculated from the appearance energies (AE) for low energy CID and ion/molecule reactions that produce these neutral species as products. These heats of formation cannot be measured directly by calorimetry nor estimated reliably from thermochemical group equivalents. The experiments presented here provide one of the few methods for acquiring these important thermochemical data.

For a CID experiment, the appearance energy or threshold energy (E_t) corresponds to the activation energy for the dissociation reaction. If there is no significant reverse activation energy, then the threshold energy is equal to the reaction enthalpy. Therefore, the heat of formation for a reactive neutral product from a CID experiment can be estimated using the measured threshold energy (E_t), and the values of the heats of formation of the product ion and the reactant ion from the literature. To illustrate this general technique, we present here our preliminary results for benzyne as well as estimates of the heats of formation for various carbenes.

Discussion:

Benzyne are generated from CID of mono-substituted phenide and benzoate ions.

E_1 can also be determined from the difference between E_2 and E_3 , thus providing an additional measure of the desired threshold energy. Our preliminary results reveal some intrinsic difficulties with this experiment. The precursor ions formed by proton abstraction from mono-substituted benzenes appear to be mixtures of ortho, meta and para-substituted phenides. This can lead to variations in the observed CID threshold energy with reaction conditions in the flow tube. For instance, for the fluorobenzene case the direct method gives a value of E_1 which is consistent with the reported literature value for the heat of formation of ortho-benzyne², while the chlorobenzene case gives satisfactory agreement only with the (E_2-E_3) difference method. We are currently studying authentic ortho, meta, and para chlorobenzoate ions. These ions will allow us to acquire heats of formation for isomeric benzyne unambiguously.

Halocarbenes can be formed by CID of halomethide ions.

Scheme 2

X = Halogen, n = 1, 2, or 3

An estimate for the heat of formation of the neutral carbene product can be obtained from the appearance energy of the product halide ion. Other carbenes which have been generated by this method are phenyl, vinyl, and cyano-substituted methylenes. Some of the results of our experiments as well as literature reference values are summarized in Table 1.

Table 1

			CXYZ ⁻ $\xrightarrow{\text{CID}}$ CYZ + X ⁻		
X	Y	Z	AE(X ⁻)	calculated H ₁ (CYZ)	reference ³ H ₁ (CYZ)
Cl	Cl	Cl	32 ± 5	58 ± 5	39 ± 5
Cl	H	Cl	37 ± 5	77 ± 5	71 ± 5
Cl	F	F	<10		
Cl	F	Cl	21 ± 5	2 ± 5	-2 ± 5
F	F	F	62 ± 5	-34 ± 5	-49 ± 3

The CID results for CF₂Cl⁻ suggest the presence of a loosely bonded Cl⁻. Support for this is obtained from the observation that CF₂Cl⁻ transfers Cl⁻ to CO₂ in an exothermic bimolecular reaction. Since the Cl⁻ affinity of CO₂ (D[CO₂-Cl⁻]) is known to be 8.5 kcal/mol⁴, then D[CF₂-Cl⁻] must be less than this. Thus, CF₂Cl⁻ can be regarded as a gas-phase carbenoid. That is, its structure is that of a ground state singlet difluorocarbene loosely associated with a chloride ion. Consequently one might anticipate that this ion could react like a neutral carbene (ie., it might undergo insertion and cycloaddition reactions). However, attempts to observe carbene type reactivity in reactions of CF₂Cl⁻ with various alkenes have thus far failed. Ab-initio calculations for CF₂Cl⁻ are consistent with the assignment of a carbene-chloride complex type structure. For example the C-Cl bond length is 3.09 Å, a value which is much larger than usual C-Cl bond lengths (1.76 Å). Also the negative charge density is largely concentrated on the chlorine atom, making the carbene carbon atom electron deficient.

Conclusions:

1. A useful method for estimating heats of formation for reactive neutral compounds has been demonstrated. The method is based on low energy CID appearance energies, and can be used to derive thermochemical data for carbenes, benzyne, enols, ylides, and other interesting species.
2. The heats of formation of some halocarbenes have been determined using Cl⁻ appearance energies from CID of chloro-substituted carbanions.
3. The CF₂Cl⁻ ion has been shown to possess an extraordinarily weak C-Cl⁻ bond. The Cl⁻ affinity of CF₂ has been estimated to be less than 8.5 kcal/mol from Cl⁻ transfer studies.

Determination of the Stability and Structure of Cluster ions $\text{Cl}^+(\text{RH})$ (Cl^+ attached with alkane) by High Pressure Mass Spectrometer

C. Li and T.B. McMahon
Department of Chemistry
Guelph-Waterloo Center for Graduate Study in Chemistry
University of Waterloo
Waterloo, Ontario
CANADA N2L 3G1

The temperature dependence of the equilibrium for the gas-phase ion-molecule clustering reaction: $\text{Cl}^+ + \text{RH} \rightleftharpoons \text{Cl}^+(\text{RH})$ (Where RH is a normal- or cyclo-alkane) has been investigated by the use of pulsed ionization mass spectrometry. The solvation of Cl^+ by solvent molecules, such as alkanes, is of importance to gain an understanding of the role of solvent on reaction mechanism.

Electron impact of CCl_4 by 2keV 50 μs pulse of electrons produces the reagent ion Cl^+ , which then undergoes association with solvent molecules of interest at the high pressure (3~6) ion source. The hydrogen bond dissociation energies (ΔH°), and entropy changes (ΔS°) have been obtained from the van't Hoff plots. Also, the stabilities and structures of the cluster ions $\text{Cl}^+(\text{RH})$ have been investigated using the Gaussian 86 program and a 4-31G basis set, and compared with experimental results.

Both experimental and theoretical calculations show that the interaction between Cl^+ and alkane molecule is very weak, electrostatic $\text{Cl}^+ \cdots \text{H-C}$ interactions appear to dominate.

Results are shown in the table below:

Reaction System	$-\Delta E$ (RHF) (kcal.mol ⁻¹)	$-\Delta H^\circ$ (kcal.mol ⁻¹)	$-\Delta S^\circ$ (cal.mol ⁻¹ .K ⁻¹)
Cl ⁻ + n-C ₃ H ₁₂		10.0	24.3
Cl ⁻ + c-C ₅ H ₁₀	7.9	8.5	19.9
Cl ⁻ + n-C ₆ H ₁₄		10.9	25.7
Cl ⁻ + c-C ₆ H ₁₂	11.4	11.2	27.2
Cl ⁻ + n-C ₇ H ₁₆		10.7	24.1
Cl ⁻ + c-C ₇ H ₁₄		10.8	24.3
Cl ⁻ + n-C ₈ H ₁₈		12.5	26.9

The Typical Time Profile of HPMS is shown in the Figure below:

The optimized structures of Cl⁻(c-C₅H₁₀) and Cl⁻(c-C₆H₁₂) are shown below:

FOURIER TRANSFORM ION CYCLOTRON RESONANCE INVESTIGATION
OF HYDROGEN BONDING IN ALCOHOL-FLUORIDE ADDUCT IONS.

The deuterium isotope effect is a commonly used method for exploring the nature of the potential energy surface for the hydrogen bond¹⁻⁵. There is considerable discussion regarding whether the potential energy surface for ion-molecule hydrogen bond interactions takes the form of a single minimum, a double minimum, or a skewed single minimum.

Hydrogen bond interactions between fluoride ion and alkyl alcohols have been investigated in this research. Strong hydrogen bonding is expected as the acidity of HF is bracketed by the alkyl alcohols in the gas phase. Equilibrium constants for fluoride transfer between isotopic alcohols have been measured for a variety of alkyl alcohols.

All experiments were performed on a Bruker Spectrospin CMS 47 FT-ICR Spectrometer, interfaced with an Aspect 3000 minicomputer. The strength of the magnetic field is 4.7 Tesla.

The low pressures of ICR mean that fluoride ion solvated by one molecule of alcohol must be generated by a sequence of bimolecular reactions (Scheme 1). A typical equilibrium plot is shown in Figure 1; the alcohol is 2-propanol and the pressure is 2.4×10^{-7} mbar.

Table 1 shows the results obtained, along with the gas phase acidities of the alcohols. When these results are plotted against the difference in acidity between HF and the alcohol, a linear relationship with zero slope is observed (Figure 2). This suggests that the equilibrium constant for the deuterium isotope effect is independent both of the acidity of the alcohol, and of the nature of the alkyl moiety. The model of potential energy surface for ion-molecule hydrogen bond interactions that is consistent with these results is a skewed single minimum.

Future plans for this project are to (i) investigate the hydrogen bond interactions between alkoxide anion solvated by one molecule of its parent alcohol, (ii) investigate the hydrogen bonding between fluoride ion solvated by two molecules of alcohol, and (iii) perform computer calculations of the equilibrium constants for some of the alcohols. The latter will also allow the evaluation of the relative contributions of translation, rotation, vibration and zero point energy to the equilibrium constant.

A HIGH PRESSURE MASS SPECTROMETRIC DETERMINATION OF EQUILIBRIUM
ISOTOPE EFFECTS OF ASSOCIATION AND EXCHANGE REACTIONS OF F⁻ AND RO⁻
WITH SIMPLE OH/OD LABELLED ALCOHOLS

J.E. SZULEJKO, F.E. WILKINSON AND T.B. McMAHON
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF WATERLOO, WATERLOO, ONTARIO,
CANADA. N2L 3G1

EQUILIBRIUM ISOTOPE EFFECTS [EIE] HAVE BEEN OBSERVED FOR IONS
IN SOLUTION [1] AND IN THE GAS PHASE [2-4.] MOST OF THE PREVIOUSLY
REPORTED WORK WAS OBTAINED BY ICR MS [2,3]. SOME EIE HAVE BEEN
OBTAINED BY PULSED ELECTRON BEAM HIGH PRESSURE MASS SPECTROMETRY
[HPMS] [4] LITTLE BIMOLECULAR EXCHANGE EIE HAVE BEEN REPORTED BY HPMS.

THE EXPERIMENTS WERE CONDUCTED ON TWO DIFFERENT INSTRUMENTS,
A HPMS [5] AND A FOURIER TRANSFORM-ION CYCLOTRON RESONANCE MASS
SPECTROMETER {FT-ICR} [6].

REACTIONS INVESTIGATED

THE DATA ARE SUMMARIZED IN THE TABLES AND SOME van't HOFF PLOTS ARE
SHOWN IN THE FIGURES.

THE FOLLOWING CONCLUSIONS WERE DRAWN FROM THIS STUDY:

- 1) IN THE ALCOHOL SERIES ROH/D, R = CH₃, C₂H₅ OR 1-C₄H₉, SIGNIFICANT EIE
ARE OBSERVED. WITH INCREASING ACIDITY OF THE ALCOHOLS, ΔH INCREASES
AND ΔS DECREASES, IMPLYING A MORE FLAT BOTTOM POTENTIAL ENERGY WELL
FOR THE HYDROGEN BOND AND MAYBE AN INCREASING BARRIER TO ROTATION OF
THE OH/OD GROUPS IN THE NEUTRALS. THIS MAY EXPLAIN THE DISCREPANCY
BETWEEN THE HPMS AND FT-ICR AS THE HPMS DATA WERE OBTAINED ABOVE
410 K. FOR LARGER ΔH VALUES, MOST OF THE EIE IS DUE TO ZERO POINT
ENERGY DIFFERENCES IN THE NEUTRALS (IN THE OH/OD STRETCH).
- 2) THE MULTIPLE SOLVATION THERMOCHEMISTRY OF F⁻ BY CH₃OH HAS BEEN
DETERMINED. THE FIRST THREE SOLVENT MOLECULES ARE MORE STRONGLY
BOUND TO F⁻ THAN FOR Cl⁻. THE FORTH ADDITION IS VERY SIMILAR [7].
- 3) THE 2,3 F⁻ AND THE 1,2 CH₃O⁻ CLUSTERING WITH CH₃OH SHOW AN
UNUSUALLY LARGE ΔS OF -32eu AND -28eu RESPECTIVELY. MOLECULAR MODELS
OF THE CLUSTER IONS PROSESS SOME STERIC LIMITATION TO THE INTERNAL
ROTATIONS. THE TRIPLY SOLVATED F⁻ IS MORE RESTRICTED THAN THE DOUBLY
SOLVATED CH₃O⁻ CLUSTERS.
- 4) NEW THERMOCHEMICAL DATA FOR THE 0,1 AND THE 1,2 CLUSTERING OF
CH₃O⁻ WITH CH₃OH ARE REPORTED HERE WITHOUT THE COMPLICATIONS OF
OXIDATION REACTIONS WHENEVER N₂O OR CH₃ONO ARE USED TO GENERATE
CH₃O⁻

STRUCTURES AND ENERGETICS OF NO_3^- FORMED IN A GLOW DISCHARGE IONIZATION SOURCE

Rick A. Flurer, Scott A. McLuckey, and Gary L. Glish
Analytical Chemistry Division,
Oak Ridge National Laboratory, Oak Ridge, TN 37831

We have recently coupled an atmospheric sampling glow discharge ionization (ASGDI) source¹ to an ion trap mass spectrometer (ITMSTM)². We have been using the MS/MS capabilities of the ITMS as well as kinetic measurements to characterize the ions and reactive neutrals that issue from the ASGDI source. During the course of this work we have obtained some unexpected results for the anions of m/z 62. We have interpreted these results based on the hypothesis that at least two structures of NO_3^- are formed in the ASGDI source and support this contention with theoretical calculations.

Figure 1a shows the MS/MS spectrum of the m/z 62 anion from normal background. Fragment ions are observed at m/z 32 (presumably O_2^-) and at m/z 46 (NO_2^-). The NO_2^- fragment is to be expected from NO_3^- with the D_{3h} structure (see Figure 2). However, an O_2^- fragment is unexpected. Figure 1b shows the MS/MS spectrum of m/z 62 when nitroglycerine was admitted into the ion source. Note that the intensity of the m/z 32 ion is unchanged while that of NO_2^- goes off scale.

We have interpreted the experimental results as being due to the formation of at least two structures of NO_3^- in the ASGDI source. Fehsenfeld et al.³ have previously hypothesized the existence of two stable structures of NO_3^- from kinetic data acquired in flowing afterglow studies. We have performed a series of calculations to elucidate other bound structures for the nitrate anion in addition to the common D_{3h} structure. Geometry optimization calculations were performed at the RHF level of theory using a 6-311+G(2d) basis set to account for the diffuse nature of anions. Subsequent single-point energy calculations including correlation effects were done at the MP2 level of theory using the same basis set. The computational results are shown in Figure 2.

In addition to the D_{3h} structure, we have located two linear structures with similar energies on the NO_3^- potential energy surface. Each linear structure can easily account for the formation of O_2^- from CID of m/z 62 formed by sampling ambient air. In each linear geometry the ON- O_2^- or NO- O_2^- bond is long and weak, especially for the NO- O_2^- species.

We have shown evidence that at least two forms of NO_3^- are formed in an ASGDI source. The form of NO_3^- obtained by sampling a typical explosive dissociates exclusively to NO_2^- , whereas at least some of the NO_3^- obtained by sampling ambient air dissociates predominantly to O_2^- . *ab initio* calculations reveal two bound linear forms of NO_3^- in addition to the common D_{3h} form. Either linear form can account for the formation of O_2^- upon CID of NO_3^- formed by sampling ambient air. However, because the alternate form of NO_3^- survives injection into the ion trap we can reasonably assume that the ON- O_2^- structure is more likely to be stored in the ion trap upon injection from the ASGDI source when sampling ambient air. The NO- O_2^- structure, due to its relatively weak O-O bond, is less likely to survive injection into the ion trap.

RATE ENHANCEMENT OF β -ELIMINATION REACTIONS BY POLAR INTERACTIONS

Terry Sumpter and John E. Bartmess

Dept. of Chemistry, Univ. of Tennessee, Knoxville TN 37996-1600

As part of comprehensive study of beta-elimination reactions in the gas phase, we report preliminary results on the nominal E2 process:

DePuy and coworkers have postulated that elimination upon alkoxide attack of ethers has some carbanionic character (ElcB mechanism), in spite of the very high energy alkyl carbanions involved. If substantial negative charge is developing at the beta-carbon in the transition state (ElcB-like), then placing an electron withdrawing substituent adjacent to that position should stabilize the transition state and accelerate the reaction. Such techniques have been utilized extensively in solution. The propyl chloride system was chosen because formation of the potential intermediate carbanion by MeS^- is endothermic by ca. 60 kcal/mol, yet the reaction is only slightly exothermic, to maximize substituent effects.

The work was done in an ICR spectrometer. Methanethiolate was generated by electron impact on MeSSMe . Chloride formed by dissociative attachment was ejected by double resonance prior to start of the kinetic measurements.

For substituents in $\text{XCH}_2\text{CH}_2\text{Cl}$ ranging from electron donating (-Et) to accepting ($-\text{CH}_2\text{CN}$), efficiencies from 4 to 25% were observed. If the observed rate constants (or efficiencies) are plotted vs. σ_I , there is a weak trend of increasing rate with electron accepting polar effect, with $\rho_I = 1.7$. This can be compared to $\rho_I = 17$ for the acidities of XCH_2OH , where a full negative charge is formed. The trend observed here correlates with a transition state possessing little carbanionic character. Even for $\text{X}=\text{Ph}$, no obvious carbanion character can be discerned; the point falls on the line. The formation of $(\text{PhCHCH}_2\text{Cl})^-$ is still too far uphill energetically. A base stronger than MeS^- or leaving group worse than Cl^- is needed to make the ElcB pathway accessible. That production of Cl^- in these reactions is the result of an elimination and not a substitution is supported by the following: (1) Olmstead and Brauman report a very low efficiency of 4.5% for $\text{MeS}^- + \text{MeCl} \rightarrow \text{MeS-Me} + \text{Cl}^-$. (2) We observe an even smaller efficiency in the case of $\text{X} = \text{Me}$. (3) We see no reaction of MeS^- with Et_3S nor with $(\text{CD}_3)_2\text{S}$.

Despite the apparent simplicity of this model system, there are competing reactions to consider. For example, Olmstead and Brauman observed production of HS^- from the reaction of MeS^- with MeSH , with 50% efficiency. We saw no ion gauge-independent production of HS^- using the substituted or parent propane thiols.

The rate constant for $\text{X} = -\text{CH}_2\text{OH}$ is ca. two times slower than expected from the σ_p correlation. The possibility of "non-productive" H-bonding, with a retardation of rate, is present here. Thus there is an alternate pathway "siphoning off" reactants otherwise going to observable products, as shown:

AN FTMS STUDY OF ALKANE ELIMINATIONS FROM GAS PHASE IONS
M.S. Ahmed, C.S. Giam, Lawrence L. Griffin and David J. McAdoo
Dept. of Marine Sciences, Texas A&M University at Galveston,
Galveston, Texas 77550 and Marine Biomedical Institute, University
of Texas Medical Branch, Galveston, Texas 77550

Unimolecular alkane eliminations from gas phase ions are considered to be ion-neutral complex-mediated [1]. We wished to determine rate constants for these decompositions. Recently Bensimon et al. [2] used FTMS to measure decay rates of some alkene ions in the $1 - 50 \text{ s}^{-1}$. Therefore we used FTMS to measure rate constants for alkane elimination. We also examined the threshold behavior of these processes using low energy collisionally activated dissociation.

REACTIONS STUDIED

EXPERIMENTAL

A Nicolet FTMS-1000 was used in all experiments. Parameters for determining rate constants for unimolecular fragmentations were electron energy = 15 eV, electron beam duration = 200-400 μs pressure = $1-6 \times 10^{-8}$ torr, magnetic field = 3 T, 64 K data points collected. For CAD experiments, electron energy = 10 eV, sample pressure = 1×10^{-7} torr, argon pressure = 5×10^{-6} torr, beam duration = 5 ms, 16K data points collected. RRKM rate constants were calculated with the program of Bunker and Hase [5].

Table 1. Measured and Calculated Rate Constants

Compounds	Measured rate ($s^{-1} \times 10^{-3}$)	RRKM rate*	
		-RH	-R
3-methylhexane	0.4	3.2×10^{10}	1.2×10^8
Isopropyl methyl ether	0.7	1.2×10^9	3.2×10^9
2-methyl-3-pentanone	0.3	2.8×10^7	1.1×10^7
2,4-dimethyl-3-pentanone	1.2	1.0×10^9	1.3×10^7

*Calculated at the critical energies.

RRKM rate constants for alkane eliminations are orders of magnitude higher than measured rates. Thus energy redistribution may not be rapid at low energies and/or in ion-neutral complexes. The breakdown curve for CAD experiments are similar to photoionization efficiency curves. The extrapolated breakdown curves for fragmentations of ionized acetone give thresholds of 0.4 ± 0.2 eV for methyl and methane losses. Correcting for thermal broadening ($0.6W_{0.5}(E_T)$) [4], the threshold becomes 0.6 eV, which is within experimental uncertainty of the 0.7 eV measured by photoionization [5].

CONCLUSIONS

1. The measured unimolecular rates for alkane eliminations are orders of magnitude lower than the RRKM predicted rates.
2. The thresholds for methane and methyl loss from ionized acetone are very similar and found to be 0.6 ± 0.2 eV, in reasonable agreement with photoionization results.

ASSIGNMENT OF ISOMERIC HYDROXYHYDANTOINS:
LINKED SCAN, TANDEM, AND HIGH RESOLUTION STUDIES

Bruce Onisko
ICI Americas Inc., 1200 South 47th Street, Box 4023,
Richmond, CA 94804-0023

Sydell Lewis
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

The mass spectral fragmentation of hydroxyhydantoin isomers has been studied by a combination of high resolution, linked scan, and collisionally activated decomposition (CAD) experiments. This endeavor resulted in the structural assignment of four pairs of hydroxyhydantoin isomers. A key feature in differentiating 1-methyl-3-aryl-5-hydroxy-2,4-imidazolidinediones from 1-aryl-3-methyl-5-hydroxy-2,4-imidazolidinediones is that under electron ionization (EI) only the 1-methyl-3-aryl-5-hydroxy-2,4-imidazolidinediones yield an ion corresponding to $[\text{MeNCHOH}]^{+}$. The analogous $[\text{ArNCHOH}]^{+}$ ion (where Ar is the aryl group) was present in the EI spectra of both isomers.

Considerable research concerning the mass spectroscopic behavior of hydantoin isomers has been done.¹⁻³ There are no reports on the mass spectrometry of hydroxyhydantoin isomers, however, even though methods to synthesize this class of compounds are available.

Low resolution EI spectra were obtained on a Finnigan Model 1020 mass spectrometer using the solids probe. High resolution EI data were obtained on a VG Model 7070E-HF mass spectrometer. Metastable decomposition studies were also done on the VG Model 7070E-HF mass spectrometer using B/E linked scans. For comparison, collision activated dissociation experiments were done on a Finnigan MAT model ISO 70 Triple Quadrupole mass spectrometer using 0.7-1 mTorr Argon at -35eV collision energy.

Reaction of 1-methyl-3-aryl-ureas with glyoxylic acid (see Scheme) gives two isomeric products, 1-methyl-3-aryl-5-hydroxy-2,4-imidazolidinediones (1-Me-3-Ar) and 1-aryl-3-methyl-5-hydroxy-2,4-imidazolidinediones (1-Ar-3-Me). Relative intensities of ions found in the positive ion EI spectra of four isomeric pairs of hydroxyhydantoin isomers are summarized in the Table. The compositions of these ions were established by high resolution experiments.

The EI spectra of isomeric pairs of compounds are very similar. Intensity differences can be seen. For example, the $\text{M}^{+}-\text{MeNCO}$, $[\text{ArCHNO}]^{+}$, and $[\text{ArCNO}]^{+}$ ions are consistently more abundant in the spectra of 1-Me-3-Ar isomers. Analogously, the $[\text{ArCH}_2\text{NO}]^{+}$, $[\text{ArNH}_2]^{+}$, and Ar^{+} ions are consistently more abundant in the spectra of 1-Ar-3-Me isomers.

The $[\text{MeCH}_2\text{NO}]^{+}$ ion is only seen in the spectra of 1-Me-3-Ar isomers. The assignment of hydroxyhydantoin isomers is based on this observation. The $[\text{ArCH}_2\text{NO}]^{+}$ ion was expected in the spectra of only the 1-Ar-3-Me isomer, however it was found in the EI spectra of all of the compounds examined. Linked scan and tandem experiments offer an explanation. The $[\text{ArCH}_2\text{NO}]^{+}$ ion from the 1-Me-3-Ar isomer was found to arise from the molecular ion by losses of carbon monoxide and methylisocyanate. Similarly the $[\text{ArCH}_2\text{NO}]^{+}$ ion from the 1-Ar-3-Me isomer arises from the molecular ion by losses of the same two neutral molecules. These analogous fragmentations suggest that the $\text{M}^{+}-\text{CO}$ ions from either isomer have the same structure. The fact that the metastable decomposition spectra of these ions are nearly identical supports this hypothesis. A possible structure for the $\text{M}^{+}-\text{CO}$ ion is a cyclic ion formed by loss of carbon 4 of the hydantoin ring as carbon monoxide.

THE TRIMETHYLSILYL IUM (Me_3Si^+) AFFINITY OF ALKYLAMINES

J.A.Stone and X.Li
Queen's University, Kingston, Ontario, Canada K7L 4J1

The Me_3Si^+ affinities of monoalkylamines have been measured as an extension of previous studies of the association of Me_3Si^+ with oxygen and aromatic bases(1) and alkenes (2). A high pressure mass spectrometer with pulsed electron beam is used to obtain van't Hoff plots for the reaction

where B_1 and B_2 are amine or reference base.

Quantitative data for the binding energy (ΔH°) of Me_3Si^+ to ammonia, monoalkylamines and dimethylamine have been obtained by reference to previous absolute values for oxygen bases (1). Ethyl acetate and ethyl ether are the reference bases for ammonia. Ethyl benzoate is the reference base for the other amines.

The binding energy (ΔH°) increases with increasing polarizability of the alkyl group: $\text{NH}_3 < \text{MeNH}_2 < \text{EtNH}_2 < \text{BuNH}_2$. The butylamines however are not in the expected order (t-BuNH_2 i - BuNH_2 n - BuNH_2) which may be due to steric hindrance between the Me_3Si and the t-Bu- and $i\text{-Bu-}$ groups.

Accurate proton affinities of N-alkyl-trimethylsilylamines may be derived from the Me_3Si^+ affinities, provided that the enthalpies of formation of the N-alkyl trimethylsilylamines can be correctly estimated from the single literature value for $\Delta H_f^\circ(\text{Me}_3\text{SiN}(\text{Me})\text{H})$ (3). The values in Table 1 show that $\text{Me}_3\text{SiN}(\text{R})\text{H}$ has a slightly lower proton affinity than $\text{Me}_3\text{CN}(\text{R})\text{H}$ in agreement with theoretical predictions of the effect of replacing carbon by silicon (4).

Qualitative investigations of Me_3Si^+ transfer from ethyl benzoate to trialkylamines show that the Me_3Si^+ affinities of these amines are significantly greater than those of the monoalkylamines. However no oxygen base has been found with sufficiently high Me_3Si^+ affinity that it may be used as reference base for quantitative equilibrium transfer experiments with trialkylamines. In addition Me_3Si^+ transfer between trialkylamines is so slow that equilibrium is not attained during the available

ion residence times so that even the relative binding energies of these amines cannot be determined. This slow exchange is ascribed to steric hindrance. With the exception of dimethylamine, quantitative data has so far not been obtained for dialkylamines. Equilibrium was apparently obtained in Me_3Si^+ transfer experiments but the resulting van't Hoff plots are non-linear. The reason for this is not immediately obvious although in some, but not all, cases it can be ascribed to an ion induced isomerization of the amine.

Non-FT/ICR/MS: Bayesian Spectral Analysis for ICR Mass Spectroscopy

Joseph E. Meier and Alan G. Marshall

Department of Chemistry and Department of Biochemistry
The Ohio State University, 120 West 18th Avenue, Columbus, Ohio 43210

Of the many methods for obtaining a discrete frequency-domain spectrum from a discrete time-domain signal, the (discrete) fast Fourier transform (FFT) is computationally fastest, but is not necessarily the "best".¹ For example, the "causality" assumption (namely, that only one spectrum fits the time-domain data) of the FFT method is no longer valid when noise is present. Moreover, truncation of the time-domain data can produce an FT spectrum with unwanted "Gibbs oscillations". Depending on the frequency separation between peaks, the time-domain signal-to-noise ratio, and number of frequency-domain peaks, non-FT methods can offer mass resolution and/or mass accuracy superior to that from FFT data reduction of the same time-domain discrete data. In this abstract we compare Bayesian and FFT analysis of experimental electron-ionization ICR time-domain discrete 16K signals for a mixture of N₂ and CO (Fig. 1) and for various xenon isotopes (Fig. 2).²

Bayesian spectral analysis iteratively determines the most probable spectrum that fits the time-domain data, conditional on any prior information ("prior") and on the likelihood function of the data.³ Figures 1B and 2B show the results obtained with a "prior" which assumes that the time-domain data (first 4096 points only) consist of a sum of exponentially damped sinusoids plus noise. Figures 1A and 2A show the corresponding magnitude-mode spectra computed by FFT from the full 16,384-point data sets. The Bayesian spectral peaks appear visually sharper, with higher signal-to-noise ratio, than those produced by FFT. A better comparison is provided in Tables 1 and 2, which list the ICR frequency differences for ions of various m/z at 3.016 tesla. The "true" frequency separations computed from the isotopic masses (minus the mass of an electron) relative to CO⁺ or ¹³²Xe⁺, respectively, are compared to those determined by Bayesian or FFT spectral analysis (in which the FFT peak frequencies are determined by 3-point parabolic fit to the three highest-magnitude points for each peak). From Tables 1 and 2, it is clear that Bayesian analysis gives a more accurate estimate of ICR frequency (and thus more accurate m/z) than does the discrete FT for signals that are close together in frequency (or m/z), even though the Bayesian analysis was based on only the first 1/4 of the time-domain data set subjected to FFT data reduction.

Experimental results based on a maximum-entropy "prior" have also been investigated. The entropy "prior" assumes no prior functional form for the signal, except that Gaussian-distributed random noise is present. Thus, the spectrum that has maximum entropy and still fits the time-domain data to within the standard deviation of the noise is found. We shall report elsewhere on our comparison of the two forms of Bayesian spectral analysis and the discrete FT.²

MSCOINT: A COMPUTER PROGRAM DEVELOPED FOR THE INTERPRETATION OF COLLISIONALLY ACTIVATED MASS SPECTRA

D. Zidarov and Michel J. Bertrand

Regional Center For Mass spectrometry, Department of Chemistry,
University of Montreal, P. O. Box 6128, Montreal, Canada H3C 3J7

The program MSCOINT (Mass Spectrum Computerized Interpretation) is currently being developed in our laboratory with the aim to assist in the interpretation of mass spectra generated by high energy collision activation of organic molecules. The objective of the project is to produce a list of probable candidate-structures using mass spectral data such as the exact mass of the parent ion and the CAD spectrum. The program is structured in four parts that are related to the identification process:

- i) FOREMP: this is the first part of the program and its role is to generate empirical formulae, $C_xH_yO_nN_z$, from the exact mass of the parent ion.
- ii) ANALYS: this second part of the program decomposes all empirical formulae generated by FOREMP in linear combinations of predefined superatoms.
- iii) GENSTR: this is the part of the program that generates probable structures from the sets of superatoms that have been determined by ANALYS.
- iv) STAT: this last part of the program is responsible for determining and ranking the most probable candidates.

The first two parts of the program presently perform adequately. Using measures of the accurate mass of the parent ion and a set of constraints, the program generates a list of empirical formulae that correspond to the compound under study. Then, the second part of the program decomposes all the empirical formulae generated into sets of predefined superatoms using equation 1.

$$C_xH_yO_nN_z = \sum X_i S_i + \sum Y_j S_j \quad (1)$$

The sets of superatoms that constitute solutions to the equation are obtained by determining the frequencies of occurrence X_i and Y_j of the unsaturated and saturated superatoms i and j . Then the sets are used by the third part GENSTR to generate candidate-structures which will be ranked by STAT.

Several approaches can be considered in order to generate chemical structures from the sets of superatoms and there are also several ways to correlate the structures to the mass spectra and rank the most probable candidates. In initial trials that were conducted in order to verify the feasibility of using the program MSCOINT to assist in the interpretation of collisionally activated mass spectra, the sets of superatoms generated by ANALYS were arranged in structures using predetermined acyclic pseudo-alkane structures. This simple approach was found to be adequate to obtain all possible acyclic structures but it requires a data base of alkane structures to be constructed. The approach is very useful when a small number of superatoms are involved but as their number increases, the predetermined structures that have to be considered become very large and the size of the data base is enlarged considerably. For example, a data base of structures including up to 16 superatoms would require 18030 entries [1] which can create a problem. In context, it was deemed important to develop an algorithm that would generate only the structures that have a good correlation with the experimental spectrum. In this way, constraints to be defined by the user would be involved in the generation of the probable structures and their number would be decreased substantially by comparison to the former approach. This strategy has the added advantage that it does not require a permanent data base to be constructed.

The algorithm GENSTR, using the sets of superatoms provided by ANALYS generates exhaustive acyclic structures in a recursive fashion by linearization of structures of higher complexity. Since all double and triple bonds are initially included in the predefined superatoms, all the structures generated represent pseudo-alkanes in which carbon atoms are replaced by superatoms or clusters of superatoms. At each step of the construction process, the symmetry (equivalence of objects and positions) of the chain is verified in order to avoid redundancies. In order to show how the construction process operates, examples can be used by considering the

generation of simpler structures. The solutions (sets of superatoms) obtained from equation 1 are in the form of partition vectors PV as shown in equation 2 where {SP}, {SS}, {ST} and {SQ} are the lists of primary, secondary, tertiary and quaternary superatoms respectively. To each partition

$$PV = \{ \{SP\}, \{SS\}, \{ST\}, \{SQ\} \} \quad (2)$$

$$DV = (p, s, t, q) \quad (3)$$

vector is associated a distribution of superatoms DV where p, s, t and q are the cardinal numbers of {SP}, {SS}, {ST} and {SQ}. The total number of superatoms (n) is given by the sum of all types of superatoms as shown in equation 4 and the connectivity rule given in equation 5 must also be respected [2]. Thus the structures can be expressed as distribution vectors of p, s, t and q.

$$n = p + s + t + q \quad (4)$$

$$0 = t - p + 2q + 2 \quad (5)$$

For example, a distribution vector $DV_1 = (2, S_1, 0, 0)$ would represent linear structures with two terminal superatoms of valence one (p) and S_1 superatoms of valence two, and a distribution vector $DV_2 = (3, S_2, 1, 0)$ would represent branched structures with three terminal superatoms of valence one, S_2 superatoms of valence two and one superatom of valence three (t). The distribution vectors and the corresponding structures are shown below. For the construction of the structures

corresponding to the distribution vector DV_2 , a new distribution vector DV'_2 is considered in which the ensemble t_1-p_1 represents a cluster of superatoms as shown by the rectangle on the structure DV'_2 . It can be seen that the new structures represented by the distribution vector DV'_2 are now

conceptually equivalent to linear structures having seven divalent superatoms (S'_2) and two terminal superatoms (p_1, p_2) of valence one. Therefore it is possible to generate the appropriate structures using a given set of superatoms in a fashion totally analogous to the one used for the structures represented by DV_1 and it can be seen that any given distribution vector of higher order i.e. $DV_x = (p_x, s_x, t_x, q_x)$ can be reduced in a recursive manner to a vector $DV'_x = (2, S'_x, 0, 0)$ of lower order representing linear structures. In the example shown, clusters of superatoms corresponding to t_1-p_1 , t_2-p_2 and t_3-p_3 would be included in the structure generation process and tried in all the positions allowed within the constraints of non-redundancies and spectrum correlation requirements. For structures involving very high symmetries, the linearization process is not recommended because it produces redundant structures and in those cases, a different approach which is more suitable is used. Thus, the new GENSTR algorithm that has been developed and described allows more flexibility and has been incorporated in MSCOINT to replace the former approach.

AN AUTOMATED CHEMICAL STRUCTURE ELUCIDATION SYSTEM (ACES) FOR MS/MS SPECTRA

K.J. Hart and C.G. Enke

Department of Chemistry, Michigan State University
East Lansing, Michigan 48824

The goal of this work is the development of software tools for use in the construction of an "expert" structure elucidation system for MS/MS data. The software capable of producing and applying reliable substructure identification rules (MAPS: Method for Analyzing Patterns in Spectra) is crucial to the success of this system. The rules produced by a new generation method have greatly increased reliability *and* recall (i.e. 100% reliability and 100% recall for the "promazine" feature combination rule). This new method uses "feature combinations" rather than individual MS/MS spectral features as a basis for the rules. Collision gas pressure was also explored to determine the effect that different pressure regimes have on the content of the MAPS rules. Examination of MAPS rules derived from data at two different collision gas pressures reveals that the majority of the features for a given rule at one pressure are different than those for the same rule at a pressure three times higher (i.e. P1 vs. P2 as defined below).

A reference database which contains MS/MS spectra for 74 regulated drugs and 31 other standards was constructed. A total of 14,097 spectra were collected including 105 primary mass spectra, 6001 daughter spectra at P1 (0.4 mtorr Ar), 6001 daughter spectra at P2 (1.2 mtorr Ar), and 1990 daughter spectra at P3 (1.8 mtorr Ar). The compounds run include barbiturates, amphetamines, antipsychotics, morphine substitutes, stimulants, and phenols.

Substructure identification rules were generated using the MAPS software. The original method utilizes a uniqueness and correlation filter to determine the features included in a rule. The following rule was produced for the "promazine" substructure using U = 40% (feature uniqueness factor) and C = 50% (feature correlation factor):

IF	"PD (58.0 30.0)	[40,62]	{F1}
and	"PD (58.0 43.0)	[53,62]	{F2}
and	"PD (70.0 27.0)	[42,85]	{F3}
and	"PD (70.0 44.0)	[50,69]	{F4}
and	"PD (84.0 42.0)	[41,54]	{F5}
and	"PD (99.0 70.0)	[70,54]	{F6}

THEN substructure "PROMAZINE" is present.

The recall estimate for a rule is a measure of the ability to predict the presence of a substructure. The reliability estimate for a rule is a measure of the accuracy of the predictions. These estimates are calculated by applying the rules against the spectra for each of the reference compounds. The following table shows the

recall and reliability estimates for the promazine rule at four different match factors.

MF (%)	RECALL (%)	RELIABILITY (%)
100	15 [2/13]	100
80	38 [5/13]	100
60	62 [8/13]	73
50	77 [10/13]	43

PROMAZINE SUBSTRUCTURE

The match factor specifies the percentage of the rule clauses that must be present in the MS/MS spectra of an unknown for the substructure to be identified as being present. Since it is necessary to maintain 100% reliability for the structure generation phase of the analysis, the 80% match factor is used for this rule (with a corresponding recall of 38%).

Another rule for the "promazine" substructure was generated using the feature combination method. This new method calculates a uniqueness and correlation value for each combination of features produced by a permutation of a given number of starting features. The rule produced for the "promazine" substructure is:

IF	F1 and F2 and F5	[100,38]
OR	F3 and F6	[100,54]
OR	F2 and F6	[100,31]
OR	F4 and F6	[100,38]

THEN substructure "PROMAZINE" is present.

The numbers in brackets are the uniqueness and correlation values for the combination. This combination rule has a total recall of 69% and a reliability of 100% when applied against the reference database. A third rule was generated using more features. This rule contained 27 feature combinations and had **100% recall**. Thus, the use of feature combinations greatly enhances the recall and reliability of the MAPS rules.

MASSPEC: A GRAPHICS BASED DATA SYSTEM
FOR CORRELATING A MASS SPECTRUM WITH A PROPOSED STRUCTURE

Marshall M. Siegel*, Gregory Gill

American Cyanamid Company, Medical Research Division,
Lederle Laboratories, Pearl River, NY 10965

A graphics-based user friendly tool was developed to aid in the analysis of a mass spectrum when a proposed molecular or fragment ion structure is provided. The program correlates the observed ion masses with the fragment masses of the proposed structure. The program is written in VAX FORTRAN and ReGIS graphics.

INPUT DATA AND INPUT COMMANDS

Three inputs to the program are required: 1- Exact or nominal ion masses observed in the mass spectrum (NOLMAS), 2- The proposed structure described as a set of bonded superatoms, and, 3- A set of non-bonded superatoms to describe possible rearrangements, adduct ions and neutral/radical losses. (Superatoms are groups of atoms which do not readily fragment.)

The system allows the chemist to draw the proposed chemical structure on the terminal screen by positioning the superatom locations by use of a mouse or cursor keys. Bonded superatoms are entered by use of the ADD command which also requests a label and mass for the superatom. The BOND command draws bonds between the bonded superatoms of any desired bond order. Non-bonded superatoms are entered by use of the FREE command which also requests a label, mass and minimum and maximum numbers allowed for the non-bonded superatoms. Additional commands, HIGHLIGHT, REDRAW, CONNECT, LABEL, MOVE and ERASE, manipulate the drawn superatoms. The drawn superatoms can be SAVED and retrieved (GET) from the computer memory. The MACCS .MOL file structure is used for representing the chemical structures.

ALGORITHM

The masses of all possible combinations of bonded superatoms (MM1) and non-bonded superatoms (MM2) are computed. The method used to produce the combinations of connected superatoms is referred to as the "Bond Removal Method" [1]. The mass difference between the observed ion mass (NOLMAS) and masses MM1 is searched in the table of masses MM2. All successful searches are possible solutions. All possible solutions having bond order sums of the cleaved bonds (NBROKE) less than the desired upper limit (Kmax) and satisfying fragmentation rules [1] are the final substructure solutions. (See the accompanying MASSPEC Flow Diagram.) The EXECUTE command implements the above computations.

ANALYSIS OF FINAL SUBSTRUCTURE SOLUTIONS

The final substructure solutions are accessed using the OUTPUT command. The accompanying Figure illustrates the typical graphics of the terminal screen for the final substructure solutions. The lower portion of the Figure illustrates the table of solutions consisting of the computed masses with corresponding bonded and non-bonded superatoms, bond cleavages and mass error for high resolution data. This table can be scrolled UP, DOWN and by MASS. A desired entry in the table can be displayed in the upper right portion of the screen. Superatoms present in the proposed fragment ion structure are enclosed in rectangles, those absent are not enclosed. The upper left portion of the screen contains the fragment ion mass and the sum of the bond orders of the cleaved bonds and information about the non-bonded superatoms for the proposed structure.

The full structure in the Figure corresponds to the m/z 211 fragment ion produced in the thermospray mass spectrum of the cephalosporin antibiotic cefixime [2]. The fragment ion masses were those observed in the TSP/MS/MS spectrum of the m/z 211 ion. The observed spectrum and its interpretation obtained using the MASSPEC program are illustrated.

MACPROMASS - A COMPUTER AID FOR THE ANALYSIS OF MASS SPECTRAL DATA OF PEPTIDES AND PROTEINS

Terry D. Lee and Sunil Vemuri, City of Hope, Duarte, CA 91010

A computer program called MacProMass has been written which is designed to assist in analyzing FAB mass spectral data of peptides and proteins. Written in QuickBasic, the program will run on any MacIntosh with 1 Mb of memory. Full advantage is taken of the MacIntosh user interface. All functions of the program are readily accessible through pull down menus, and many of the commands have keyboard equivalents. Protein sequence data entry can be done through the keyboard or reading a file from the hard disk. MacProMass is designed to read any text file; so sequences down loaded from a protein data base are readily accommodated. Once entered, sequences are easily edited using standard MacIntosh editing commands. The six letters of the alphabet not permanently assigned to the common amino acid residues can be programed to code for any residue selected from a list of unusual amino acids or amino acid derivatives. Similarly, lists exist for selecting N-terminal and C-terminal substituents. The user can make his own entries to any of these lists. Displayed on the main screen (Fig. 1) along with the sequence for all, or a selected portion of the sequence are: amino acid composition; elemental composition; average and monoisotopic mass values for the protonated molecular ion; Bull and Breese free energy values; and the Browne, Bennett and Solomon HPLC index.

In connection with the main display are a full complement of search routines including: searching for a given sequence, searching for and replacing specific amino acid residues, searching for a mass corresponding to a protonated molecular ion of a protein fragment, and a search from a list of protonated molecular ions.

The main feature of MacProMass is series of subroutines that calculate the expected fragments produced when a protein is chemically or enzymatically degraded. The program supports directly the enzymes trypsin, chymotrypsin, Staph. Aureous, and Asp-N in addition to cleavage with cyanogen bromide. A theoretical enzyme called Superzyme allows the user to program any endopeptidase activity. The program calculates values for each peptide fragment for the mass of the protonated molecular ion, the free energy, and the HPLC index. The list of peptide fragments can be sorted using any of these values. Additionally, a routine is included which will systematically consider all of the single amino acid substitutions which will

account for the mass difference between an observed mass in an enzyme digest mixture and those calculated based on the expected sequence. This is a very useful feature when searching for variants of a known protein.

Included in the program is the capacity to calculate predicted mass spectral fragments for a peptide or protein fragment. This facilitates the assignment of fragment ions in FAB mass spectra. Values in the table of fragments can be searched and marked to show correspondence with spectral data.

A subroutine has been included for plotting hydrophobicity values for sequence data. Presently, the program supports the scales of Hopp and Woods; Kyte and Doolittle; and Engleman, Steitz and Goldman. The hydrophobicity plots can be displayed on the screen, sent to either a Laserwriter or Imagewriter printer, or copied to the clipboard for export to other Macintosh applications.

Copies of MacProMass and an instruction manual are available from the authors.

Fig. 1

IMPROVED RETRIEVAL OF HIGH RESOLUTION UNKNOWN MASS SPECTRA
WITH EXACT MASS-PROBABILITY BASED MATCHING

S. Loh and F. W. McLafferty

Chemistry Department, Cornell University, Ithaca, NY 14853-1301.

The Exact Mass-Probability Based Matching (EM-PBM) algorithm is now fully operational. This evolution of PBM uses elemental composition information contained in high resolution unknown mass spectra to aid in their retrieval and identification. During the EM-PBM matching process, unit resolution reference spectra from the Wiley/NBS Registry of Mass Spectral Data are compared to the unknown for possible matches. Against unit resolution unknown spectra, it has been shown that approximately half of incorrect retrievals have also incorrect chemical formulas,¹ and would be expected to benefit from knowledge of elemental composition.

PBM's probability base stems from the calculation of a confidence (K) value which reflects the probability that a peak matching in the unknown and reference spectrum occurs by chance. EM-PBM modifies the K value of a match to include the composition uniqueness (U_x value):

$$U_x = -\log_2(P_c)$$

where P_c is the probability of the composition occurring randomly in the reference library.

Because the Wiley/NBS library contains unit resolution electron ionization mass spectra, the probability of elemental compositions was calculated by a computer program that assigned compositions based on logical neutral losses from the molecular ion. The validity of this assignment process is shown by comparison of the results to the probabilities determined to mass 150 in Mass Spectral Correlations.²

Figure 1. Computed and known uniqueness values.

EM-PBM uses a two part strategy to improve the estimation of peak comparisons between reference and unknown. First, peak matches are nullified if the peaks have different compositions. Since the reference spectra are unit resolution, this determination is made only on the reference molecular ion, and small neutral losses. Other unknown peaks however, must have compositions compatible with that of the reference molecule. Second, reference and unknown peaks with matching compositions have a K value augmented by a Ux value.

On a set of 385 unknown spectra selected from the Wiley/NBS reference library, EM-PBM gains an additional 14% in correctly retrieved spectra. Duplicate spectra are retrieved at an average predicted reliability increase of 10%. Figure 2 shows a change in reliability versus recall comparing EM-PBM with PBM. Recall is defined as the percentage of all correct reference spectra retrieved, and reliability is the percentage of retrieved spectra that are correct. The data were calculated from 90 values of from 99 to 10 percent predicted reliability. An improvement in retrieval performance is indicated by a shift toward higher reliability at a given recall value.

Figure 2. Reliability vs. Recall for PBM and EM-PBM

QUALITATIVE EFFECTS OF ION ABUNDANCE TUNING CRITERIA
ON MODERN QUADRUPOLE MASS SPECTROMETER SYSTEMS,
RESULTS FROM AN INTERLABORATORY STUDY

A. D. Sauter, Andrew D. Sauter Consulting, Henderson, NV 89014;
D. Bottrell, U.S. EPA, EMSL/LV, Las Vegas, NV 89114; and J. Fisk, U.S. EPA
OERR, Washington, D.C. 20460.

Work over the last few years (1, 2, 3, 4 and 5), and the evolution of instrumentation over the last 15 years (including data systems, mass spectral libraries, and software), have prompted a study to examine, in part, the qualitative effects of ion abundance tuning on modern quadrupole mass spectrometer (QMS) systems. We have reviewed computer ranking and matching information obtained from 7 different laboratories. Each laboratory acquired data under five different tune regimes over at least 5 concentration ranges for at least 82 semi volatile priority pollutants and pesticides using different QMS systems. In this paper we present selected results from this effort.

Review of the computer ranking and matching results (approximately 40,000 individual determinations) shows that exceeding the 1975 DFTPP criteria has little, if any, effect on the ability of modern QMS systems to identify targeted analytes. The primary 1975 assertion (that a QMS tuned to the 1975 DFTPP criteria "will, in general, generate mass spectra of organic compounds which are very similar to spectra generated by other types of mass spectrometers") implied that data outside of the published ion abundance boundary would not match library spectra. This study does not support this utilization of these criteria. To illustrate, we calculated the recognition rate for computer matching results for the complete study (see Table 1). In a number of instances, "out of tune" results were found to be numerically higher or equivalent to "in tune" results. The statistical significance of this observation is a moot point, as from a global perspective, most analytes were identified most of the time, almost irrespective of whether, for example, m/z 198, 442, or "low" m/z rearrangement ions were the base peak. While the specific results for each system need to be considered, it was, not surprisingly, observed that when ion current, as indicated by the electron impact mass spectrum of DFTPP was suppressed at high mass, certain analytes, such as the chlorinated pesticides, were not efficiently identified. Concurrently, when ion current was suppressed at low mass, significant non linearity was observed for many targeted analytes. Consequently, new criteria, if they are developed, need to consider the lower levels of ion abundance windows carefully from a qualitative analysis perspective.

However, because of the results of this study, we have been led to question at a fundamental level the utility of the DFTPP ion abundance criteria as an aid for the qualitative identification of both targeted and non targeted analytes, as there seems to be little correlation between compound qualitative identification and the ion abundance criteria tested in this study. This was noted except at tune extremes, where "low mass" or "high mass" sensitivity was greatly suppressed. This global observation is probably due to a number of factors, including: (1) the great difference in spectral characteristics of the targeted analytes, as compared to the ion abundance reference compound; (2) the evolution of library search routines (some of which utilize a library relative retention time weighting factor); (3) hardware evolution; and other factors. Whatever the driving force or forces, the primary observation of our work to date is that the old DFTPP ion abundance criteria have little meaning in regards to the ability of modern QMS systems to identify targeted analytes.

Table 1.
Semivolatile Analyte Recognition Rate
(N = 82 Analytes)

<u>Tune</u>	<u>Laboratory</u>						
	<u>1</u>	<u>2</u>	<u>3</u>	<u>4</u>	<u>5</u>	<u>6</u>	<u>7</u>

REPORTING ANALYTICAL RESULTS WITH PC SOFTWARE

Norman Low
Hewlett-Packard
Scientific Instruments Division
Palo Alto, CA 94304

PROBLEM

Comprehensive reports of analytical studies are difficult to produce. The task may entail consolidating large amounts of information from many different types of instruments to produce a series of data tables. The problem is further complicated when graphical data from multiple instruments must be compared. Output from different data systems are usually combined by much trial and error graphics enlargement and reduction to produce a comparably scaled image. The manual operations involved are both time-consuming and error-prone.

APPROACH

The problems may be minimized by consolidating the raw data files from multiple instruments into a single data format and creating standard intermediate files for use in personal computer software. In this study, we used the Hewlett-Packard RTE Mass Spectrometer Data System as the point of central storage and data processing.

The RTE data system can accept raw data files from a number of sources. GC/MS and LC/MS data files can be transferred from both the HP Pascal and the Unix ChemStation series of data systems. Gas and liquid chromatographs attached to the HP Laboratory Automation Systems and the HP 3392 integrator may also be used.

Once the files are on the MS computer, the user can convert it for use with the applications software to display, print, or plot the data. The Aquarius target compound software can also be used to quantitate GC and LC data as easily as standard GC/MS data.

The standard software was used to produce a number of different standard output files. Some of these files are used directly (optical character recognition and barcode), while others are intermediate files for PC applications. We have produced simple ASCII files, tagged files, field delimited files, character delimited files, reduced results files, and HPGL files. In all of these cases, the files may be produced automatically through a single command line entered manually or as part of a sequence.

RESULTS

We will show representative reports created with various common personal computer software from intermediate RTE files. These applications include word processors, spreadsheets, desktop publishing software, and others. By directly creating intermediate files on the RTE data system for these applications, the likelihood of transcription error is reduced and the speed of report production is increased. In all cases, the intermediate files are accepted directly without additional formatting.

CONCLUSIONS

GC, LC, and MS raw data can be consolidated on the RTE MS Data System for processing.

Standard intermediate data files can be created automatically via procedure files.

These intermediate files can be used directly in PC applications, without additional operations.

Data Transcription from Hewlett Packard GCMS Workstation
to IBM Personal Computer (or compatible)
Gardner, J.M., Quick, A.N. and Fennessey, P.V., University of Colorado
Health Sciences Center, Mass Spectrometry Facility, 4200 E. 9th Ave.,
C232, Denver, Colorado 80262

Data manipulation and transfer can become time consuming and labor intensive in a laboratory where a large volume of samples are processed daily. Our laboratory has two Hewlett Packard Mass Selective Detectors, each fitted with an auto injector, which combine to process approximately 24,000 samples annually. The lack of commercially available software requires that the data be manually transcribed if personal computer based spreadsheets and databases are utilized. To process data on the H.P. workstations (models 216 and 300) all data acquisition must stop while data is being processed. The data storage space of the H.P. workstation (20 megabytes on the model 216) limits the operation of the mass selective detector to one or two days of automated data acquisition. This limited space impedes long term storage and archiving of data files. Our inability to electronically transfer and store data prohibited the rapid processing, analysis and reporting of these large volumes of data.

We initially tested commercially available software from a number of different suppliers. The programs were found to be completely unsatisfactory. They were found to be user unfriendly and destructive to our operating system. As a result, we have designed, built and tested an interface package called 'Siphon' using "off the shelf" components.

Siphon software transfers, stores and archives H.P. data files. It is a user-friendly, menu-driven and extensively tested program that ensures that the data will be transferred rapidly and processed accurately. Once the data has been transferred to the PC, your chemstation is free to acquire more data. Siphon provides an exact copy of the original data file containing: sample name, bottle number, retention time, peak areas, peak heights, library matches, bar code, time, and date. This file can be stored on hard disk, floppy disk, hard cartridge, or magnetic tape. This allows easy access of the file information and the archiving of data files. Siphon's parsing option allows the user to extract the pertinent information from the original data file, which can reduce the file size up to 90%. This type of processing can be customized for each user. Siphon generates two file formats: a quick reference file and spreadsheet importable file. The quick reference file is used for checking the data for anomalies and precision. The spreadsheet import file is readable by Lotus, Supercalc, databases and other programs that import using the same file formats.

The program is controlled on the H.P. side by a series of soft keys and on the PC side by a series of menus. The Siphon transfer softkeys are inserted in the H.P. software and can be stored for future use. This softkey execution of the transfer reduces the problems associated with add-on software because the program becomes an integrated part of the H.P. software. Siphon is user-friendly, in that, the menu's instructions are clearly described and easily executed. Siphon resides on the PC's hard disk saving disk space on the H.P. and allowing for easy access of the program.

Siphon's hardware and software requirements:

- H.P. 200 or 300 series workstation
- IBM or IBM compatible personal computer
- 232 Siphon custom cable
- Siphon Transfer Software
- Tablers - H.P. Freeware program

Siphon requires H.P. software's version to be from 1.1 to 3.1, software version 3.2 will not work until H.P. provides a new version of Tablers. The model 216 requires a custom cable because of the centronix pin configuration and will not work with a standard null-modem cable.

This high performance, user friendly, fully automated program enables the efficient processing of vast amounts of data. Our laboratory has benefited by the use of Siphon in that our transcriptions errors have been significantly reduced, while increasing our productivity.

MASS SPECTROMETRY DATA CENTRE

S.Bellard, M.Corkill, S.Down, R.Reid

Royal Society of Chemistry
Thomas Graham House
Science Park
Milton Road
Cambridge CB4 4WF
U.K.

The Mass Spectrometry Data Centre (MSDC), Royal Society of Chemistry (RSC), UK offers a unique information service to the mass spectrometric community. At present this service is 3-fold: production of the *Mass Spectrometry Bulletin* (MSB), a monthly current awareness journal; production of the *Eight Peak Index of Mass Spectra*, the largest printed index of mass spectral data in the world; collection and validation of mass spectral data for input to the NIST/EPA/MSDC Mass Spectral Database. For the MSDC to continue to make its important contribution to mass spectrometry, it is imperative for existing or potential users to contribute their own ideas and suggestions about the services. To do this, however, users must first be aware of the MSDC's current activities.

The MSDC was established in 1966 at the Atomic Weapons Research Establishment, Aldermaston and was transferred to the Chemical Society (now the RSC) in 1978. The Centre employs 4 professional and 3 clerical staff and is supported by other departments of the RSC. The technical activities of the Centre are overseen by a Technical Advisory Committee composed of renowned mass spectrometrists representing industrial, academic and government interests.

The majority of staff time and effort is spent producing the *Mass Spectrometry Bulletin*. Coverage of the literature to find papers for inclusion in the MSB is comprehensive: more than 900 primary journals are covered, along with relevant conference proceedings, books, technical reports and patents. Coverage of the subject matter is comprehensive too: instrument design and techniques, isotopic analysis, chemical analysis, organic chemistry, atomic and molecular processes, surface phenomena and solid state studies, thermodynamics and reaction kinetics. From each selected article the title, authors and publication details are abstracted. In addition, each article is analysed with respect to mass spectrometric content, and index terms and a mass spectrometric content/data indicator are assigned. The abstracted information is checked thoroughly for accuracy and consistency by means of an extensive proofreading and cross-checking system, thus ensuring a high quality product. Most articles appear in the MSB within two months of receipt of the original document at the MSDC. With an annual input of approximately 10,000 items, the MSB contains more than 3 times as many references as CA Selects: Mass Spectrometry. This, along with its unique series of indexes (subject, compounds classification, elements, general, author), makes the MSB a most important method by which mass spectrometrists can keep up-to-date with the current literature. The MSB is available in printed and PC versions and online via ESA-IRS.

The *Eight Peak Index of Mass Spectra* is an excellent aid for identifying unknown compounds. It is also a convenient single point of entry to the various full mass spectral collections and to mass spectral data appearing in the scientific literature. The spectra, collected from a variety of sources, are put through an extensive checking process to ensure the high quality and consistency of the data. Individual spectra are checked and corrected; they are then compared with one another and selected (or not) for inclusion in the Index. Of an original 100,000 spectra, 66,720 spectra, covering 52,332 compounds, were published in the 3rd edition. Data in the Index are sorted in three different ways for ease of use:

- Volume 1: by molecular weight and formula
- Volume 2: by molecular weight and m/z
- Volume 3: by m/z of most abundant ion

The third aspect of the MSDC's activities is the collection and validation of mass spectral data: the MSDC collects and prepares data for inclusion in the NIST/EPA/MSDC Mass Spectral Database. A variety of checks, including checks on chemical name and formula, molecular weight and the mass spectral data, are carried out by the MSDC. The data are then sent to the original contributor for further verification. In 1988 the MSDC expanded its activities in this area by joining the National Institute of Standards and Technology in the marketing and distribution of the PC Version of the NIST/EPA/MSDC Mass Spectral Database.

The MSDC provides an information service for you, the mass spectrometrists. It is from your comments and suggestions that we hope to provide you with an even better service with new products and enhancements to existing services.

QUANTITATION IN DATA EDITOR USING HP 3.2 CHEMSTATION SOFTWARE

John T. Cody

Air Force Drug Testing Laboratory, Brooks AFB TX 78235-5000

The ability to read/write user defined files in the 3.2 Revision of HP ChemStation Software allows the user to carry out quantitative analysis within the Data Editor program. This ability saves significant time in the processing of data and allows a completely customized output from the system. Previous revisions of ChemStation software required the quantitation be accomplished in the Report program or be manually calculated. The addition of this new capability saves time by not having to load the Report program with each sample which must be quantitated. This loading process typically takes 15 seconds to accomplish. This is significant in a process that takes a total of just over one minute, thus giving a time savings of approximately 25%.

Both single and multipoint calibration curves may be generated. Linear, log, power, exponent and second order curve fits can be applied to multipoint calibration curves. Preparation of a single point calibration curve is the simplest procedure. The area (or height) of the internal standard and the area (or height) of the compound in the calibration standard is written to a user defined file during the data analysis of the standard. During the data analysis of an unknown sample, the user defined file is read to allow comparison of the unknown to the calibration standard. The equation used is as follows:

$$[Dy] = \frac{\text{Area } Dy}{\text{Area } Ds} \times \frac{\text{Area } ISs}{\text{Area } ISy} \times [Ds]$$

Multipoint calibration requires the storing of area (or height) data from a number of calibration standards. This can be accomplished in several ways, one of which is using the file append option for a user created file if the data are written after each standard is injected. Another option is to inject all of the standards followed by the data analysis of each, one after the other, writing the data from each to the file then closing it. Once all data are stored in this file, the calibration curve parameters are calculated using the CREATE function to generate the dataset (user object). The CURVEFIT command can then be used to compute a number of statistical functions. These include the slope and intercept as well as the correlation coefficient for the fit of the data to the line. This results in a calibration curve which can then be used to quantitate unknown samples. The number of calibration points used in the curve is virtually unlimited. The data may also be appended to develop an average of data over a number of calibration curves.

The capability also exists to plot the calibration curve as is seen in the detailed internal standard report. This is easily accomplished by defining the title, X and Y axis labels as a part of the CREATE function. Once defined, the curve can be drawn to any window or redrawn to a plotter. An example of a five point linear calibration curve created in the Data Editor is shown in Figure 1. The STATPARM function can be used to return the slope and intercept. These two values can then be stored in a data file and used with unknown samples using the equation for a straight line. The fit of the data points can be demonstrated by computing the correlation coefficient. This value is returned with the CORRCOEFF function after the CURVEFIT function is executed.

Time can be saved in the analysis of every sample due to the simplicity of the quantitation within the Data Editor. More advantageous is the ability of the quantitation report to look exactly like the user wants rather than settling for the standard format provided by the vendor.

$$\text{Response Ratio} = 8.15332\text{E-}001 (\text{Amt Ratio}) + 3.39847\text{E-}001$$
$$r^2 = 9.98767\text{E-}001$$

REAL-TIME REACTION MONITORING BY CONTINUOUS INTRODUCTION ION SPRAY TANDEM MASS SPECTROMETRY

Edgar D. Lee*, Wolfgang Muck**, and Jack D. Henion
Drug Testing and Toxicology, New York State College of Veterinary Medicine,
Cornell University, Ithaca, New York

The study of reaction mechanisms and kinetics is fundamentally important for characterizing synthetic pathways of chemical reactions and for understanding biochemical processes occurring in life sciences. Nearly all known analytical techniques have been used to follow reaction mechanisms and kinetics. The objectives and challenges imposed by the complexity and speed of the reaction under investigation require instrumentation possessing the necessary selectivity and sensitivity to follow the reaction to completion.

The high degree of specificity of mass spectrometry for the identification of molecular species in mixtures, and its excellent sensitivity are attractive for studying reaction mechanisms and kinetics. Mass spectrometry and in particular Fourier transform mass spectrometry have been the most powerful techniques for monitoring reaction mechanisms of gas phase chemistry. The assumption that prior vaporization is a prerequisite of ionization prevented mass spectrometry from playing an important role for the real-time investigation of liquid phase reactions. It has not been until the advent of soft ionization techniques that allows direct sampling of liquids such as FAB, Thermospray, and electrospray that the mass spectrometer has been able to monitor reactions occurring in solution.

For these reasons we have developed a continuous introduction/ion spray inlet with mass spectrometry for real-time monitoring of reactions in solution. The purpose of the study was not to show highly sophisticated reaction studies, but to introduce electrospray ionization at atmospheric pressure as a tool for the continuous monitoring of condensed phase reactions by mass spectrometry. The potential of this new analytical approach was demonstrated using simple, well understood model systems.

A temperature-controlled reaction vessel was closely coupled to the ion spray LC/MS interface on a atmospheric pressure ionization mass spectrometer and used to study mechanistic and kinetic aspects of reactions taking place in solution. Free access to the reaction vessel and temperature control as well as minimal sample consumption make continuous introduction ion spray mass spectrometry a useful approach for real-time measurement of reactions. The reaction medium, reactants, and products are

transferred to the ion source of the mass spectrometer in less than a second. The half-life for the solvolysis of methandrostenolone sulfate to epimethandrostenolone in aqueous medium was determined to be 4.5 min. The Michaelis-Menten constant was determined to be 4.2 mM for the enzymatic hydrolysis of O-nitrophenyl- β -galactopyranoside by lactase to galatose and O-nitrophenylate. The enzymatic hydrolysis of dynorphin 1-8 by chymotrypsin and aminopeptidase and the reduction of the disulfide bridge in oxytocin with β -mercaptoethanol were observed on-line to emphasize the technique's capability for peptide sequencing and structural elucidation.

Lineweaver-Burke plot for the enzymatic hydrolysis of O-nitrophenyl- β -galactopyranoside by lactase to galactose and O-nitrophenylate. Conditions: 1, 2, 4, 5, and 10 mM solutions of OPNG prepared in 5-mM ammonium acetate; 2 drops of lactase was diluted with 20-mL of water after which a 100 μL aliquot was added to a 1-mL volume of the OPNG solution in the reaction vessel.

DETERMINATION OF CHARGE STATE OF IONS IN THERMOSPRAY MASS SPECTROMETRY

K.W. Chan, D. Wintergrass, T. Ho, and K. Straub
Syntex Research
Palo Alto, California 94304

Protonated molecular species $(M+H)^+$, multiply charged ions $(M+nH)^{n+}$, and cluster ions $(nM+H)^+$ are often observed in mass spectra obtained by thermospray ionization (TSP). To obtain unambiguous molecular weight information, it is necessary to properly assign the number of charges that are present on an ion. Differentiation of multiply charged species in spectra obtained on single stage quadrupole instruments is not straightforward (1-3), especially when data are obtained and displayed in centroid mode. Therefore, we have developed a simple procedure for identifying the charge state of ions by analysis of the peak profile of their isotopic clusters. Experimental results and theoretical calculations are presented to verify this procedure. The applicability of this technique is illustrated by the characterization of a peptide of MW 5090 daltons using TSP-MS on a quadrupole instrument.

TSP mass spectra were obtained on a Finnigan TSQ-70 mass spectrometer. Typical operating conditions were: jet, 210-240 °C; vaporizer, 92-95 °C; repeller, 75-135 V; flow rate 1.2 ml/min. The mobile phase for loop injections was 30% acetonitrile in water with 0.1% trifluoroacetic acid. Centroid spectra were obtained by scanning the mass range of interest in two seconds. Profile data were obtained by scanning a twenty m/z units window centered around the ions of interest; scan time was 0.2 second.

Figures 1 and 2 show the full scan, centroided TSP mass spectra of two peptides, Met-Arg-Phe-Ala (MRFA, MW 523.3 daltons) and Syntex compound RS-26306 ($C_{40}H_{113}N_{14}O_{12}Cl$, MW 1568.8 daltons), respectively. If the most intense ions detected in the two spectra were singly charged $(M+H)^+$, the MW of MRFA and RS-26306 would be interpreted as 523 and 785, respectively. Alternatively, if those ions were doubly charged species $(M+2H)^{2+}$, the MW of the two peptide would be assigned as 1046 and 1568. Thus, to unequivocally determine the MW of these two peptides, unambiguous assignment of the charge state of the ions detected is necessary.

By monitoring the profiles of the ions detected, we observed that isotopic ions of a multiply charged species, which would appear at fractional m/z values, are not resolved when the analyzer is operated at unit mass resolution. This observation allowed us to determine the charge state of the ions present in the spectra shown in Figures 1 and 2. Figures 3 and 4 show the profiles of the most intense ions in Figures 1 and 2, respectively. Figure 3 clearly shows that all the isotopic ions are resolved; therefore, the ion of m/z 524 is the $(M+H)^+$ of MRFA. Figure 4 shows the profile of the isotopic cluster of the ion at m/z 785.5 in Figure 2. The various isotopic ions are not resolved. Experimental conditions were such that unit mass resolution was achieved in this mass region, and was verified by obtaining isotope profile data on singly charged ions in this m/z region. Therefore, the ion at m/z 785.5 can be assigned as $(M+2H)^{2+}$ and the MW of RS-26306 is determined to be 1569 daltons.

To confirm that the profile observed in Figure 4 is due to a doubly charged species, we modified the computer program "THEOMS" (4) to generate theoretical isotopic profiles of multiply charged species from a given elemental composition and instrument resolution. The simple modification involves the use of m/z values of the elements in place of isotopic masses for calculations. Figure 5 shows the theoretical profile of the $(M+2H)^{2+}$ ions of RS-26306 at a resolution of 750. The widths at half height of the experimental and theoretical profiles are both 1.9 m/z units. Theoretical calculation, therefore, confirms the assignment of the profile shown in Figure 4 as a doubly charged ion cluster.

As we extended these calculations, we observed that the width at half height of a multiply charged ion cluster decreases as the number of charges increases. This observation has facilitated the identification of doubly and triply charged ions of a peptide whose MW (5090 daltons) is above the mass range of the instrument used (m/z 10-4000).

Figure 6 shows the centroid TSP mass spectrum of a peptide consisting of amino acid residues 1 to 44 of bovine growth hormone releasing factor (bGRF). The average MW of the peptide is 5089.9 daltons. The ions at m/z 2546 and 1698 can be assigned as the $(M+2H)^{2+}$ and $(M+3H)^{3+}$ of bGRF, respectively. However, from the data shown in Figure 6, one could not be sure that these ions were generated by bGRF or by extraneous species in the sample. The profiles of these two ion clusters are shown in Figures 7a and 7b. The width at half height of the doubly and triply charged ion clusters are 2.7 and 2.1 m/z units, respectively. The relative width of the triply charged species with respect to the doubly charged ions is therefore 0.78. For comparison, the theoretical profiles of the two ions are shown in Figures 8a and 8b. The theoretical widths at half height for the $(M+2H)^{2+}$ and $(M+3H)^{3+}$ are 2.2 and 1.7 m/z units, respectively. These profiles were generated using a resolution of 1700 for the triply charged ions and a resolution of 2500 for the doubly charged ions. The resolutions chosen were the ideal conditions where the quadrupole instrument would have unit mass resolution at the m/z region where the two ions were detected. The experimental resolutions were lower, however, which resulted in larger widths at half height of the ions detected. Nevertheless, the width of the triply charged ions relative to the doubly charged cluster, measured from the calculated profiles, is 0.76. The relative widths, observed experimentally and calculated theoretically, differ by less than 3%. These data support the identification of the two ions and therefore confirm the MW of the peptide as 5090 daltons.

In conclusion, we propose the use of this "Isotope Profile Monitoring" technique to acquire data in conjunction with ionization techniques where multiply charged species can be generated. In addition to the ability to determine the charge state of ions detected, this technique (similar to selected ion monitoring) provides improved signal-to-noise ratio over conventional full scan data acquisition, since more time is spent monitoring the ions of interest and signal averaging is readily carried out.

**Thermospray LC/MS With a Quadrupole Ion Trap and
Recent Applications of Ion Injection**

R.E. Kaiser, Jr., J.D. Williams, J.C. Schwartz, S.A. Lammert and R.G. Cooks
Purdue University, West Lafayette IN 47907
D. Zakett, Dow Chemical Co., 1897 Bldg., Midland MI 48664

As both a reactor for gas phase ion/molecule reactions and as a sensitive mass analyzer, the quadrupole ion trap mass spectrometer has proven to be a versatile tool for the qualitative and quantitative analysis of volatile organic compounds. The sensitivity of ion traps and the ability to efficiently dissociate ions in tandem experiments, has increased the value of these instruments. Recent developments in ion trap technology have allowed injection of externally formed ions into an ion trap for reaction and mass analysis. (1) Ions generated via electron-impact ionization or desorption ionization have been successfully trapped.

Cs⁺ desorption ionization offers a versatile method for the analysis of biological compounds. Figure 1 illustrates the instrumentation. A Cs⁺ ion gun is used to ionize either solid samples or samples dissolved in a liquid matrix. The pulsed extractor lens allows Cs⁺ projectile ions to desorb sample from a probe as a pulsed ion beam. Figure 2 shows a spectrum of 200 pmol of a peptide (in 1:1 thioglycerol:glycerol) with the sequence: Lys-Pro-Ala-Glu-Phe-(4-NO₂)Phe-Arg-Leu. Both fragment ions and matrix ions are observed in the spectrum obtained by using axial modulation. (2) An alternative method of ion injection is illustrated in Figure 3. Ions of a selected mass are introduced into the hybrid instrument of a BET (BE/ion Trap) configuration. (3) Figure 4 illustrates the FAB mass spectrum of leucine-enkephalin injected with 50 eV energy into the ion trap. Lower injection energies yield less fragmentation of the peptide.

Yet another application of ion injection into an ion trap is the interfacing of a thermospray (TSP) source. The weaknesses of TSP, such as relatively poor sensitivity for some compounds, poor quantitative capabilities and a strong dependence on experimental parameters should be alleviated by accumulating ions in a trap over a period of time. The instrument, shown in figure 5, utilizes a large vacuum cradle to allow alignment of the trap with a Finnigan TSP source. Two turbomolecular pumps, 550 L/sec and 170 L/sec, are used to keep an operating pressure of 2×10^{-4} torr at an effluent rate of 0.5 ml/min. The vaporized effluent is differentially pumped using a cold trap and a roughing pump. The ions are generated by discharge ionization and are injected into the ion trap using a gated lensing system. Figure 6 illustrates a TSP mass spectrum of 100 ppm phenylalanine dissolved in 80:20 methanol:water. Solvent cluster ions are observed at masses below 100 Da. An I/M product, methylated phenylalanine, is observed at m/z 180; however, at lower injection times, the relative abundance of the I/M product is decreased. Figure 7 is a second example of a TSP generated mass spectrum. Adenosine, again dissolved in 80:20 methanol:water, shows only slight fragmentation.

One problem with ion traps is the limited number of ions which can be trapped without loss in sensitivity and resolution. As observed in Figures 6 and 7, injection of solvent ions causes "space charging" of the trap, thereby decreasing the sensitivity of the system. Methods to eliminate space charging due to the solvent are required. Resonant ejection of solvent ions is possible by applying a supplementary AC voltage to the endcap electrodes during injection in resonance with the solvent ions.

MASS SPECTROMETRIC INSIGHTS INTO BIOLOGICAL REDOX REACTIONS

Kevin J. Volk, Anna Brajter-Toth, and Richard A. Yost
University of Florida, Department of Chemistry
Gainesville, FL 32611

The on-line combination of enzymes and electrochemistry can provide valuable insight into the metabolic and degradation reactions. The sensitivity of mass spectrometry and the time resolution of an on-line system allows the detection of intermediates and products formed during enzymatic and electrochemical (EC) redox reactions. Since metabolism and degradation processes often involve redox reactions, electrochemical methods can provide insight into these processes. The electrochemical and enzymatic oxidation pathways of a model compound, uric acid, were determined by on-line thermospray/tandem mass spectrometry (TSP/MS/MS). In addition, the electrochemical oxidation pathway of 6-thiopurine, a potent antineoplastic agent, was also investigated.

The products and intermediates formed as a result of electrooxidation of uric acid were monitored as the electrode potential was varied. As can be seen in Figure 1, electrooxidation of uric acid generates a highly reactive diimine which can undergo a hydration reaction to form the imine alcohol (MW 184) or an amination reaction to form the imine amine (MW 183). Tandem mass spectrometry was used to characterize these intermediates and provides convincing evidence that the primary intermediate produced during both the enzymatic and electrochemical oxidation of uric acid has a quinonoid diimine structure.

By coupling an enzyme column on-line with TSP/MS, products and intermediates formed as a result of the enzymatic oxidation of can be monitored as the enzyme-substrate reaction time is varied. In the enzymatic oxidation of uric acid with peroxidase and H_2O_2 , the same intermediates and products were observed as in the electrochemical oxidation. The TSP/MS information obtained using an on-line high pressure enzyme reactor indicates that the electrochemical and horseradish peroxidase catalyzed oxidations of uric acid proceed by similar, if not identical, chemical mechanisms. Figure 2 illustrates the negative ion mass spectra of the electrochemical and enzymatic oxidation intermediates and products obtained when the uric acid substrate residence time in the reactor is ca. 1 min. Comparison of the mass spectra obtained from the peroxidase-catalyzed and the electrochemical oxidation of uric acid shows that the intermediates and products formed in the enzymatic oxidation are the same as those formed in the electrochemical oxidation. Most importantly, the results show that the on-line combination of electrochemistry with thermospray/tandem mass spectrometry provides otherwise difficult to obtain information about redox and associated chemical reactions of biological molecules such as the structure of reaction intermediates and products, as well as providing insight into reaction pathways.

The compound 6-thiopurine (6-TP) is known to be extensively metabolized along several routes such as the transformation to its nucleotide and nucleoside. However, Hyslop and Jardine have recently described a previously unknown oxidation pathway of 6-TP which involves activation by cytochrome P-450 with subsequent binding to protein via mixed disulfide bonds (Figure 3).

Using EC/LC on-line with UV-VIS spectrophotometry and mass spectrometry, we have determined that at potentials $> +0.50$ V vs Pd the thiol group of 6-TP can be oxidized to purine-6-sulfinic acid (RSO_2H), purine-6-sulfinamide (RSO_2NH_2), and purine-6-sulfonic acid (RSO_3H). Figure 4 illustrates the on-line EC/LC chromatogram of the oxidation products of 6-TP at $+0.90$ V with UV-VIS detection. Since solution-phase reactions are responsible for producing both RSO_2NH_2 and ROH (hypoxanthine) which form only during electrooxidation of 6-TP at potentials $> +0.50$ V, these products must be the result of either hydrolysis or amination reactions with a very reactive intermediate such as a sulfinic acid ($RSOH$). Since RSO_2H has been identified, it is reasonable to assume that once $RSOH$ is formed via a direct two electron transfer reaction, it could be easily oxidized at these potentials to RSO_2H . Although this reaction is a net four-electron oxidation process, only a direct two-electron transfer mechanism is required to form the primary electrochemical intermediate, $RSOH$ (Figure 5). The fact that disulfide production still occurs at potentials $> +0.50$ V supports this theory of a competing two-electron reaction mechanism at higher potentials.

MASS-FLOW ENHANCEMENT APPROACHES IN LC/MS

J. van der Greef^{1,2}, W.M.A. Niessen² and U.R. Tjaden²

1. TNO-CIVO Institutes, P.O. Box 360, 3700 AJ Zeist, The Netherlands
2. Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

The coupling of liquid chromatography and mass spectrometry (LC/MS) has been effectuated by various interface approaches and has proven to be a powerful tool in the analytical laboratory.

The characteristics of the various interfaces are quite different with respect to the possibility of applying conventional HPLC systems. However, since the mass spectrometer is a mass-flow sensitive detector all approaches can benefit from mass-flow enhancement techniques. The general formula for the mass-flow is given by :

$$dm/dt = C(t) F$$

where $C(t)$ is the concentration profile of the analyte after the chromatography, and F is the flow-rate of the mobile phase.

In principal, two approaches are possible in mass-flow enhancement, i.e. concentration enhancement by peak compression (A) and flow-rate programming (B).

A. Peak compression by Phase-System Switching.

"Phase-System Switching" (PSS) is based on a simplified column switching system allowing trapping, concentration and flow-rate adaption on the second column. Besides the compatibility improvement of LC/MS by PSS it was found that peak compression can be obtained. These effects were observed in (a.o.) the analysis of metoprolol enantiomers in plasma using Thermospray and for dextromethorphan detection with continuous-flow FAB.

In the case of metoprolol the chromatographic separation was optimized using an al-acid-glycoprotein chiral stationary phase and a 20 mmol/l phosphate buffer, while after trapping and peak compression 20% methanol in 50 mmol/l ammonium acetate was used for the thermospray-MS/MS experiments. For each enantiomer a detection limit of 37 pmol could easily be obtained.

B. Mass-flow programming.

An other approach in mass-flow programming can be realized by increasing the mass flow after chromatography. This can be achieved in various ways, of which belt speed programming using a moving belt interface is an example. Another approach, applicable with miniaturized chromatographic columns is the following: The system comprises of a trapping loop after the miniaturized chromatographic

system operated at flow-rates of about 10 $\mu\text{l}/\text{min}$. After trapping the peak(s) of interest in the loop the introduction of the analyte(s) is performed by flushing the loop with a flow rate of 1.5 ml/min into a Thermospray source. The experimental setup and the results for the betablocker metoprolol are given in Figure 1.

High performance alkaline anion exchange liquid chromatography (HPAELC) provides efficient separation of saccharide positional isomers and epimers which is not always possible with more conventional normal or reverse phase HPLC techniques. Unfortunately HPAELC presents special challenges for its direct interfacing to mass spectrometry, primarily removal of non-volatile mobile phase salts. We are currently evaluating several interfaces to combine HPAELC with MS for carbohydrate analyses. One of the most challenging is the direct coupling of HPAELC to thermospray MS (TSP MS). We have successfully constructed an on-line interface between HPAELC and TSP MS. Using a dialysis membrane, or suppressor, between the HPAELC column outlet and the TSP MS inlet permits removal of non-volatile components (i.e. NaOH) from the chromatographic mobile phase after the separation is performed and prior to entrance into the TSP MS source. Thus the chromatograph and mass spectrometer may be operated somewhat independently of each other. Our work has shown nearly 100% removal of Na⁺ from the mobile phase by the suppressor. Figure 1 illustrates the on-line total ion chromatogram for the isocratic separation of N-acetylglucosamine (GlcNAc), N-acetylmannosamine (ManNAc) and N-acetylglucosamine (LacNAc) obtained using the integrated HPAELC/TSP MS system. A polymeric anion exchange column and a 10 mM NaOH mobile phase were used to achieve the separation.

Figure 1. HPAELC/TSP MS total ion chromatogram of isocratically eluted N-acetylated sugars GlcNAc, ManNAc, and LacNAc.

Conventional direct injection (i.e. no column) TSP mass spectra of various N-acetylated sugars were shown to be similar to those obtained with the integrated HPAELC/TSP MS system. Figure 2 compares the TSP mass spectrum of GlcNAc obtained by direct injection to that obtained on-line by isocratic elution through the HPAELC/TSP MS system. The spectra are very similar, with the protonated molecular ion appearing at m/z 222.

Figure 2. Comparison of GlcNAc TSP mass spectra obtained by direct injection and isocratic elution from the interfaced HPAELC/TSP MS system.

In addition to isocratic chromatographic separations the HPAELC/TSP MS system is also capable of operating in the gradient elution mode, thus reducing the time required for the chromatographic separation to be completed. The total ion chromatogram for a sodium hydroxide gradient separation of GlcNAc, ManNAc, and LacNAc is shown in Figure 3.

Figure 3. HPAELC/TSP MS total ion current chromatogram for a sodium hydroxide gradient separation of GlcNAc, ManNAc, and LacNAc.

The on-line gradient mass spectra are similar to those obtained with isocratic elution, but with an increase in intensity due to higher analyte concentration in the chromatographic bands due to peak compression caused by the gradient profile. Sensitivity studies were conducted using a mixture of the three N-acetylated sugars listed above. The results demonstrated the ability of the interfaced HPAELC/TSP MS system to provide minimum detection limits in the microgram range.

DEVELOPMENTS IN SUPERCRITICAL FLUID CHROMATOGRAPHY MASS SPECTROMETRY

W.M.A. Niessen¹, E.R. Verheij^{1,2}, R.A.M. van der Hoeven¹, U.R. Tjaden¹ and J. van der Greef^{1,2}

1. Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.
2. TNO-CIVO Institutes, P.O. Box 380, 3700 AJ Zeist, The Netherlands.

Introduction

Supercritical fluid chromatography (SFC) and its on-line coupling with mass spectrometry (SFC/MS) is now a well-established analytical tool in various application areas, e.g. polymer- and petrochemistry. In the last two years significant progress has been made in the field of bioanalytical applications of SFC and SFC/MS [1]. In bioanalysis several problems are encountered, e.g. the limited sample loadability of the capillary SFC columns, the detrimental effects of the free silanol groups in the analysis of polar compounds with packed column SFC, and the relatively (compared to LC) small injection volumes. Furthermore, the injection of aqueous solutions in SFC is prohibited. Other polar solvents may upon injection dramatically influence the retention characteristics of the SFC system, which will especially be a problem in the analysis of pretreated real samples.

Experimental

Packed column SFC and SFC/MS experimental were performed with a laboratory built SFC system, described in detail elsewhere. A Finnigan MAT HSEQ-30 hybrid mass spectrometer equipped with a moving belt interface, or a Finnigan MAT TSQ-70 mass spectrometer equipped with a thermospray interface were used.

Results and discussion

In order to enable the direct analysis of aqueous samples from biological origin (and in environmental analysis as well), a valve switching approach was developed, which is based on the pre-column technology designed for LC [2]. The analytical procedure, called 'phase-system switching' consists of the following three steps, schematically depicted in figure 1: First, the aqueous sample is injected onto a short pre-column, either directly or in a stream of water. Next, the pre-column is washed to remove water soluble constituents and dried with preheated gas to remove the excess of water. Finally, the pre-column is switched in a stream of a supercritical fluid, which desorbs the analytes of interest, transfers them to an analytical packed SFC column, where separation takes place. Detection is performed with either UV or MS. This approach has been applied in the analysis of diuron in plasma using a moving belt interface [3], and of the cytostatic drug mitomycin C (MW 334), using a thermospray interface (see figure 2).

The phase-system switching approach in SFC and SFC/MS has several interesting features. Not only a change in the phase-system from aqueous solutions to a supercritical mobile phase is accomplished, also preconcentration and on-line sample pretreatment, both based on the solid-phase isolation technique used, are achieved.

Figure 1: Schematics PSS approach. Figure 2: PSS-SFC/MS of Mitomycin C in plasma

Packed column SFC/MS can be performed with either a moving belt interface giving EI or CI spectra, or a thermospray interface, in which the vaporizer capillary is used as the back-pressure restriction. Applying the thermospray ion source in the discharge-on mode it is possible to alter the ionization conditions by changing the potential at the repeller electrode, which is positioned opposite to the sample cone in our Finnigan MAT thermospray source. At low repeller potential and a mobile phase containing 2-15% of methanol as an organic modifier proton transfer CI spectra are observed, resulting in hardly any fragmentation, while at high repeller potentials charge exchange type of spectra are obtained, showing considerable fragmentation. By choosing an appropriate repeller potential it is possible to get either a strong protonated molecule for quantitation or fragmentation for identification. These effects are clearly demonstrated in figure 3 by the spectra of caffeine, obtained at two different repeller potentials.

Figure 3: Thermospray SFC/MS spectra of caffeine at two repeller potentials

OPTIMIZATION AND APPLICATION OF PARTICLEBEAM HPLC/MS
FOR COMPOUNDS OF PHARMACEUTICAL INTEREST

R.D. Voyksner, P.C. Knox, and C.S. Smith

Analytical and Chemical Sciences, Research Triangle Institute,
P.O. Box 12194,
Research Triangle Park.. NC 22709

HPLC/MS plays an important role in pharmaceutical research. The particlebeam (PB) HPLC/MS interface allows the acquisition of EI and CI spectra for structural elucidation, making particlebeam HPLC/MS technique very powerful for identification of unknowns. PB sensitivity, as with most HPLC/MS techniques, is dependent on the HPLC and interface operating parameters. This presentation evaluates various particlebeam interface conditions, HPLC conditions and MS conditions to determine their effect on sample sensitivity. Furthermore, EI and CI spectra generated by particlebeam were compared to thermospray to help determine the role each interface plays in pharmaceutical analysis.

The main variables in the particlebeam interface are the nebulizer position, desolvation temperature, and nebulizer helium flow rate. The nebulizer position is a critical parameter in the interface that requires adjustment to achieve optimum sensitivity. The particlebeam interface uses a coaxial nebulizer where a 100 μ M fused silica capillary can be moved towards or away from the nebulizer orifice in a helium stream to optimize aerosol formation. The optimization of the nebulizer position using a methanol HPLC mobile phase showed two maxima for spectinomycin response. The major maximum was at the position where the capillary tip was retracted 0.52 mm from the nebulizer tip. This position provides an aerosol formation that results in the best mass transport for the chosen solvent/solute system under the existing desolvation conditions. This position can vary for various HPLC solvents, but was close to the optimum distance ($\pm 10\%$) for most compounds tested. Varying the desolvation temperature between 30-70°C did not change the total ion current by more than 15% when using a methanol mobile phase (Figure 3). Operating with high percentages of aqueous solvent or at flow rates above 0.6 mL/min required the desolvation temperature to be increased to maintain sensitivity. Higher desolvation temperatures are needed at higher flow rates or with solvents with large ΔH_{vap} to replace heat lost by adiabatic expansion (evaporation).

The helium flow rate into the nebulizer affects sensitivity and the position the fused silica capillary in the nebulizer. For a fixed capillary position in the nebulizer, changes in the helium flow rate can change signal level. Comparable signals (within 20%) could be achieved at other helium flow rates if the capillary position in the nebulizer was reoptimized. The best overall sensitivity was achieved using higher helium flow rates with the fused silica tube in the nebulizer optimized for the helium flow employed.

HPLC conditions including solvent choice, buffer choice and flow rate play an important role in particlebeam operation. The particlebeam interface sensitivity varied with different reversed-phase HPLC solvents. Particlebeam sensitivity was optimal when using a high percentage of organic in the mobile phase. Sensitivity decreased as the percentage of water increased, indicating particlebeam sensitivity would vary across a HPLC gradient. It is important to note that the optimal position of the fused silica tube in the nebulizer varied with the HPLC solvents chosen. The change in solvent from methanol to water increases the surface tension/density ratio resulting in the formation of larger droplets. The desolvation of these larger droplets becomes more difficult due to size and the greater heat capacity of water over methanol. It is interesting to note that the order in sensitivity (methanol>acetonitrile>isopropanol>water) is inversely related to the heat capacity of the solvents.

The use of buffers in the particlebeam interface was not required, but volatile buffers can be employed to achieve a desired separation. Three volatile buffers, including ammonium acetate, acetic acid, and ammonium hydroxide, did not play a role in particlebeam sensitivity.

HPLC flow rate is another variable in particlebeam performance. The interface operates best at low flow rates 0.2-0.6 mL/min when using low boiling point solvents such as methanol. Increasing the aqueous content of the solvent further restricted the upper HPLC flow rate even when the desolvation temperature was raised to 70°C.

The source temperatures played a role in the signal response observed in particlebeam MS. Since the particlebeam interface currently relies on gas phase ionization techniques,

it is not surprising that the best responses were obtained at high source temperatures when particularly the lack of volatility for many pharmaceuticals is considered. However, it is not always possible to analyze a compound at the highest temperatures due to thermal decomposition. For these reasons spectra are usually acquired at source temperatures between 200-300°C.

The analysis of a variety of compounds (including β -lactams, cephalosporins, tetracyclines, methylene blue, furosemide, spectinomycin, cytidine, 2-chloro-4-nitrobenzamide, and thiamine) was possible using the particlebeam interface. The success of particlebeam MS under EI conditions relates to compound stability and volatility. Samples that are thermally unstable or nonvolatile would be best analyzed under particlebeam CI conditions or thermospray HPLC/MS. Thermospray/MS proved to be the best method for the analysis of the β -lactams, cephalosporins, and cytidine. The thermospray spectra exhibited $[M+H]^+$ ions as well as structurally important fragments. The analysis of more stable or volatile compounds (thiamine, methylene blue, 2-chloro-4-nitrobenzamide, spectinomycin and furosemide) proved inadequate by thermospray since only $[M+H]^+$ ions and one or two simple fragment ions were detected, insufficient for validation (Table I).

This research was supported by the Health and Human Services of the Food and Drug Administration under Cooperative Agreement No. FD-U-000244-01.

INTERMEDIATE TERM STABILITY OF ION INTENSITIES AND
ELECTRON IMPACT MASS SPECTRA WITH PARTICLE BEAM
LIQUID CHROMATOGRAPHY MASS SPECTROMETRY SYSTEMS

Thomas A. Bellar, Thomas D. Behymer, and William L. Budde

U. S. Environmental Protection Agency
Office of Research and Development
Environmental Monitoring Systems Laboratory
26 West M. L. King Drive, Cincinnati, OH 45268

With the development of several types of particle beam interfaces for high performance liquid chromatography/mass spectrometry (HPLC/MS) systems, a new approach has emerged for the determination of compounds (nonvolatiles) not amenable to capillary column gas chromatography mass spectrometry (GC/MS). Two critical issues are the stabilities of integrated ion intensities over a minimum of an eight-hour period, and the relative stabilities and reproducibilities of the electron impact (EI) mass spectra over a similar time period. Ion intensity stability over a minimum of an eight-hour period is required so that concentration calibrations maintain validity for a reasonable number of samples. Similarly, EI spectra must be relatively stable to permit automatic peak identifications via reverse search algorithms and spectra from reference data bases.

Stabilities of signal intensities and EI spectra over two-day periods were studied for sixteen compounds shown below that are not amenable to GC/MS (nonvolatiles).

Compound Name	MW	Compound Class	Capillary Col. GC Status
aldicarb sulfone	222	carbamate (S)	no peaks
carbaryl	201	carbamate	decomp.
carbofuran	221	carbamate	decomp.
methiocarb	225	carbamate (S)	decomp.
methomyl (Lannate)	162	carbamate (S)	no peaks
mexacarbamate (Zectran)	222	carbamate	decomp.
o-chlorophenyl thiourea	186	N-substituted thiourea	decomp.
diuron	232	N-substituted urea (Cl)	no peaks
ethylene thiourea	102	N-substituted thiourea	no problem
linuron (Lorox)	248	N-substituted urea (Cl)	decomp.
N-(1-naphthyl)thiourea	202	N-substituted thiourea	no peaks
siduron	232	N-substituted urea	no peaks
benzidine	184	aromatic diamine	marginal
3,3'-dimethoxybenzidine	244	aromatic diamine	marginal
3,3'-dichlorobenzidine	252	aromatic diamine	marginal
rotenone	394	natural product	no peaks
DFTPP	442	the greatest	perfect

Experiments were conducted with two commercial particle beam HPLC/MS systems: (1) a Hewlett-Packard (HP) system consisting of an HP model 1090 HPLC, an HP particle beam interface, and an HP model 5988 mass spectrometer; and, (2) a system consisting of a Waters PB 600 MS HPLC, an Extrel Thermabeam interface, and an Extrel ELQ 400-1 mass spectrometer.

Other equipment and operating conditions were the same on both systems. All HPLC injections were made with autoinjectors. The HPLC column was a Waters Bondapak 30 cm x 2 mm (id) packed with 10 micron silica particles with octadecyldimethylsilyl (C-18) groups chemically bonded to the silica surface. Supelco LC-18 or DuPont C-18 guard columns were used to protect the analytical column. The mobile phase was a mixture of acetonitrile and water containing 0.01 M ammonium acetate. The solvent composition was held for one minute at 30% acetonitrile, then programmed to 100% acetonitrile in 29 minutes. Injection size was 5 μ L and the flow rate 0.4 mL/minute. The ion source temperature was 250 $^{\circ}$ C, and the electron energy 70 eV. The mass spectrometers were repetitively scanned from 62-450 amu at 1.5 seconds/scan which gave at least 10 scans per HPLC peak.

All mass spectrometric data acquired was from injections of the 16 compound mixture into the HPLC analytical column, and injections without the analytical column were used only for preliminary tuning of the instrument systems.

Compound Name	System A		System B	
	Rel. Resp. (RSD)		Rel. Resp. (RSD)	
aldicarb sulfone	0.12	(14)	0.15	(7.0)
carbaryl	0.19	(8.8)	0.18	(14)
carbofuran	0.06	(6.4)	0.07	(18)
methiocarb	0.11	(8.5)	0.08	(17)
methomyl (Lannate)	0.03	(11)	0.04	(15)
mexacarbate (Zectran)	0.04	(14)	0.07	(23)
o-chlorophenyl thiourea	0.23	(10)	0.30	(12)
diuron	1.00	(12)	1.00	(26)
ethylene thiourea	0.37	(8.2)	0.59	(17)
linuron (Lorox)	0.02	(21)	0.02	(22)
N-(1-naphthyl)thiourea	0.11	(11)	0.31	(8.6)
siduron	0.86	(8.3)	0.60	(26)
benzidine	0.22	(7.4)	0.53	(10)
3,3'-dimethoxybenzidine	0.31	(8.1)	0.51	(18)
3,3'-dichlorobenzidine	0.39	(7.0)	0.47	(23)
rotenone	0.09	(9.4)	0.10	(15)

The relative responses shown above are for the integrated abundances of the quantitation ions over the HPLC peak. The quantitation ions were the base peaks in the EI spectra above mass 62. The relative standard deviations (RSD) were calculated from the means of the responses for 10-14 injections into the HPLC column over two working days. The amounts of each compound injected were 0.385-1.53 μ g.

Incorporation of MS/MS Detection for the Characterization of Peptide Digests
by Continuous Flow FAB LC/MS

B.L. Ackermann, T.-M. Chen, and J.E. Coutant

Merrell Dow Research Institute, Cincinnati, OH 45215

The use of continuous flow FAB (CF-FAB) as an interface for capillary HPLC has made possible the analysis of peptide mixtures at picomole levels. As utilization of this technology grows, there is a need to investigate the advantages of MS/MS detection. Traditionally, MS/MS has been used to increase either the selectivity or structural content of MS analyses. The latter application would be useful for confirming assignments given to peptides based on molecular weight; particularly when post-translational modifications are present or if non-specific enzymes are used. Ultimately, LC-MS/MS should be investigated as a means for increasing the efficiency of peptide sequencing by tandem MS.

As a starting point for these investigations, trypsin and chymotrypsin digests of glucagon (290 pmol) were analyzed by LC-MS/MS using capillary CF-FAB. In each case, daughter ion spectra were recorded for the major hydrolysis products observed in the LC/MS profiles. Although the entire sequence for glucagon was not verified, sequence ions which supported the proposed assignments were present in the daughter spectra of each digestion product examined. In the example involving chymotrypsin, evidence for trypsin cleavage of chymotryptic digestion products was obtained using MS/MS.

The system developed for capillary LC/MS incorporated the following features: gradient elution, on-line UV detection, and coaxial post-column matrix addition. Separation was performed using a (25cm x 0.320mm i.d.) fused silica column, slurry-packed in-house with 5 μ m Spherisorb ODS particles, at a flow rate of 2 μ L/min. The matrix-containing solution (ACN:H₂O:glycerol:thioglycerol, 4:2:1:1) was added post-column at a flow rate of 1 μ L/min. The entire eluent (3 μ L/min) was transferred to a VG ZAB2-SE double focusing mass spectrometer using the probe supplied by the manufacturer. Daughter ion spectra were recorded using B/E linked scanning at a parent ion attenuation to 30% with helium.

Figure 1 displays the UV and total ion profiles from the LC/MS analysis of 290 pmol glucagon (trypsin digest). A linear gradient from 5 to 60% ACN in water (0.1% TFA) was performed over 30 min. The data indicate a total analysis time of less than 40 min. and that the chromatographic integrity was preserved by the CF-FAB interface. The sequence of glucagon, indicating the observed sites of hydrolysis, is shown in Figure 2. Despite the relative simplicity of this mixture, only 3 of the 4 tryptic peptides were detected by direct FAB analysis. The profiles in Figure 1 indicate that all 4 tryptic peptides were separated and detected. In addition, evidence for a minor chymotrypsin cleavage product: T_{3c} (MH⁺ 1162) was also obtained from the analysis.

In a subsequent analysis, daughter ion spectra were acquired for each of the 4 tryptic fragments identified by LC/MS. Figure 3 shows a single daughter ion scan recorded for tryptic fragment T₃ (MH⁺ 1352). Nearly complete sequence information was obtained (290 pmol injected). These results indicate the ability to acquire satisfactory daughter spectra from subnanomole quantities of peptides in mixtures using capillary CF-FAB and encourage further work in this area.

We have recently reported the design of a coaxial continuous flow-fast atom bombardment interface in which the analytes and the FAB matrix are independently delivered to the probe tip (1,2). Briefly, the coaxial CF-FAB interface consists of a fused silica column (typically 10 μm id) which is surrounded by a second fused silica column (typically 150 μm id) in which the FAB matrix is introduced. As a result, there is no mixing of the matrix with the analytes until both have reached the FAB probe tip. This coaxial continuous flow design is advantageous since the chromatography is not affected by the matrix. In addition, the ability to independently control both the OTLC flow rate and the matrix flow rate and composition is desirable. We have also adapted this coaxial design for use as a coaxial capillary zone electrophoresis/FAB interface (3).

In this paper, we demonstrate the ability to obtain on-the-fly (i.e. chromatographic real time) MS/MS spectra of biomolecules as they elute from the capillary column. MS/MS spectra of the $(M + H)^+$ ion of the tripeptide Met-Leu-Phe were acquired on-the-fly from a 220 pg injection (Fig. 1) as well as a 22 pg injection. The mass spectrometer was scanned at 3 sec/dec resulting in a total acquisition time of 2 seconds. The $(M + H)^+$ ion for m/z 410 fragments into the common backbone cleavages of A_2 , B_2 , and Y_2 as shown.

This coaxial CF-FAB interface is equipped with an injection system such that a continuous flux of analyte solution can be introduced into the mass spectrometer over extended periods of time (i.e. hours) as well as over short time periods (i.e. seconds). The MS/MS spectra of a variety of compounds, including peptides, sugars, phospholipids, fatty acids, and steroids, have been obtained using the coaxial CF-FAB interface to deliver a constant flux of analyte. This constant flux of analyte can be advantageous for the acquisition of collisionally activated decomposition spectra that may be otherwise cumbersome (e.g., MS/MS/MS spectra). The MS/MS/MS spectrum of the tetrapeptide, Phe-Gly-Leu-Met-NH₂, is shown in Fig. 2 and is representative of 500 ng of material. Upon CA, the $(M + H)^+$ of m/z 466 fragments to give the ion of m/z 318 which corresponds to the loss of HMetNH₂. In the MS/MS/MS experiment, the ion of m/z 318 fragments to give the loss of CO and the Leu residue (fragment B_2). The daughter ion of m/z 119 (fragment A_1) corresponds to the loss of CO from the Phe residue.

Using a packed microcapillary (50 μm id packed with 10 μm particles), the separation of a mixture of Met-enkephalin (2 picomoles) and Met-Leu-Phe (3 picomoles) was obtained. As the analytes were eluting from the column, their MS/MS spectra were acquired (Fig. 3) while scanning the mass spectrometer at 5 seconds/decade. Fragmentations resulting from typical backbone cleavages were observed for both of the analytes studied.

The coupling of capillary zone electrophoresis with mass spectrometry has recently become an area of increased interest. The primary advantage of capillary zone electrophoresis over liquid chromatography is the much superior separation efficiencies which can be obtained with CZE. Using the coaxial continuous flow-FAB interface, we have developed an on-line coaxial continuous-flow capillary-zone electrophoresis/FAB interface. The design is such that active electrophoretic transport of the analytes directly to the FAB probe tip occurs. Since a transfer line from the end of the CZE capillary to the probe tip is obviated, no zone broadening that would otherwise occur is observed. The electrophoretic separation of mixtures of peptides has been obtained. For example, a mixture of proctolin and Met-

Leu-Phe was obtained and as the Met-Leu-Phe was eluting from the CZE column, the $(M + H)^+$ ion was collisionally activated. The MS/MS spectrum which was acquired is shown in Fig. 4 and corresponds to 130 femtomoles of the tripeptide.

SURFACE-CATALYZED REACTIONS OF AROMATIC AMINES
WITH OXYGEN AND NITROGEN IN NICI MASS SPECTROMETRY*

Elizabeth A. Stemmler and Michelle V. Buchanan

Bowdoin College, Brunswick, ME 04011
Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6120

In previous studies it was found that the O_2/N_2 negative ion chemical ionization (NICI) mass spectra of polycyclic aromatic hydrocarbons (PAH) and methyl-substituted PAH showed unusual ions that could not be explained by simple electron-molecule (1) or ion-molecule (2-4) reactions. These unusual ions dominate the O_2/N_2 NICI mass spectra when the ion source temperature is elevated to 300°C, are observed under positive CI conditions, and exhibit characteristic tailing ion chromatograms when gas chromatography is used for sample introduction. Recent studies [Org. Mass Spectrom. 24, 94-104 (1989)] indicate that these ions result from surface-catalyzed oxidation reactions followed by electron-capture ionization (reaction 5).

Under similar conditions, unusual ions appearing at $[M+11]^{\bullet -}$ and $[M+14]^{\bullet -}$ were observed in the spectra of amino-substituted aromatics such as 1- and 2-aminonaphthalene and 1- and 2-aminoanthracene. These ions were also enhanced when the ion source temperature is elevated, were observed under positive CI conditions, and exhibited tailing ion chromatograms, which suggested that they were also formed by reaction (5). Studies to ascertain the identity of these ions were carried out using Fourier transform mass spectrometry (FTMS). The $[M+11]^{\bullet -}$, $[M+14]^{\bullet -}$, and an additional ion at $[M+13]^{\bullet -}$ were observed when the FTMS cell temperature was elevated to approximately 200°C. Exact mass measurements indicated that the ion at $[M+14]^{\bullet -}$ corresponds to $[M+O-2H]^{\bullet -}$, while the ions at $[M+11]^{\bullet -}$ and $[M+13]^{\bullet -}$ correspond to $[M+N-3H]^{\bullet -}$ and $[M+N-H]^{\bullet -}$, respectively.

The ion at $[M+14]^{\bullet -}$ was further studied using a quadrupole instrument equipped with a chemical ionization source. Both O_2 and $^{18}O_2$ were added to the N_2 reagent gas. The $[M+14]^{\bullet -}$ ion was significantly enhanced by the addition of O_2 , and an ion at $[M+16]^{\bullet -}$ was observed upon addition of $^{18}O_2$. These observations support the $[M+O-2H]^{\bullet -}$ assignment made using FTMS. Additional studies using aniline- ^{15}N and aniline-2,3,4,5,6- d_5 indicated that the $[M+O-2H]^{\bullet -}$ ion results from oxygen addition at the amino nitrogen to produce a nitroso group.

The ions at $[M+11]^{\bullet -}$ and $[M+13]^{\bullet -}$ were also studied to determine the source of added nitrogen. On the quadrupole instrument the $[M+11]^{\bullet -}$ ion was much more intense than the $[M+13]^{\bullet -}$ ion. It was found that the intensity of the $[M+11]^{\bullet -}$ ion increased as a function of % N_2 when argon was used as the buffer gas. These results, in conjunction with experiments using aniline- ^{15}N indicated that the nitrogen reagent gas, not the amino group, was the source of nitrogen in the $[M+N-3H]^{\bullet -}$ ions. Measurements of the spectra of aniline- ^{15}N and aniline-2,3,4,5,6- d_5 indicated the nitrogen addition occurred in conjunction with loss of the two amine hydrogens and one ring hydrogen.

The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. DE-AC05-84OR21400. Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U.S. Government purposes.

Examination of the spectra of various methyl-substituted anilines indicated the the $[M+N-3H]^+$ ion was not observed when two methyl groups were substituted ortho to the amine group. This result suggested that a site ortho to the amine group was needed for nitrogen addition. The resulting $[M+N-3H]^+$ product may correspond to a ring-opened dicyano compound (see Scheme 1). This hypothesis is based upon the documented lead tetraacetate oxidation of ortho-substituted diaminoaromatics. For example, the spectra of 1,2-diaminoanthraquinone shows an $[M-4H]^+$ ion, which is not observed in the spectrum of the corresponding 1,4-isomer (see Scheme 2). The $[M-4H]^+$ ion is also observed in the spectra 2,3- and 3,4-diaminotoluene (ortho-substituted diamines), but not in the spectra of the 2,4- or 2,6-diamino isomers (meta-substituted diamines).

In conclusion, these experiments indicate that the O_2/N_2 NICI mass spectra of aromatic amines show unusual ions that result from surface-catalyzed oxidation reactions with both oxygen and nitrogen prior to ionization. The products of these reactions are enhanced by elevated ion source temperatures, show tailing ion chromatograms, and are observed under positive chemical ionization conditions. Certain ions can be used to differentiate diamino and methyl-substituted aminoaromatics.

IONIZATION EFFICIENCY IN AN ELECTROSPRAY SOURCE

S. F. Wong and J. B. Fenn
Department of Chemical Engineering
Yale University, New Haven CT 06520-2159

In evaluating the analytical sensitivity of a mass spectrometer system one would like to know the overall efficiency with which analyte molecules entering the system actually contribute to the output signal. In other words, what fraction of those molecules end up as ions at the detector. That overall efficiency is the produce of two major components: the fraction of analyte molecules that become transformed into ions in vacuo and the fraction of those ions entering the vacuum system that finally reach the detector. We report here on the first of these components, the effectiveness with which an Electrospray (ES) ion source transforms injected analyte molecules into ions in vacuo.

Figure 1 shows the essential features of the apparatus. The ES source has been previously described. (1) It produces a dispersion of ions in bath gas at atmospheric pressure. Some of that ion-containing bath gas enters an orifice or a glass capillary tube and emerges as a supersonic free jet expanding into a vacuum system. The glass capillary tube was used this work because it provides design flexibility and decreased exposure to the hazards of high voltage. The total ion current leaving the capillary was measured by intercepting the entire free jet flow with a Faraday cup connected to ground through a picoammeter. Because we were interested in how the ionization efficiency depended on analyte molecular weight measurements were made with a series of poly ethyleneglycols (PEGs) whose average molecular weights ranged from 200 to 17,500. Samples comprised about 11 μ L of a solution of PEG at concentrations of 0.1 or 0.05 μ g/ μ L in 50-50 methanol-water. They were injected into a steady 3.5 μ L/min flow of the same solvent entering the ES source.

The gross current I_g due to PEG ions reaching the Faraday cup was taken as the the peak value of the free jet current reached after sample injection. MS studies had shown that the presence of PEG suppresses the formation of ions from smaller solvent and solute molecules so there was no need to subtract a "background" current that was measured when only solvent was flowing. It seems highly unlikely that all the PEG molecules in a charged droplet are desorbed as molecular ions. Therefore, each droplet must leave behind some residue that includes any undesorbed PEG as well as any charge left on the droplet after individual ions stop desorbing. It is important to determine the contribution of these charged residues and subtract it from the total ion current I_g in order to arrive at In the net current due to ions that are charged individual molecules. We determined that contribution by applying a retarding potential V_r to the ions en route to the Faraday cup.

In principle it is possible to determine this fraction from an I_g - V_r curve. Alternatively, because the charged residues have lower mobility than the individual molecular ions it is possible to adjust the countercurrent bath gas flow rate so as to prevent those residues from entering the capillary. We found that the latter approach gave more definitive and reproducible results. Clearly, because the distribution of fields and flows in the

source chamber are not well defined and uniform, a bath gas flow rate sufficient to sweep away the residues will also prevent some of the single molecule ions from entering the capillary. Thus, the ionization efficiencies that we determine are conservative in the sense that they do not include all the single molecular ions actually produced that could have entered the vacuum system if the bath gas flow rate had been lower.

Figure 2 shows curves of I_g vs V_r when the solute ions were Tetrabutylammonium ($M = 243$) and Tetraheptylammonium ($M = 441$). The inflection points on the curves indicated by the arrows occur as they should at a value of V_r equal to the kinetic energy of a singly charged solute ion accelerated in the free jet expansion to the actual velocity of the bath gas. Because of distortions by stray fields, velocity lags, and "contact potentials" due to differences in the work function of the metalized exit face of the capillary and the skimmer-grid structure used as a Faraday cup, such agreement cannot always be expected. Figure 3 displays I_g - V_r curves for two PEG samples. The scale in the upper right hand corner shows the abscissa position for the kinetic energy that ions with indicated m/z values would have at the actual velocity of the bath gas.

Figure 4 shows the values of I_n for solutions at two concentrations of PEG covering the range of molecular weights M for which we have samples. Flow rates were 3.5 $\mu\text{L}/\text{min}$ in both cases. There is clearly a definite increase in current as M increases. To be remembered is that increasing M corresponds to a decreasing number flux of PEG molecules. We know from our earlier study of PEG how the number of charges per ion increases with increasing M . (2) The effects of these factors on I_n are calculable so we can determine the effect of M on "charge yield" in coulombs/ μg , a frequently used index of ionization efficiency. Figure 5 shows this dependence. It is also possible to determine the number of ions in the current flux so we can arrive at a value for "ion yield," the fraction of injected analyte molecules that enter the vacuum system as ions. The dependence of this "ion yield" on M is shown in Figure 6. It is clear that both of these measures of efficiency increase substantially with increasing M . We do not yet understand the reasons for this welcome trend but it does not seem to be shared by most other ionization techniques. Also of note is that since this work was done some source changes have resulted in a 100 fold gain in ion current.

SPECULATION ON THE MECHANISMS(S) OF ELECTROSPRAY IONIZATION

Richard D. Smith, Harold R. Udseth, Joseph A. Loo, Charles G. Edmonds and
Charles J. Barinaga
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory
Richland, WA 99352

As originally reported by Fenn and coworkers,¹ proteins can be effectively addressed by electrospray ionization (ESI), yielding a distribution of charge states. Reasonable mass spectra can be obtained with picomole quantities of protein and the molecular weight of unknown substances can be accurately calculated based upon any two peaks (assuming one knows that the peaks are related). Given typical distributions, such as shown in Figure 1 for a mixture of horse heart cytochrome c and tuna cytochrome c, the calculation is straightforward and the accuracy of the determination (generally 0.005 to 0.05% depending upon sample purity and S/N) is enhanced by use of several peaks. Simple mixtures may be readily addressed and the MW of each component determined.

Figure 2 shows a plot of the highest charge state detected vs. the number of basic amino acids for a representative set of proteins, showing a crude linear relationship. We have as yet seen no charge state distributions for large proteins for which a maximum intensity is indicated above m/z 1700, suggesting that electrostatic restrictions may exist on the desorption rates for higher m/z ions. The maximum charge state for proteins is accurately predicted by the number of readily protonated sites, as shown by the good linear correlation observed up to about 25,000 dalton between the maximum number of charges and the number of basic amino acid residues (e.g., arginine, lysine, histidine, etc.). For example, angiotensin I (MW 1296) contains 1 arginine and 2 histidine residues in its sequence (along with an N-terminal amino group), consistent with the $(M + 4H)^{4+}$ ion being the maximum charged species observed experimentally. The $(M + 5H)^{5+}$ and $(M + 6H)^{6+}$ are the most abundant and most highly charged species, observed for melittin from bee venom, a peptide for which protonation sites include the 5 basic amino acids and the terminal NH_2 group.³

Dithiothreitol (DTT) is a reagent which reduces disulfide bonds between cysteine residues has been found to have a significant effect on the maximum charge state observed. The effect is illustrated in Figure 3 for lysozyme and in Figure 4 for bovine albumin. The substantial increase in maximum charge state apparently results from the greater accessibility of the basic amino acid residue charge sites in the electrospray droplets, and greater extension (i.e., loss of tertiary structure) of the gas phase ion. As shown in Figure 2, bovine albumin treated with DTT more closely approaches the maximum charge state expected.

VISCOSITY EFFECTS IN FAST ATOM BOMBARDMENT MASS SPECTRA

J. Shiea and J. Sunner
Department of Chemistry
Montana State University, MT

Fast atom bombardment (FAB) spectra are known to be strongly dependent on matrix temperature, T_b . At low temperature, the spectra tend to degrade to a series of non-descript peaks. The reason for this strong effect has been unclear, however. In a previous study¹, we suggested that it was not the temperature per se, but rather the viscosity, that affect the FAB spectra. Here, we report investigations into the effect of viscosity on FAB spectra of some simple systems.

As the glycerol matrix is cooled from +25°C to -30°C, the viscosity increases from 10^3 to 10^6 centiPoise (cP). In order to be able to distinguish temperature effects from viscosity effects, it is necessary to be able to change the viscosity at constant temperature. This can be done by mixing in up to 60 w% (c_a) glucose into the glycerol. This is nearly ideal since glucose is chemically similar to glycerol and also, because of its low gas-phase basicity, almost "transparent" in the spectra. In this study, the viscosity has been varied in two ways, by varying the temperature (T_b) and by varying the glucose concentration (c_a). Figure 1 compares the results for glycerol. The two graphs are seen to be quite similar. The major glycerol ions decrease strongly in both cases and the noise ion intensity increases. Also, there is a gradual decrease in glycerol clustering and an increase in fragmentation. Figure 2 shows the result for a 10 mol% solution of diethanolamine (DEA) in glycerol. Again, the T_b and the c_a studies are quite similar. In addition to the features in Fig. 1, a rapid decrease for the analyte ions is also seen. The trends seen in Figs 1 and 2 were seen in all investigated systems. The figures also show that severe spectral degradation sets in at a much lower viscosity, when DEA is added, 3,000 vs 50,000 cP. This additional degradation is due to increases for noise ions like $(M+14)H^+$ which must be products of radiation chemistry.

Despite the significant similarities between the T_b and the c_a experiments, there are also differences. As an example, Fig. 3 shows the analyte to matrix ion ratios for the T_b and the c_a studies of a 1.7 mol% solution of adenosine in glycerol. The rapid increase observed in the c_a experiments can be understood as a result of changes in the rates of the various transport processes at the liquid/vacuum interface. Evaporation of the matrix tends to increase the surface concentration of an involatile analyte. However, this tendency is opposed by diffusion and sputtering. In the T_b experiment both evaporation and diffusion is slower at high viscosity. In contrast, in the c_a experiment, diffusion is slower but the effect on evaporation is small. The result is increased analyte surface enrichment as reflected in Fig. 3. This figure also shows an increase in the analyte to matrix ion ratio at the lowest temperature. This effect was observed for most other systems. The tentative interpretation is that this reflects that a direct desorption, precursor ion formation mechanism is becoming more efficient at very high viscosity.

It is concluded that temperature per se has a small effect on FAB spectra and that the viscosity is a more important parameter. The viscosity effects in turn are due both to changes in desorption mechanism and to changes in the transport processes and to how these effect surface concentrations and radiation chemistry.

ON THE FORMATION AND DISSOCIATION DYNAMICS OF CLUSTER IONS IN FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Michel J. Bertrand, Helene Perreault and Qingmei Zha
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada H3C 3J7

Fast atom bombardment has been, for several years, used widely as a desorption-ionization technique for the mass spectral analysis of polar and high molecular weight compounds. The technique is appealing because it is experimentally easy to use and can contribute useful information in a wide number of analytical applications such as peptide identification and sequencing. However, the mechanisms responsible for the ionization and generation of the mass spectra are still not fully understood and are presently the topic of several investigations¹⁻³. The matrix plays an important role in fast atom bombardment mass spectrometry and recently studies have been focussed on the function of the liquid matrix in the ionization-fragmentation processes. The function of the matrix is not only to dissolve the analyte and allow the bombarded surface to be renewed, but it also has a determining role in defining the types of ions that will be observed and their intensities. When polar matrices such as glycerol, thioglycerol or diethanolamine are used, several types of cluster ions are observed in the mass spectrum. For example, when glycerol is used for the analysis of peptides, several types of cluster ions are observed and they are of the type G_nH^+ , $G_nA_mH^+$ and A_mH^+ where G and A represent glycerol and the analyte respectively.

Since cluster ions are believed to play an important role in the generation of the FAB spectra, studies have been undertaken in order to identify important experimental factors that influence the dynamics of formation and dissociation of these clusters in the hopes that valuable information leading to a better understanding of the generation of FAB mass spectra could be obtained. In initial studies to determine whether FAB desorption-ionization was mainly a solution or a gas phase process, comparison was made between normal FAB using glycerol as the liquid matrix and CI using glycerol as the reagent gas. The results of those experiments revealed that even if some aspects of the spectra were similar, dissimilarities related to fragmentation and presence of higher cluster ions existed². Similar results were obtained by other groups who could not generate cluster ions G_nH^+ with more than two molecules of glycerol under conditions of chemical ionization³. Following these experiments, a series of solution parameters were varied in FAB experiments in order to investigate their effects on the formation and dissociation of the different types of clusters observed. MS/MS experiments demonstrated that the higher clusters, whether they be of the type G_nH^+ or $G_nA_mH^+$, dissociated unimolecularly by loss of one molecule of glycerol giving fragments of the type $G_{n-1}H^+$ or $G_{n-1}A_mH^+$. At higher internal energies, such as those that can be achieved by collision activation, the clusters dissociate by loss of one or several molecules of G or A to give lower mass clusters or fragments corresponding to those observed in conventional FAB spectra thus indicating that the FAB spectrum could be generated and explained by the decomposition of these clusters. Results of experiments related to the formation of the positively and negatively charged clusters indicated that solution parameters such as pH of the matrix and concentration of the analyte had an influence on the intensities and internal energies of homogeneous (G_nH^+ , A_mH^+) and inhomogeneous $G_nA_mH^+$ clusters. Figure 1 shows the important effects of pH and analyte concentration on the intensities of G_nH^+ clusters. Figures 2A and 2B show the influence of analyte concentration on the variations of the intensities of both positively and negatively charged clusters of the type $G_n\pm H^\pm$, $A_m\pm H^\pm$ and $G_nA_m\pm H^\pm$. The effect of concentration on the internal energies of mixed clusters of the type $G_nA_m\pm H^\pm$ has also been investigated and the results obtained for the negatively charged clusters $G_nA_m-H^-$ are given in figure 3. It is found that the internal energies of both positively and negatively charged clusters increase with the concentration of the analyte.

Thus the type and intensities of the clusters that are formed are intimately related to the composition and conditions of the liquid matrix as it has been reported in experiments on mixtures of glycerol and diethanolamine¹. However, even if hypotheses have been suggested, it is still difficult to explain all the experimental evidence with regards to the factors affecting events in the gas phase and in solution. A series of experiments have been designed so that some of these factors can be isolated. This can be done by examining the incorporation of ¹³C glycerol, in

the vapor phase of a tight source, to clusters generated by FAB using ^{12}C glycerol as a liquid matrix.

Solute Introduction and Liquid SIMS

Peter J. Todd
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-8121

Theories proposed to explain the enhanced emission of solute secondary ions from glycerol solutions may be divided into two main areas. The first group concerns the overall mechanism by which secondary ions are emitted. A second group of theories concerns the effects that surface activity, diffusion, radiation damage, etc., have on the intensity of characteristic secondary ions emitted. Within the second group, it is often impossible to rectify evidence supporting one rationalization, such as the effect of surface activity without the implication that another conceivable factor, such as the low rate of diffusion, is an unimportant factor. In this report, we compare LSIMS spectra obtained from a series of alkylamines introduced onto the surface of a glycerol sample with spectra obtained from solutions obtained from the corresponding alkylammonium halides. When the amines are admitted as a gas, it can be demonstrated that diffusion does not play a role in the intensity of characteristic secondary amine ions, so that the role of surface activity can be examined cleanly.

For the present work, surface activity and Henry's Law Constants for C_4 - C_{10} alkylamines in glycerol solutions were measured. When introduced via the gas phase, the intensity of amine-characteristic secondary ions was found to vary with pressure and as a linear function of the inverse Henry's Law constant. For intensity to be a linear function of surface concentration when amines are introduced via the gas phase, the intensity would have to be both a linear function of the surface activity and an inverse function of the Henry's Law constant. Consequently, the results indicated the origin of secondary ions was not the surface monolayer, but rather some layer beneath it. This result is in direct conflict with conclusions of others. Furthermore, for the corresponding spectra of the amine HCl solutions, there was a direct correspondence between the intensity of secondary protonated amine ions and their respective surface activities.

The conflict was resolved by the curious correlation between the surface activity and Henry's Law Constants for the amine/glycerol systems studied. Figure 1 shows that when the log of each set of constants is plotted as a function of alkyl chain length, the plots are parallel. This means that any function that correlates with Henry's Law Constant also correlates with surface activity. A plot of sensitivity ($d[M+H]/dP$) vs. surface activity is shown in Figure 2. Since it is observed that intensity correlates with pressure, correlation with surface activity rather than Henry's Law requires that the surface precursor to the detected amine-characteristic ion be other than free base amine, and is most likely adsorbed protonated amine. If the precursors to detected secondary amine ions were adsorbed free base amine, then secondary ion intensity would correlate with the quotient of surface activity and Henry's Law Constant. The correlation of secondary ion intensity with pressure must arise because the pressure determines the rate at which amine molecules strike the surface, are adsorbed, and then protonated. Reactions 1-3 describe the mechanism and are consistent with results:

Reaction (3) indicates that adsorbed protonated amine, $AmH^+(a)$, concentration is in equilibrium or near equilibrium with dissolved protonated amine, $AmH^+(l)$ that is diffusing into the liquid sample from the surface. Equations (1)-

(3) indicate the surface concentration of protonated amine is determined by the surface activity of the protonated amine, and the partial pressure of amine. This is because surface activity determines the rate at which the protonated amine leaves the surface, and amine pressure determines the rate that adsorbed protonated amine can be formed. Under the steady-stage conditions of the experiments, the two rates must be equal. Since neither of these rates is a function of Henry's Law, no correlation between sensitivity and Henry's Law Constants would be expected.

Fig. 1. Surface activity and k_H^{-1} vs. alkyl chain length. A feature peculiar to amine/glycerol solutions is that these two functions are linearly related.

Fig. 2. Correlation between sensitivity and surface activity. Secondary ions are emitted from the surface.

NEGATIVE MOLECULAR IONS FROM SAMPLES ADSORBED ON NITROCELLULOSE FOR keV AND MeV PARTICLE BOMBARDMENT

W. Ens, K.G. Standing, Physics Dept., Univ. of Manitoba, Winnipeg, Canada, R3T 2N2;
B.U.R. Sundqvist, D. Fenyö, P. Håkansson, Div. of Ion Physics,
Uppsala University, Box 535, S-751 21 Uppsala, Sweden.

In recent comparisons between keV and MeV particle bombardment mass spectrometry, the strong similarity between positive ion spectra of organic molecules (mostly peptides) from insulating surfaces has been emphasized [1,2,3], although the yield for MeV bombardment is higher especially for large molecules.

For peptides adsorbed to nitrocellulose, the yield of negative molecular ions ejected by MeV bombardment is about 5 to 10 times lower than that for positive molecular ions. We were therefore surprised to observe that for keV bombardment, the signal-to-noise ratio for negative molecular ions of insulin (MW 5733) is comparable to that of positive molecular ions as shown in fig. 1. Similar results have been obtained for glucagon (fig. 2) and renin substrate (MW 1760). We have also observed a small 1^- peak for phospholipase A_2 (MW 13980) and a broad peak that may correspond to 2^- (fig. 3).

The two measurements in fig. 1 were made by reversing the polarity of the target from +12 kV to -12 kV so the energy of the incident Cs^+ ions emitted at 22 kV is very different in the two cases: 10 keV for positive acceleration and 34 keV for negative acceleration. For these rather different energies, the absolute yield for insulin is approximately the same. Since the fission fragment yield drops by a factor of 5, changing target polarity (and thereby increasing the incident energy of keV Cs^+ ions) increases the ratio of keV to MeV yield by a factor of 5 under the present conditions. Much or all of this increase is probably due to the increase in incident energy.

The results have implications on the mechanism of energy loss associated with the desorption of large molecules by keV bombardment. From our previous comparison with positive molecular ions [3] the absolute yield of insulin molecular ions from nitrocellulose is about 20 times higher for fission fragment bombardment than for 18 keV Cs^+ bombardment. For negative molecular ions of insulin, the present results therefore indicate the yield is only a few times higher for MeV bombardment than for 34 keV Cs^+ bombardment. The desorption of molecular ions by MeV bombardment is clearly associated with the electronic stopping power, i.e. inelastic collisions with the target electrons. For ^{252}Cf fission fragments the electronic stopping is about 500 eV/Å. However, Cs^+ ions in the 10 keV range lose about 100 eV/Å by collisions with the target nuclei (nuclear stopping) but only about 10 eV by electronic stopping. Given the strong (approximately quadratic) dependence of yield on energy loss for MeV bombardment, it seems unlikely that the observed yield for negative molecular ions of insulin with keV bombardment is associated with electronic stopping.

The results also have some practical value: For a positive primary ion beam the energy at the target is higher for negative acceleration than for positive by twice the acceleration voltage. Furthermore, the primary ion energy does not limit the negative acceleration potential because the acceleration field does not retard the primary ions. Fig. 4 shows the spectrum of insulin taken with -15 kV acceleration instead of -12 kV of fig. 1. The improved detection efficiency of higher velocity ions and the increased incident energy gives a higher yield and better signal-to-noise ratio. In addition to molecular ions, the negative spectrum of insulin also shows much more intense peaks for the A and B chain fragments than does the positive ion spectrum.

In summary, negative ion spectra from nitrocellulose targets are practical for keV bombardment (in contrast to MeV bombardment) and in some cases give information complementary to the positive spectra. The high yield of negative molecular ions suggests that for keV bombardment, nuclear stopping is responsible for desorption.

ELUCIDATION OF ELECTRONIC AND VIBRATIONAL ENERGY LEVELS OF MOLECULAR IONS BY HIGH RESOLUTION TRANSLATIONAL ENERGY SPECTROSCOPY:

M Hamdan and A G Brenton*

Mass Spectrometry Research Unit,
University College of Swansea, Swansea SA2 8PP, UK.

The electronic and vibrational states of small molecular ions has been investigated at very high energy resolution, by means of Translational Energy Spectroscopy (TES). A high resolution spectrometer, of novel design, has been used which is capable of resolving energies ≤ 0.1 eV for collisions of ≤ 8 keV ions with collision gases. The technique is primarily suited to the detection of quasibound (metastable) states. It has similarities with photoelectron spectroscopy except that applications can now be made to ionic species which do not have stable neutral counterparts and also to multiply-charged ions.

This presentation concentrates on the selected dications CO^{2+} , NO^{2+} and N_2^{2+} which will illustrate the utility of the technique. The high-resolution translational energy spectrum of 6 keV CO^{2+} scattered off Ne and the energy change spectrum of single-electron capture by the same ion in collision with a Ne target, the latter is shown in Figure 1. Both the spectra and the dependence of the observed reaction channels on the ionising electron energy clearly show that only ground-state $\text{CO}^{2+}({}^3\Pi)$ and possibly $\text{CO}^{2+}({}^1\Sigma^+)$ ions live long enough (~ 1 μs) to reach the target cell. The excited state at 1.7 eV above the $\text{CO}^{2+}({}^3\Pi)$ ground state reported recently was not observed. The double ionisation energy of CO was measured to be 41.76 ± 0.1 eV.

Transitions among the three lowest $\text{X}^2\Sigma^+$, $\text{A}^2\Pi$ and $\text{B}^2\Sigma^+$ bound states of NO^{2+} are investigated by means of high resolution (0.08 - 0.35 eV FWHM) translational energy spectroscopy (TES). As well as electronic transitions between the ground and the two lowest electronic excited states, the spectra clearly show two distinct groups of vibrational transitions having average vibrational spacings of 0.22 eV and 0.17 eV respectively, shown in Figure 2. The two groups of vibrational levels are assigned to transitions involving $\text{NO}^{2+}(\text{X}^2\Sigma^+, 7_{\text{v}} \rightarrow 3 \leftrightarrow \text{v}=0)$ and $(\text{A}^2\Pi, 6_{\text{v}} \rightarrow 3 \leftrightarrow \text{v}=0)$. The measured vibrational spacings are in accord with the values of 0.158 eV and 0.242 eV predicted by the latest *ab initio* calculations of Cooper.

The high-resolution translational energy spectrum of 6 keV ${}^{29}\text{N}_2^{2+}$ scattered off He and energy change spectra of one-electron capture by the same ion in collision with He and Ne atomic targets are shown in Figure 3. The electron capture spectra recorded at different ionising electron energy indicate the presence of two metastable excited states at energies of 1.2 and 1.5 eV above the $\text{N}_2^{2+}(\text{X}^3\Sigma_g^-)$ ground state. Based on the latest *ab initio* configuration interaction quantum chemical calculations the two states are assigned to $\text{N}_2^{2+}(\text{C}^1\Delta_g, \text{b}^1\Pi_u)$ and $(\text{C}^3\Sigma_g^+)$ respectively.

Finally, energy loss spectra have recently been obtained for the excitation of ion beams, for example, of noble gases, of with surfaces. A channel plate array was employed and driven into the ion beam. Although the technique requires further refinement it shows great promise in enabling processes requiring high excitation energies and also allows measurement of excitation and de-excitation without the presence of the precursor ion beam, which is blocked off.

Structure Elucidation of Distonic Radical Ions
by Low-Energy Collision-Induced Dissociation

V.H. Wysocki, Chemistry Division, Naval Research Lab., Washington, DC 20375;
H.I. Kentamaa, Chemistry Dept., Purdue University, West Lafayette, IN 47907.

The properties of distonic ions have been the focus of intensive research since it was discovered that these unusual ions are often kinetically as well as thermodynamically more stable than their conventional counterparts.¹ The present study of these ions has a two-fold goal: (i) to better understand the differences between two different activation methods used to study ion structures in quadrupole mass spectrometry and (ii) to provide further insight into the gas-phase chemistry of some interesting ionic species. We are especially interested in the stability of the isomeric compounds under multiple collision conditions, experimental conditions that are commonly used in quadrupole instruments and that are known to cause rapid isomerization of many ions prior to dissociation. We examined the dissociation behavior of several distonic radical ions and their conventional counterparts in a triple quadrupole mass spectrometer (Finnigan TSQ70) and in a Paul-type quadrupole ion trap (prototype Finnigan ITMS). Ions investigated include $[\cdot\text{CH}_2(\text{CH}_2)_n\text{OH}_2^+]$ vs. $[\text{CH}_3(\text{CH}_2)_n\text{OH}]^{+\cdot}$ ($n=0-2$) and the pyridine isomers, ionized 4-methylpyridine $[\text{CH}_3\text{C}_5\text{H}_4\text{N}]^{+\cdot}$ vs. $[\cdot\text{CH}_2\text{C}_5\text{H}_4\text{NH}^+]$. The ions of the $\text{C}_n\text{H}_{2n+2}\text{O}^{+\cdot}$ series have previously been studied by keV CID, metastable ion dissociation, NRMS, and ion/molecule reactions. The pyridine isomers have not been studied previously; the distonic isomer is representative of a series of ions produced by alkyl radical losses from compounds of the general type $^+\text{XCH}_2(\text{CH}_2)_n\text{CH}_3$. The ions of this series are of interest as possible intermediates and products of remote-site (charge-remote) fragmentation.²

The results indicate that low-energy (eV) collision-induced dissociation (CID), under single or multiple collision conditions in a triple-quadrupole instrument, can be used to distinguish the above pairs of isomers. For example, ionized ethanol $[\text{CH}_3\text{CH}_2\text{OH}]^{+\cdot}$ fragments by loss of methyl radical to produce protonated formaldehyde while the distonic isomer, $[\cdot\text{CH}_2\text{CH}_2\text{OH}_2^+]$, produced by electron ionization of 1,3-butanediol, fragments predominantly by loss of H_2O . Results obtained on the triple-quadrupole instrument are summarized in Table 1 and illustrated in Figure 1. For the $\text{C}_n\text{H}_{2n+2}\text{O}^{+\cdot}$ isomers, the quadrupole ion trap CID spectra were indicative of distinct structures only for the isomers $[\text{CH}_3\text{CH}_2\text{OH}]^{+\cdot}$ vs. $[\cdot\text{CH}_2\text{CH}_2\text{OH}_2^+]$. This may be explained by the fact that no products which required deposition of more than 1.3 eV were observed in the ion trap CID spectra; the light helium target used for collisional activation in the ion trap makes fragmentation pathways with high internal energy requirements inaccessible. The results from the two different types of instruments suggest that the isomerization barrier between the ions of the pair $[\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}]^{+\cdot}$ vs. $[\cdot\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}_2^+]$ is lower than the barriers associated with the shorter chain homologues ($n=0$ or 1), which is consistent with results recently obtained for the nitrogen analogues. The data obtained, in conjunction with thermochemistry from the literature, suggest isomerization barriers of > 29 eV ($n=1$) and approximately 12 eV ($n=2$) for the conversion $[\cdot\text{CH}_2(\text{CH}_2)_n\text{OH}_2^+] \rightarrow [\text{CH}_3(\text{CH}_2)_n\text{OH}]^{+\cdot}$ (Figures 2 and 3). These values are consistent with previous estimates.

TANDEM MASS SPECTROMETRY OF LARGE BIOMOLECULES:
WHAT IMPEDES ITS USE FOR STRUCTURAL CHARACTERIZATION.

D. H. Russell
Department of Chemistry
Texas A&M University
College Station, Texas 77843

Tandem mass spectrometry is used in a number of laboratories for the structural characterization of complex organic and inorganic molecules. The degree of success of this work varies widely and is strongly dependent upon the type of molecule examined. As a general rule, tandem mass spectrometry studies of peptides and related molecules are the most successful, but even for this class of molecules the studies are limited to molecular weights of approximately 1500 daltons. Although one can find exceptions to the general statement, there are few cases where MS-MS spectra of peptides above m/z 1500 contain analytically useful data. It is also quite surprising that MS-MS data for peptides obtained on keV energy sector instruments is comparable to that obtained on triple quadrupole instruments. In fact, it can be argued that the low energy triple quadrupole data is superior (in terms of the signal-to-noise ratio and, presumably, the fragment ion yield) to that obtained for keV energy collisions with high performance sector instruments. *The questions that I wish to consider in this paper are directed toward understanding what physical processes limit the use of tandem mass spectrometry to analytical problems of biomolecules.*

Collision-induced dissociation is the most commonly used method for acquiring MS-MS spectra, but it is now well known that the efficiency for dissociating the $[M+H]^+$ ions of large molecules decreases as the size of the molecule increases. Although Derrick and co-workers have shown that a large fraction of the translational energy of the incident ion is lost upon collision with the neutral target,¹ work from this laboratory shows that only a small fraction of the energy loss value actually appears as internal energy of the ion.² In fact, studies performed by ion cyclotron resonance suggest that the cross-section for endothermic charge transfer reactions between the incident ion and the neutral target is much greater (by at least two orders of magnitude) than collisional activation of the incident ion.³ On the basis of earlier work,⁴ the greater cross-section for charge exchange (electronic excitation) (at keV energy collisions) is not at all surprising! *What then is the mechanism for keV energy collisional activation?* Undoubtedly, keV energy collisional activation involves vibrational excitation of the incident ion, and the vibrational excitation occurs by multiple collisions between the incident ion and the target neutral. Experiments performed in this laboratory on energy loss accompanying collisional activation and obtained by using a biased activation cell⁵ show clearly that large energy loss values are only obtained at high collision gas pressures, and above the threshold pressure where large energy loss values are observed the energy loss increases linearly with pressure (see Figure 1). Clearly, these data are consistent with collisional activation occurring by a multi-collision process.

Studies on the mechanism of charge-inversion CID also are consistent with the proposed involvement of multi-collision in CID of polyatomic species. The energy loss values accompanying CID of either positive or negatively charged metal ions, e.g., $M(CO)_y^{+/-}$ ($y=1-5$), are constant for all product ions. Conversely, the energy loss values for charge-inversion increase as the m/z ratio of the product ion decreases. In addition, the abundance of the low m/z product ions increases as the pressure of the target gas is increased (pressure measurements were correlated with %attenuation of the incident ion beam).

Another factor which greatly limits the development of tandem mass spectrometry is the current trend in instruments. Mass spectrometry is a complex field and the trend toward larger, more complex and costly instruments only serves to make the use of the methods more difficult for the biochemist in need of analytical information. There are less costly high performance instruments (with greater mass resolution, sensitivity, and experimental versatility) available than the highly complex four-sector instruments that are currently in vogue. Time-of-flight mass spectrometers are capable of performance which rival the most sophisticated sector instruments, especially at high mass. A separate paper from this laboratory describes a new instrument under development which has a high resolution sector for MS-I and a high performance TOF as MS-II. Instruments of this type will become more common over the next few years and will ultimately be the instruments which solve the structural characterization problems provided by the biotechnology scientific community. These types of instruments will make tandem mass spectrometry the long promised analytical method.

THE PHOTODISSOCIATION AND METASTABLE DECOMPOSITION OF FAB PRODUCED IONS IN AN EXTERNAL SOURCE-FOURIER TRANSFORM MASS SPECTROMETER

C.B. Lebrilla, D. T.-S. Wang, R.T. McIver, Jr.
Department of Chemistry, University of California, Irvine

The external-ion source, quadrupole-FTMS(1) is ideal for studying the internal energy and fragmentation mechanism of FAB produced ions. In this report, laser photodissociation (PD)(2) is used to probe the structure of FAB produced ions and evidence for metastable decomposition and their rates are provided.

With small tetrapeptides, fragment ions produced by both FAB and PD (single pulse, 193 nm, 20 mJ) are derived from similar if not identical dissociations. For example, fragments from the tetrapeptide methionyl-arginyl-phenylalanyl-alanine (MH^+ , m/z 524) correspond to cleavages primarily along the peptide bonds in both processes. By far, the most abundant fragment ions correspond to the protonation of the terminal methionyl and the basic arginyl amino acids suggesting that, as with FAB, photofragmentation is governed by simple thermodynamic considerations. In general, photodissociation provides a greater abundance of low mass ions. The only evidence for photo specific processes is from the presence of m/z 120 corresponding to phenylalanyl immonium ion. Although present in the FAB spectrum, this ion is strongly enhanced in the PD spectra of all phenylalanine-containing peptides. The phenyl group is a stronger chromophore than the carbonyl group. Ejection pulses preceding each laser shot eliminates uninteresting ions. Thus even low intensity signals can be confidently assigned in the photodissociation spectrum.

The effectiveness of laser PD becomes more evident when used to determine the structures of FAB fragment ions. With the FTMS spectrometer, it produces more fragmentation and is more convenient to use than collisionally induced dissociation. For example, the FAB spectrum of the cyclic, symmetrical decapeptide, gramicidin S (MH^+ , m/z 1142) contains a half-fragment (m/z 571) which can be one or some combination of five isobaric pentapeptide species. Isolation of m/z 571 by selective ion ejection and subsequent photodissociation (Figure 1) yields granddaughter ions corresponding to sequential losses of amino acids, as well as all combinations of dipeptide, tripeptide, and tetrapeptide ion fragments. Analysis of the granddaughter ions prove unequivocally that the structure is that of a single species, corresponding to 1.

By using short injection pulses (5 msec) and short detect delay (1 msec to 100 msec) the metastable decomposition of the FAB produced ions are observed. Figure 2 shows an exponential decay for the relative intensity of the molecular ion of the undecapeptide, substance P (MH^+ , m/z 1346). The curve is a combination of two competing processes: a fast process with a rate of 30 s^{-1} and a slow process with a rate of 0.7 s^{-1} . The fast process is significantly faster than the collision frequency (10^{-4} s^{-1}) associated with the analyzer chamber pressure (10^{-10} torr). It is also strongly mass dependent being faster for lower massed gramicidin S (Table 1), and too rapid to be observed for the tetrapeptide valyl-alanyl-alanyl-phenylalanine (m/z 407). The rapid process is most likely due to the excess energy associated with FAB ion formation. Experiments are currently being performed to vary the conditions during ion formation and to determine their effect on the rate of the fast process.

In contrast, the slow process is essentially mass independent within the mass range we have studied (i.e. 500 to 1400 amu). Additional experiments must be performed to determine the source of this process.

Metastable Decomposition of Substance P

Excited State Proton Transfer in Laser Mass Spectrometry
M.P. Chiarelli, A.G. Sharkey, Jr., and D.M. Hercules, Department of Chemistry,
University of Pittsburgh, Pittsburgh, PA 15260

The purpose of these investigations is to determine the analytical utility of excited-state proton transfer (ESPT) as an ion generation process in resonant laser mass spectrometry (LMS). Many aromatic compounds will undergo a functional group-specific change in pKa upon excitation to the S_1 state (1). ESPT has been cited in many resonant LMS investigations as a possible ion generation mechanism, however, no direct evidence for this process has been obtained prior to this study (for instance, see reference 2).

The laser desorption of both 1- and 4-fluorene-carboxylic acid with LiCl yields significant abundances of $(M-2H+3Li)^+$ ions (Figure 1) under LAMMA 1000 detection conditions at power densities around 10^8 W/cm², a wavelength of 266 nm and total energies of 9-12 μ J. The trillithiated molecular ion is formed by hydrogen-lithium exchange on the 9'-CH₂ bridge whose pKa changes from 20.5 in the S_0 state to -8.5 in the S_1 state (3) (equation 1). The abundances of the trillithiated ions probably provide a low estimate of proton detachment because proton reattachment should occur more readily than lithium attachment due to the greater mobility of the proton.

The laser desorption of some hydroxybenzoic acids with LiCl demonstrate that the lifetime of the excited state influences ion formation as well as pKa change. Salicylic acid forms $(M-2H+3Li)^+$ ions almost exclusively while p-hydroxybenzoic acid forms equal amounts of $(M-H+2Li)^+$ and $(M-2H+3Li)^+$ ions under approximately the same desorption conditions described above (Figures 2 and 3). The differences in the relative abundances of these ions formed upon irradiation may be attributed to the longer lifetime of the zwitterionic phototautomer of salicylic acid formed in the S_1 state when the pKas of the hydroxy and carbonyl groups invert (equation 2). However, if these ion formation processes were governed by ground state behavior just the opposite trend in ion abundances should be observed because the hydroxy pKa of the alpha isomer should be 4 units larger than the 4' isomer (Table 1). In order to verify this hypothesis, 2- and 4-hydroxybutanoic acid were codesorbed with LiCl under almost similar conditions of irradiation. These two compounds were chosen because they should mimic the ground state behavior of the hydroxybenzoic acids at a desorption wavelength of 266 nm. It is expected, based on the pKa data given in Table 1, that 4-hydroxybutanoic acid will yield more trillithiated molecular ions than 2-hydroxybutanoic acid and indeed this is what is observed (Figures 4 and 5). Many of the spectra show the 4' isomer forms the $(M-2H+3Li)^+$ ions exclusively while the 2' isomer forms only $(M-H+2Li)^+$ under the same desorption conditions. The differences in the desorption characteristics of the hydroxybutanoic and hydroxybenzoic acids verify that the molecular ion formation mechanism of the latter are governed by an excited state. Scheme 1 describes how excited state lithiation takes place.

In the next set of experiments we sought to ascertain direct evidence of protonated molecular ion formation by ESPT. 9-d₂-4-fluorene-carboxylic acid was synthesized in the same manner as 9-d₂-fluorene (5). The deuteration was determined to be 97% complete by EI mass spectrometry. The deuterated compound was codesorbed with several amino acids for the purpose of comparing the abundances of $(M+D)^+$ and $(M+H)^+$ ions (equation 3). It is known that the lattice energies of the amino acids are much larger than their neutral sublimation and gas-phase protonation energies (6). This means that the direct desorption of a preformed $(M+H)^+$ ion would not be thermodynamically favored over the plasma formation of a $(M+D)^+$ or $(M+H)^+$ ion. However, no $(M+D)^+$ ions were observed in these experiments. Furthermore, the codesorption of 9-d₂-4-fluorene-carboxylic acid and LiCl yielded no substantial abundances of $(M-(H+D)+3Li)^+$ ions. The reason for this is that deuterium loss is much slower than hydrogen loss. Murdoch and coworkers (7) determined that the kinetic isotope effect is almost 10 for lithium exchange with a deuterium on the CH₂ bridge of fluorene. Additionally, it was concluded in early fluorescence studies of fluorene that anion emission was not observed because hydrogen loss was slow with respect to fluorescence (2).

The investigations currently being undertaken are like those described above except with the acid and amine functional groups being deuterated and the 9' bridge is left hydrogenated.

Mechanism of Excited State Lithiation

DRY FAB MASS SPECTROMETRIC TECHNIQUES INCREASE PRACTICALITY
OF AND ACCESS TO TRACE METAL ANALYSIS IN MAN
P.V. FENNESSEY AND L.V. MILLER, UCHSC, DENVER, COLORADO

The absorption of trace elements, when they are consumed in a normal diet, depends upon a number of basic physiological and chemical interactions. The transport of a specific trace metal may be under direct homeostatic control (Cotzias 62) and the loss of a trace metal from the systemic circulation may also be regulated (Cousins 84). Determining these interactions is made more complex by specific interactions of the trace metal with components in food and with other metals and anions (Davis 80, Aggett 83). These interactions can take place in either the GI track or in the plasma after absorption (Solomons 82, Turnlund 84, Sandstrom 87).

Stable (non-radioactive) isotopes do not present the same health concerns as radioactive compounds but are considerably more difficult to measure (Hachey 87, Janghorbani 80). The analysis of isotope enrichment of trace metals in human nutritional research has been traditionally carried out using either neutron activation analysis (NAA) or a variety of different mass spectral techniques including ICP and thermal ionization (TI) mass spectrometry (Turnlund 84). In 1983, Smith showed that dry fast atom bombardment (FAB) could be used for the analysis of stable calcium isotopes in urine.

After the original report by Smith (83), three other laboratories, including ours, have reported on isotope analysis techniques using dry FAB/MS and have used them to carry out clinical studies (Peirce 87, Pratt 87, Lehmann 88). This approach has the advantage that it can be carried out on a shared, organic instrument; that it has adequate precision (1%); and that it has proven capability for Ca, Fe, Cu and Zn. This approach required a sample that is relatively free of species such as Na and K that compete for ionization in the FAB ionization beam.

When our laboratory began to experiment with FAB for the analysis of the trace element Zn, it was not clear that this technique would have adequate sensitivity because of the low levels of this metal in the human diet (i.e. mg in contrast to gm levels of calcium). For this reason, we began our research using fecal samples where the concentrations would not be limiting.

In the initial experiments it was clear that we had adequate sensitivity to measure Zn in the expected concentration range. This sensitivity was evaluated by using pure zinc standards in acid solution. However, other metals found in the biological matrix (in particular Na, K, and Ca), suppressed the Zn signal to such a degree that the analysis could not be completed without a chemical separation step. A simple ion exchange technique that had been described by Kraus (53) and used for separation of trace elements by Turnlund (82) was employed. In this technique, divalent metals are retained by the ion exchange resin as $(MCl_3)^-$ and after other metals are removed in the initial wash, the Cl concentration is reduced in steps so as to allow each metal to elute as its neutral metal chloride (MCl_2) .

A separate problem, that also led to suppression of the Zn signal, was caused by the standard FAB target. The stainless steel of the target contributed significant peaks from Cr, Fe and their oxides. This problem was initially overcome by wrapping pure gold foil around the target. Recently, we have fabricated a target out of pure silver rod and this is the system we are presently using. We have reported the observed improvement in zinc signal strength as each of the above steps were included in the analysis (Peirce 87).

Although the sensitivity was adequate for our fecal studies, we noted that the observed isotope ratios did not match the theoretical. Initially, we believed the deviation from the theoretical was due to instrument parameters and we launched an investigation into the cause.

After a rather detailed study of as many of the ion optic parameters that could be changed on our VG 7070 EHF, we concluded that our observed isotope ratios were caused by fractionation during the FAB ionization process (Miller 86). This hypothesis led to a separate study of this phenomenon. A summary of this work has been reported (Miller 87). A similar relationship has been reported in the SIMS literature (Shimizu 82, Jull 82). Fractionation plots (see Figures A, B & C) have been completed for a number of elements. The negative slope of the line indicates that the lighter isotopes are, apparently, more abundant than the heavier isotopes. The value of the slope (e.g. 2.12‰/amu for Nd) is a measure of the magnitude of the fractionation. The regression line passes through "0" deviation at the average molecular weight of the specific element. Similar plots have been reported in the SIMS literature (Schwarz 87).

A separate observation taken from these fractionation plots shows that FAB metal ions are affected by "hydride" peaks. These are most often seen when there is a small isotope peak preceded by a larger isotope by 1 amu. For example, Nd-142 and Nd-144 +H contributes to the Nd-143 and Nd-145 peaks, respectively. The hydride contribution can be corrected out of the fractionation regression (see Figures A & B). However, this process of hydride formation leads to a greater error in the measured isotope ratios and should be considered when one is selecting isotopes for enrichment studies. Further work needs to be done in understanding how to minimize or eliminate this effect.

Results from recent patient studies using the techniques described above have exceeded our initial expectations. For example, we have been able to detect an effect of standard dye markers on Zn absorption (Johnson 89). The absorption of Zn during normal and stress situations (i.e. pregnancy) has been easily measure (English 89). The cumulative fecal excretion curves also reveal a positive slope. We believe that this is due to metal that has been absorbed and is being

lost from the circulation back into the GI track. A study where a subject was given dual isotopes (i.v. & oral) supports this hypothesis. These data show the fecal content after an oral dose of Zn-68 isotope and a simultaneous dose of Zn-70 isotope i.v. The fact that the slopes of these two curves are very close in magnitude would suggest that they are both a measure of the same biological activity (resecretion).

Recently, two additional laboratories have reported the use of dry FAB ionization for the measurement of Cu, Zn and Fe isotopic enrichment in human absorption studies (Pratt 87, Lehmann 88). Although we recognize that methods such as thermal ionization mass spectrometry are more precise than the methods that we are using, the increased sample throughput, the availability of organic mass spectrometers fitted for FAB ionization and the normal biological variation of trace metal absorption in different subjects offset the precision issue. Clearly, there are many applications where the FAB method is competitive. The availability of a large number of organic mass spectrometers fitted for FAB ionization provide a means of sharing the results of our research to other facilities.

In spite of the exciting and very encouraging success that we have experienced using this method, there is much that is yet to be accomplished. Progress must be made in the area of required sample size. As mentioned earlier, the fecal samples provide adequate sample quantities (0.5-2.0 ug) for our present studies. However, studies involving infant plasma or urine will only provide 1/10 of the sample amount for analysis. For example, we presently need 15 to 30 ml of blood for our adult investigations. For infants, we must reduce this requirement to no more than 1 ml and, ideally, to 0.2 ml. In order to reach this goal we will explore, at least, the following: (1) data acquisition using selected ion monitoring; (2) improvement in ionization efficiency; (3) improvements in ion collection; (4) improved computer models to aid in both the interpretation of our data and in the development of a better experimental strategy.

NEW DEVELOPMENTS IN NEGATIVE THERMAL IONIZATION MASS SPECTROMETRY AND ITS APPLICATIONS

K.G. Heumann, M. Köppe and M. Wachsmann
Institute of Inorganic Chemistry, University of Regensburg, Germany

Introduction

Due to its advantages negative thermal ionization mass spectrometry (NTI-MS) has increasingly been used for isotope ratio determinations during the last few years. The principles and preparation techniques for NTI have been described elsewhere [1]. Up to now, procedures for isotope ratio determinations have been developed for the following elements or species of these elements: B, C, N, O, S, Se, Te, Cl, Br, I, Mo, W, Tc, and Re. The main advantages of NTI-MS are the selective ionization method, relatively high ion currents, only a few interferences and, normally, simple sample preparation techniques.

Improvement in selenium isotope ratio measurements

Because of the importance of selenium as a toxic as well as an essential element the improvement of the isotope ratio measurement of this element and its applications is an important topic. Using a double-filament (Re) ion source and about 30 µg barium oxide on the ionization filament Se^- ion currents of approx. 10^{-12} A could be observed. This is valid for ionization filament temperatures of 940-990°C using 0.5 µg selenium as selenious acid. The ion current could be increased by a factor of 40 when a mixture of the selenium sample and 10 µl of a silica gel suspension were deposited on the evaporation filament. We believe that the silica gel prevents the evaporation of selenium at a temperature too low for a sufficient formation of Se^- ions.

Whereas the precision of selenium isotope ratio determinations of samples with natural isotopic composition lies in the range of 0.3-0.6% for the old technique [2], the new technique results in precisions in the range of 0.1-0.3%. With the silica gel technique it should be possible to reduce the uncertainty of the atomic weight of selenium, which is presently due to the insufficient precision and accuracy in the determination of selenium isotope abundances. Other fields of application are the determination of natural isotope variations, selenium trace analyses with IDMS and bioavailability studies. In three sediments (BCR standard reference materials No. 277, 280 and 320) selenium concentrations of $(2.03 \pm 0.06) \mu\text{g/g}$, $(0.73 \pm 0.03) \mu\text{g/g}$ and $(0.198 \pm 0.003) \mu\text{g/g}$ could be analysed with NTI-IDMS. These results agree well with the certified values.

Formation of PO_x^- and AsO_x^- ions

A new development is the production of negative thermal oxide ions of the monoisotopic elements phosphorus and arsenic. These ions were formed from phosphates and phosphites or from arsenates and arsenites in a single-filament (Re) ion source after depositing the sample compound, 30 μg $\text{Ba}(\text{OH})_2$ and 5 μl silica gel suspension on the filament. The optimum filament temperature is 1250°C where high ion currents ($> 10^{-10}\text{A}$) of PO_2^- and PO_3^- or of AsO_2^- and low intensities of AsO^- and AsO_3^- were produced. The intensity ratio $\text{PO}_2^-/\text{PO}_3^-$ depends on the temperature and increases with higher temperatures.

In principle, the formation of PO_x^- and AsO_x^- ions could be used in the following fields of application: production of phosphorus and arsenic containing ion beams, semiquantitative determination of these elements by their ion intensity, indirect quantitative analyses with IDMS using spike compounds labelled with ^{18}O and direct oxygen isotope ratio measurements in phosphates and arsenates. For the last two topics there is a problem due to possible oxygen isotopic exchange between the sample oxygen and the oxygen traces in the ion source under the high temperature conditions. This isotopic exchange reaction can influence the measured isotope ratio. Additional investigations must therefore be carried out to gain better control of this effect. Table 1 shows the results of an oxygen isotopic ratio measurement and the isotopic abundances, which were calculated from these data. ^{16}O in the phosphate sample of natural isotopic composition was determined with a relative standard deviation of 0.002%, ^{18}O with 0.5%.

Sulfur isotope ratio measurements

We developed a NTI-MS method for the direct measurement of sulfur isotope ratios in inorganic solids, e.g. in sulfates and sulfides, which also works well with sulfuric acid. Up to now, two different methods have been established for precise isotope ratio determinations of sulfur. The first one is the measurement of SO_2 or SF_6 in a gas mass spectrometer with a precision of about 0.05%. The second one is positive thermal ionization mass spectrometry using AsS^+ ions for detection with a precision of 0.1% [3]. The disadvantage of these two methods is the fact that all sulfur compounds must be converted into SO_2 , SF_6 or As_2S_3 .

Our new method does not require a conversion of the sulfur compound to be analysed. A double-filament (Re) ion source is applied. The sample is mixed with 5 μl of a silica gel suspension and then deposited on the evaporation filament. A solution of 30 μg $\text{Ba}(\text{OH})_2$ is deposited on the ionization filament and evaporated to dryness. Using a few micrograms of sulfur as sulfate or sulfide S^- ion currents up to 10^{-11}A could be observed at the detector side of the mass spectrometer MAT 261 under the optimum temperature for the ionization filament of 1100°C (the evaporation filament is normally not heated).

SO^- and SO_2^- ions could also be detected but with relatively low abundances. Measuring the isotope ratio $^{34}\text{S}/^{32}\text{S}$ with $(\text{NH}_4)_2\text{SO}_4$, Na_2S and Ag_2S samples relative standard deviations of 0.1-0.5% could be obtained.

The major topics we plan to investigate with the new NTI technique for sulfur are natural isotope variations, sulfur traces with IDMS and biochemical reactions with ^{34}S labelled compounds.

Tungsten isotope ratio measurements

Besides the measurement of non-metals with NTI-MS this method can also be used to analyse some of the transition metals using MO_x^- ions for detection. The formation of positive Na_2WO_4^+ ions had formerly only been used in a few cases for isotope ratio determinations of tungsten. Due to the low ion current obtained this is not a sufficient technique. Our NTI technique uses a double-filament (Re) ion source with about 5 μg lanthanum oxide on the ionization filament. Any tungstate compound can be used on the evaporation filament. With a 100 ng sample WO_3^- ion currents of $>10^{-11}$ A could be achieved for hours using the compact thermal quadrupole mass spectrometer THQ.

Tungsten is one of 21 elements in the periodic table where its atomic weight is uncertain by 0.015% and more due to the uncertainty of the isotopic composition of these elements. Our measurements of the isotopic abundances of tungsten with NTI show that this technique leads to improved data. The relative standard deviation we obtained was always much better than the uncertainty of the IUPAC data (Table 2) and it is also much better than most of the results given in the literature. NTI-MS can therefore be used in the future to improve the atomic weight of tungsten by a calibrated measurement. Up to now, we have applied this method for the determination of very low tungsten concentrations in different matrices with IDMS.

HIGH SENSITIVITY ISOTOPE DILUTION (IDMS)
USING THERMAL IONIZATION, RESONANCE IONIZATION,
AND SECONDARY IONIZATION MASS SPECTROMETRIES--TIMS, RIMS, AND SIMS.

J.D.Fassett, S.Mayo, D.S.Simons, R.J.Walker, T.J.Murphy, and W.R.Kelly,

National Institute of Standards and Technology
(formerly, National Bureau of Standards),
Gaithersburg, MD 20899.

Isotope dilution mass spectrometry (IDMS) is a technique of proven high accuracy that is used routinely at NIST (formerly NBS) for the certification of elemental concentrations in Standard Reference Materials (SRMs). We have recently been investigating the use of mass spectrometric methods other than the traditional thermal ionization method for IDMS. Specifically, we are interested in improving our sensitivity for the broadest range of elements while maintaining the accuracy inherent to the technique.

IDMS is based on the addition of a known amount of enriched isotope, called the "spike" to a sample. After equilibration of the spike isotope with the natural element in the sample, chemical separation of the element from the matrix is typically done. This separation need not be quantitative, a decided advantage for the technique. The isotopic ratio defines the elemental concentration and this ratio will not change with element loss. Mass spectrometry is used to measure the altered isotopic ratio(s).

IDMS is an inherently accurate technique because the sources of systematic error are readily identified and assessed. The major sources of systematic errors are: chemical "blank" or contamination which occurs in chemical processing, handling, and analysis of samples; dissolution or equilibration problems; isobaric interferences in the mass spectrometer, both elemental and molecular; and, physical or instrumental processes that change measurement efficiencies between isotopes of an element. For most analytical work at the part-per-million level and above, these potential sources of systematic error can be made negligible (e.g. for blank or background problems) and/or can be controlled. As the concentration levels drop below parts-per-million to parts-per-billion and parts-per-trillion, these sources of systematic error become much more important and much less easy to control. However, mass spectrometric instrumentation with differing strengths (sensitivity, selectivity, ratio measurement precision, etc.) can be used advantageously for ultratrace IDMS analysis. Two experiments of several that we have done are presented here. Both illustrate IDMS analysis of oyster tissue, SRM 1566a. These examples demonstrate advantages of SIMS and RIMS relative to TIMS, and the trade-offs in precision that may be made. At the ultratrace level, precision will often be limited by material variability. Thus, reduced precision can be tolerated if accuracy can be more readily obtained.

Secondary ion mass spectrometry (SIMS) is a sensitive, as well as isotopically selective, method for the direct analysis of solid materials. It is therefore surprising that only a few investigations of IDMS-SIMS have been described to date. We have made a comparison between SIMS and TIMS for the concentration measurement of uranium and thorium by IDMS. The chemical procedures for the separation and measurement by TIMS of U and Th have already been established (1) and provide a baseline against which SIMS results can be compared. We have analyzed oyster tissue and prepared samples that were split and analyzed by the two techniques.

The chemical procedure consists of spiking with ^{233}U and ^{230}Th , wet ashing, and anion exchange separation of the U and Th from the matrix and each other. The samples were dried onto a pyrolytic graphite substrate for SIMS analysis. No difficulty was encountered in generating adequate signal for the nanogram amounts of U and Th that were loaded from the samples and the picogram amounts from the blanks. The spectral background was less than a few counts per second and the samples were not exhausted during measurement. Three or four independent ratio measurements were made from different regions of each dried deposit. The variance in the ratio measurement for a set of ratios on a single spot did not significantly exceed that from counting statistics. However, the spot-to-spot variability was larger than would be from counting statistics alone for most of the samples. The results are shown in Table I.

Table 1. Isotope Dilution Results, SRM 1566a.

	Uranium (ng/g)		Thorium (ng/g)	
	SIMS	TIMS	SIMS	TIMS
OT-1	128 24	129.60	33.30	33.33
OT-2	129 91	-	35.59	-
OT-3	130 96	129.65	42.21	42.39
OT-5	-	130.03	-	32.74
OT-6	-	128.82	-	33.80
Blank-1	10.0 pg	-	43 pg	-
Blank-2	-	9.7 pg	-	176 pg

The agreement between SIMS and TIMS is about 1% or better. It can be concluded that neither technique has difficulty making quantitative measurements down to the chemical blank level. For Th the TIMS measurements near the blank level are hindered by a loading blank problem--Th that is in the Re filaments used in the measurement. The ratio of Th loading blank to sample Th increases with temperature and thus, lower temperatures (lower signals) were deliberately used. This problem seems to be readily avoidable with SIMS since the substrate material is basically inert in the measurement. The Th results illustrate the greater variability of concentration that can be expected among samples at the ultratrace level. The OT-3 concentration was significantly higher than the other samples. Although initially tempting to ascribe this result to contamination at some point before the mass spectrometry, neutron activation analysis of this same material confirms a relatively large between bottle variance for this material.

Resonance ionization provides elemental selectivity which is extremely useful when isobaric interferences are limiting in the measurement. It is not so surprising that number of IDMS-RIMS investigations are small, considering the limited number of RIMS instruments. We have applied our RIMS instrument to extensive Os/Re isotopic measurements (2). We have recently determined iodine in oyster tissue using RIMS. It is instructive to compare the technique with IDMS-TIMS procedures that have been applied in the past in our laboratory (3).

The oyster tissue samples were spiked with ^{129}I , wet ashed under controlled conditions, and separated by coprecipitation with silver chloride. For RIMS the analyte was dried as silver ammonium iodide upon a single tantalum filament from which iodine was thermally desorbed in the RIMS instrument. A single-color, 2-photon resonant plus 1-photon ionization scheme was used to form positive iodine ions. Long-lived iodine signals were achieved from 100 ng of iodine.

The ratio measurement precision for RIMS was 1.0% as determined from replicate measurements of the spike, the spike calibration samples, and the oyster tissue samples and was 1.0%. Measurement precision among samples was 1.9% for the spike calibration and 1.4% for the oyster tissue. TIMS results for SRM Powdered Milk at comparable concentrations to the oyster tissue (PM, 3.376 ppm; OT, 4.444 ppm) demonstrated 0.15% precision among samples. The blanks were higher in the TIMS experiment, 45 ng, relative to the RIMS experiment, 11 ng. However, this cannot be ascribed to the differing mass spectrometric techniques.

These RIMS measurements did not exploit the selectivity of the photo-ionization process. However, the sensitivities of RIMS and TIMS were comparable and, again, the limit was the chemical blank. The precision of RIMS was a factor of 10 poorer than TIMS. However, the IDMS-RIMS precision was still a factor of 10 better of the second technique to be used in the certification, neutron activation analysis. We felt that the RIMS was advantageous relative to TIMS in two ways, both related to the thermal, triple-filament procedure. First, we avoided the need to prepare and condition the LaB_6 ionization filament--RIMS was simpler in sample loading. Second, we avoided heating the source to 1000°C --memory effects, a problem for iodine, could be more easily controlled.

RIMS APPLIED TO ENVIRONMENTAL AND NUCLEAR RESEARCH

L. Schweikhard and H.-J. Kluge

Inst. f. Physik, Universität Mainz, P.O.Box 3980, 6500 Mainz, FRG

Laser resonance ionization mass spectroscopy (RIMS) is used in a variety of spectroscopic schemes which allow the study of optical resonances with high sensitivity, selectivity and resolution. It is well suited for the detection, identification and investigation of small amounts of material. Therefore RIMS is in many cases the method of choice for trace analysis as, e.g., for environmental studies, and in nuclear research as for the determination of nuclear ground-state properties [1].

1. Introduction

RIMS is based on stepwise, resonant excitation of atoms or molecules with laser light followed by photo-ionization. This process is called resonance ionization spectroscopy (RIS) [2,3]. The selectivity of this technique can be increased by mass spectrometry of the ions created in the optical resonance.

The sensitivity of this method is affected by a couple of factors:

- The efficiency of the source for production of free, neutral atoms
- The initial occupation probability of the atomic ground state
- The spatial overlap of the atomic beam with the RIS laser beams
- The temporal overlap of the atomic beam with the RIS laser beams
- The excitation probabilities of the RIS path
- The transmission of the mass spectrometer
- The efficiency of ion detector
- The nuclear half live in case of the investigation of short-lived nuclei.

The overall detection efficiency can be defined as the ratio of the ions detected in resonance by the ion detector to the number of atoms in the sample under investigation. It is given by the product of all the factors listed above. A low detection limit requires an optimization of each factor.

The overall selectivity is given by the product of the selectivity of each resonant excitation step and the resolving power of the mass spectrometer. The latter is typically of the order of 10^3 . The former can be estimated by comparing the density of the atomic levels (about one per eV) with the line width generally given by the Doppler broadening (about 1 GHz). Therefore the selectivity can be estimated to be of the order of 10^5 per resonant excitation. This gives an overall selectivity of about 10^{13} for a two-step excitation followed by mass spectrometry.

In the following three experiments will be described having RIMS as an essential ingredient: The first one concerns the study of nuclear ground-state properties of unstable Au and Pt isotopes; the other two are trace-analysis experiments for the detection of Pu and Tc and ^{89}Sr , ^{90}Sr in the environment.

2. Ground-state properties of gold and platinum

The nuclei near $Z=80$ and $N=104$ have attracted considerable attention following the discovery of a big change in the ground-state mean-square charge radius between ^{187}Hg and ^{186}Hg , which was interpreted as an onset of strong deformation at $A \leq 185$ [4]. A measurement of the isotope and/or isomer shift represents the most straightforward and model-independent signature for shape transitions or shape coexistence. A RIMS experiment was designed to determine the isotope shifts of short-lived Au and Pt isotopes, the neighbours of Hg in the periodic table of elements. Since no target ion-source system existed at the on-line mass separator ISOLDE at CERN for a direct production of these isotopes, they had to be obtained as daughters of Hg isotopes, which can be produced with yields up to 10^{10} atoms per second and mass number by a $\text{Pb}(p,3\text{pxn})\text{Hg}$ spallation reaction. Because of the short half-lives and the small production rates of the isotopes far from stability, the investigations had to be performed in an on-line mode. The Hg ion beam was implanted into a graphite wheel. After the Hg isotopes had decayed into Au or Pt these were desorbed by a pulsed Nd:Yag laser to create a pulsed atomic beam. The atoms were excited and photo-ionized via a 3-colour, 3-step resonant process by the light of three tunable dye lasers pumped by a second Nd:Yag laser. In case of Pt, the frequency-doubled output of the same Nd:Yag laser was used for the last step. In order to increase the signal-to-noise ratio, the photo ions were detected and mass-selected by a time-of-flight (TOF) spectrometer using an ion reflector. A background counting rate of typically one event per 1000 laser pulses was observed.

The overall detection efficiency has been determined to be $3 \cdot 10^{-5}$ (defined as the ratio of ions detected by the mass spectrometer to the number of atoms collected on the wheel). This represents an increase in efficiency by a factor of about 1000 compared to the use of an oven producing a continuous atomic beam.

With this technique the hyper fine structure and isotope shift of the short-lived, neutron-deficient isotopes ^{184}Au and ^{183}Au as well as of Pt down to ^{183}Pt have been measured [5,6].

3. Trace analysis of plutonium and technetium

Another way to reach a high temporal overlap of the RIS laser beams with the atomic beam is to use a laser with high repetition rate ν_{rep} . Since a thermal ion traverses the region of interaction with the laser light within about 10^{-4} s the duty cycle comes close to unity for $\nu_{\text{rep}} = 10 \text{ kHz}$. This strategy was followed up at Mainz for trace analysis of Pu: One or two Cu-vapour laser ($\nu_{\text{rep}} = 6.5 \text{ kHz}$) pump two or three dye laser. As in the Au/Pt experiments, the interaction takes place in the acceleration region of a TOF spectrometer. Pu samples containing between 10^{10} and 10^{12} atoms of ^{239}Pu electrolytically deposited on a Re filament have been investigated. From these experiments an overall detection efficiency of $4 \cdot 10^{-6}$ has been determined.

Plutonium is one of the most serious radioactive poisons in the environment. Therefore very sensitive and selective methods are required to study the ecological behaviour and migration in the environment. The detection efficiency corresponds to a detection limit of about 10^7 Pu atoms in the sample, which is 40 times more sen-

sitive than α -spectroscopy [7,8]. This method has been applied to technetium at a similar level of sensitivity ($2 \cdot 10^{-8}$). The detection of extremely small amounts of technetium is also important in connection with the measurement of the high-energy solar neutrino flux via ^{98}Tc formed in molybdenum ores. In test experiments, samples down to 10^8 atoms of technetium could be measured. Furthermore it has been demonstrated that molybdenum is suppressed by a factor of $5.2 \cdot 10^{-8}$ at the technetium resonance [9].

4. Trace analysis of ^{89}Sr , ^{90}Sr

The trace analysis of ^{89}Sr and ^{90}Sr is very important in the evaluation of nuclear reactor accidents. Since the conventional ^{90}Sr -determination takes at least one week, a fast but also sensitive method is required. This method must be extremely isotope-selective because of the large surplus of stable Sr isotopes. The set up currently constructed at Mainz aims at a detection limit of 10^8 radioactive atoms in 1 mg natural strontium. Therefore an isotopic selectivity of almost 10^{11} is required. This will be achieved by the combined application of different techniques: Depletion of stable Sr in the sample by use of a medium-current isotope separator, production of a 50 keV-ion beam by surface ionization, mass separation, neutralization by charge exchange in collinear geometry and RIS. The most important step in this experiment will be the use of collinear spectroscopy [10]. The mass-separated ion beam will be neutralized in a Cs gas cell and the atoms will be ionized again by RIS. Using the collinear beam technique the resonances are Doppler shifted in dependence of the mass of the isotopes leading to an isotope separation of the order of some GHz. Furthermore the Doppler broadening is largely reduced. Using cw laser an extreme resolution of $\Delta\nu/\nu = 10^{-8}$ has been achieved [11]. A selectivity of the order of 10^8 to 10^9 is expected. Adding the previous mass separations and a further selectivity by depletion of the unwanted stable Sr by optical pumping the overall selectivity will be sufficient for the measurement of $^{89,90}\text{Sr}$.

The examples given show that RIMS is a valuable and in many cases indispensable technique in environmental and nuclear research.

Synthetic Silicon Isotope Mixtures for
Absolute Isotope Abundance Ratio Measurements

G. Lenaers, Antwerpen University, B-2610 Wilrijk-Antwerpen, Belgium
T.J. Murphy, National Institute of Standards and Technology,
Gaithersburg, MD 20899, USA
S. Valkiers, P. De Bièvre, Central Bureau for Nuclear Measurements,
CEC - Joint Research Centre, B-2440 Geel, Belgium

An isotope abundance ratio measurement is called absolute when it is based on a calibration by means of quantitatively synthesized mixtures of chemically purified highly enriched isotopes. The isotope (i) ratios R_i thus obtained yield an absolute atomic weight A_r when combined with the nuclidic masses M_i of the element under study using the formula :

$$A_r = \frac{\sum_{i=1}^n R_i M_i}{\sum_{i=1}^n R_i}$$

The atomic weight of a nearly perfect Silicon crystal, $A_r(\text{Si})$, resulting from this study, is used in a redetermination of Avogadro's Constant N_A according to the formula :

$$N_A = \frac{A_r(\text{Si})}{\rho \cdot a_0^3/n}$$

This redetermination is a joint PTB-CBNM effort where PTB stands for Physikalisch Technische Bundesanstalt, FRG and CBNM for the Central Bureau for Nuclear Measurements, Belgium.

The representative isotopic composition of natural Silicon is given as follows : ^{28}Si , 92.23%; ^{29}Si , 4.67%; ^{30}Si , 3.10% [1]. The isotope ratios $^{29}\text{Si}/^{28}\text{Si}$ and $^{30}\text{Si}/^{28}\text{Si}$ are then respectively 0.050 6 and 0.033 6.

The enriched Silicon isotopes, needed to prepare the synthetic mixtures, are delivered by Oak Ridge National Laboratory in the Silicon dioxide, SiO_2 , form. The "Silicon 28 isotope" is over 99.5% enriched and both "the 29 and 30 isotopes" have an enrichment of over 96%. These SiO_2 materials are converted into Cesiumhexafluorosilicate, Cs_2SiF_6 , the precursor compound. It is from these compounds that portions are withdrawn for gravimetric mixing, for assaying and for impurity determination. The Cs_2SiF_6 mixtures are converted into Bariumhexafluorosilicate, BaSiF_6 , that releases Silicontetrafluoride, SiF_4 , on heating. SiF_4 allows the most precise Silicon isotopic measurements. The flow diagram of the chemistry is shown in Fig. 1. The Cs_2SiF_6 compound will be discussed in more detail. Note that a part of the enriched Cs_2SiF_6 's is converted to BaSiF_6 directly to allow the measurements of their Silicon isotopic composition. The natural samples, of high purity, are also converted to BaSiF_6 .

For a needed total uncertainty, from chemistry and abundances of the enriched isotopes, of around 5×10^{-4} on the ratios of the mixtures the uncertainty due to the chemistry i.e. assay, impurity determination and mass determination, should not exceed 1×10^{-4} for each of these three components. As a consequence, the precursor compound, Cs_2SiF_6 , must have, and indeed has, some unique properties :

- it attains a stable mass when dried at 300°C

- it gains only 0.008% in mass when the relative humidity is varied from 0 to 80%
- its solubility can be reduced by lowering the temperature of its aqueous HF solution and by addition of ethanol. CsF is more soluble and does not cause problems
- it is convertible to BaSiF₆ by adding BaCl₂ to its hot aqueous HF solution
- it can be accurately weighed to a few µg, in a range of a few g to 0.2 g, in a controlled atmosphere
- it can be examined for impurities by spark source mass spectrometry
- it is crystalline with an average crystal size of 2 µm
- and the inclusions in the crystals are limited and removable on heating at 300°C.

Fig. 1

The Cs₂SiF₆ compound is prepared out of the SiO₂ enriched isotope by taking this in solution with high purity HF. The solution of 0.25 M H₂SiF₆ in 0.5 M HF thus obtained is filtered and purified on a strongly acidic cation exchange column (BioRad 50W x 8, 100-200 mesh). The Cs₂SiF₆ is precipitated by adding Cesiumchloride, CsCl. Finally, the Cs₂SiF₆ is reprecipitated, filtered and dried at 300°C.

Two synthetic mixtures are prepared and they bracket the natural (WASO 17.2 crystal) ratios as shown in Table 1.

	$^{29}\text{Si}/^{28}\text{Si}$	$^{30}\text{Si}/^{28}\text{Si}$
MIX 1	- 0.284%	- 2.862%
MIX 2	+ 1.659%	+ 2.604%

Table 1

The results of assay, impurity determination and mass determination of the enriched Cs_2SiF_6 's together with 2s uncertainties are compiled in Table 2.

Enriched Material	Assay		Impurity determination		Mass determination	
	Result (%)	Unc. (%)	Result (ppm)	Unc. (ppm)	Approx. mass (g)	Unc. (μg)
$\text{Cs}_2^{28}\text{SiF}_6$	99.996 2	0.002 4	13	50	1.400	5
$\text{Cs}_2^{29}\text{SiF}_6$	6 5	3 6	37	50	0.070	2
$\text{Cs}_2^{30}\text{SiF}_6$	4 8	1 2	30	50	0.045	2

Table 2

The resulting 2s uncertainty contributions, from the chemistry and the abundance determination of the enriched isotopes, on both ratios of e.g. synthetic mixture 2 are expressed in 10^{-5} in Table 3. Those resulting from the chemistry are considerably smaller than the 10^{-4} requested.

Ratio	Total	Mass spec.	Assay	Impurities	Mass determinations
$^{29}\text{Si}/^{28}\text{Si} :$ $5.155\ 3 \times 10^{-2}$	62.7	62.5	2.0	2.1	2.7
$^{30}\text{Si}/^{28}\text{Si} :$ $3.433\ 4 \times 10^{-2}$	37.6	37.3	2.0	2.1	4.0

Table 3

Using these synthetic mixtures an absolute atomic weight of a Silicon single crystal (WASO 17.2) is determined as 28.085 382 with a 2s uncertainty of 1.67 ppm.

This atomic weight and uncertainty are used in a redetermination of Avogadro's Constant N_A .

FACILITATING DESORPTION OF MULTIPLY CHARGED IONS

Kelsey D. Cook and Johnny D. Reynolds, Department of Chemistry,
University of Tennessee, Knoxville, TN 37996-1600.

Mass spectrometry of multiply charged ions has grown in importance both from intrinsic interest in obtaining confirmatory evidence for theoretical predictions of cation and anion stability, and for more immediately practical advantages offered by the potential for extending instrumental mass range through reduction of m/z . The high energies accessible for multiply charged ions with ordinary accelerating potentials also present interesting possibilities, particularly in the context of high-mass MS/MS.

Although there are instances of multiple ionization of both gas-phase and solid-phase samples (including field and plasma desorption), most approaches successful in M.S. sampling of multiply charged organic cations and anions have exploited the facile ionization of polar materials in solution (e.g., thermospray, electrospray, electrohydrodynamic, and, occasionally, fast atom bombardment). This reliance on solution chemistry provides an opportunity for fundamental studies of ion-solvent systems and sampling mechanisms [1,2], but can complicate optimization and spectral interpretation, especially for true "unknown" samples. Even in simple model systems, a choice must often be made between optimum overall sensitivity and optimum sensitivity for multiply charged ions. Of course, the more experimental parameters available (e.g., primary beam or spray interface parameters), the more complex the job of optimization. Reasoned effort at optimization can make orders-of-magnitude differences in sensitivity.

Among the solution chemical factors affecting sensitivity to multiply charged ions are ion pairing, solvation/desolvation, and redox chemistry. The first two can be seen to interact in the electrohydrodynamic (EH) MS of the diquatery ammonium ion M^{2+} in glycerol solutions containing various sodium salts as supporting electrolyte [3].

There is a direct correlation between the overall sensitivity to M^{2+} and the intensity ratio $i(MX^+)/i(M^{2+})$, where the numerator is the intensity of the ion pair involving M^{2+} and the anion X^- . Here, the reduced solvation of the ion pair results in increased sampling efficiency; overall sensitivity is increased when the abundance of multiply charged ions is reduced by employing a counterion that pairs extensively in glycerol (e.g., NO_3^-). Of course, pairing of singly charged ions (e.g., $(\text{CH}_3)_4\text{N}^+$) reduces sensitivity by depleting "pre-formed" ions in solution. This is evident even in FAB spectra (Table 1), despite the complications introduced by atom bombardment (*vide infra*).

The effect of solvation is also evident when comparing spectra obtained from a mixture of M^{2+} and $(\text{CH}_3)_4\text{N}^+$, with the ESA set to pass either ions with full acceleration energy, or ions with lower energy [4]. In the latter case, dications dominate. Due to relatively strong solvation, they are sampled with their solvation sphere partially intact; subsequent in-flight desolvation reduces ion kinetic energies. This effect accounts at least in part for the greater success of electrospray and thermospray experiments employing quadrupole, rather than sector, instruments.

When multiply charged ions are generated by ion association (rather than salt dissociation) in solution (as in most electrospray experiments), charge may be enhanced by selecting a thermodynamically preferred cation for attachment. For example, both poly(ethylene glycol) [5] and 18-crown-6 [6]

show a strong preference for potassium relative to other alkali metals.

Efforts to sample multiply charged ions can be frustrated by electrochemical reduction. This can result both from intrinsic solvent chemistry (e.g., the quantitative reduction of $\text{Ru}(\text{bpy})_3^{3+}$ to the corresponding $\text{Ru}(\text{II})$ complex by solvent glycerol [7]), and from beam-induced reduction (e.g., the further reduction of the $\text{Ru}(\text{II})$ complex to $\text{Ru}(\text{I})$ in FAB [8,9]). In the latter case, the extent of reduction can be mitigated [10] by employing a matrix with improved radical scavenging capabilities (e.g., m-nitrobenzyl alcohol, Figure 1), by reducing beam flux (Figure 2), and/or by increasing beam energy.

Comparison of EH, FAB, field desorption, and thermospray MS of the divalent cation of tubocurarine [2] suggests that high fields in the ionization region (either applied, as in EH; or self-developed during field evaporation, as in electrospray and thermospray) facilitate sampling of dications. This may account in part for the recent remarkable advances in high-charge electrospray MS, and for the ability of EH MS to sample doubly negative ions without fragmentation or oxidation. Due to the absence of perturbing effects from bombardment or droplet evaporation, EH spectra generally reflect relative solution equilibria in comparing similar systems. Note, for example, the reflection of relative pK_a s in comparing the spectra of Indigo Carmine and Bromcresol Green (Table 2)

SOME MASS SPECTROMETRIC IMPLICATIONS
OF MULTIPLY CHARGED IONS

M. Mann, C. K. Meng, S. F. Wong and J. B. Fenn
Department of Chemical Engineering
Yale University, New Haven, CT 06405

In the past few years non-traditional techniques including Field Desorption (FD), Plasma Desorption (PD), Fast Ion Bombardment (FIB or SIMS), Fast Atom Bombardment (FAB), Electrohydrodynamic (EH), Aerospray (AS or APIE), Thermospray (TS) and Laser Desorption (LD) ionization have been able to produce unfragmented molecular ions from parent species of ever increasing size and complexity. Along with this increase in ion size has been an increase in ion charge. Even so, because the ions with more than one charge are usually in the minority, mass spectrometrists still tend to think almost entirely in terms of singly charged ions. In the last year large ions with extensive multiple charging have begun to demand more attention because Electrospray (ES) ionization has shown a remarkable ability to produce them in great abundance. Here we call attention to some emerging aspects multiple charging that seem at once interesting and important.

1. Formation. Although there is no unanimity as to the ion formation process that seems to be shared by ES, AS and TS the most widely accepted mechanism assumes that an already existing ion is desorbed from a droplet by an electric field whose strength is determined by the density of charge on the droplet's surface. The solvation forces binding that ion to the droplet surface are roughly proportional to its size. The lifting force required for desorption is proportional to the number of its charges. Ergo, the bigger the ion the more charges it must attach in order to become desorbed and observable. In sum, multiple charges are not only consequent to ES ionization of big molecules they are responsible for it. A corollary of this desorption model is that the greater the initial charge/mass ratio in a newly formed droplet, the greater are the charge multiplicity and the size of the ions that can be formed ions, the efficiency of forming them and, therefore, sensitivity of species detection. ES achieves higher charge multiplicity and analytical sensitivity than either AS or TS because its initial droplets have a higher charge/mass ratio. It follows that any attempt to "assist" ES atomization of sample liquid, e.g. by thermal or aerodynamic forces, is in this perspective counter-productive because it inevitably decreases the charge/mass ratio of the initial droplets. To date, experience seems to confirm these conjectures.

2. Mass Analysis. Because most mass analyzers measure m/z , the mass/charge ratio, of the ions they process, multiple charging extends their effective mass range by a factor equal to the number of charges per ion. Thus, ions with molecular weights up to 130,000 have been analyzed with quadrupole mass filters whose nominal upper limit for ion mass is around 1600 daltons. Indeed, all the evidence thus far strongly suggests that for the reasons already mentioned, m/z values for the largest ions that can be produced by desorption from droplets will never be more than 4 kDa or so. It seems to follow that high resolution should have a higher priority than high mass capability in evaluating an

analyzer. Therefore, a marriage between an ES source and an FTICR analyzer would seem to be made in a mass spectrometrists' idea of heaven. Because of their modest m/z values, ES ions of the largest mass would have the high cyclotron frequencies that make for high resolution and reduced residence time requirements. Moreover, ions with a large number of charges moving at high velocity would induce a large signal in the detection circuit. In addition to the reduced residence time they would have a larger momentum than would singly charged ions having either the same mass or the same m/z . Therefore, their trajectories should be less perturbed by collisions with background molecules than would singly charged ions of the same mass or the same m/z . Consequently, multiple charging may relax the requirement for ultrahigh vacuum that has been the bane of ICR mass analysis. The problems of transferring ions from ES source to an ICR cell remain to be solved but do not seem overwhelming.

Charge multiplicity in ES ions is always accompanied by peak multiplicity in their mass spectra. It turns out that each of the peaks is an independent measure of parent ion mass. Therefore, one can in effect "signal average" over those peaks and substantially increase the precision and confidence with which one can assign a mass value to the parent ion. The methods and advantages of such averaging will be set forth in some detail elsewhere. (1) Meanwhile, recent work in our group suggests that this peak multiplicity may also provide an intrinsic calibration of the analyzer's mass scale.

3. Detection. Very large singly charged ions have been known to present detection problems because they may require awkwardly high accelerating voltages to produce secondary electrons from a multiplier dynode. Because it's all a matter of m/z , the multiply charged ions from ES sources have been readily detected without significant post acceleration no matter how high their mass. Even so, problems arise for quantitative analysis because we do not yet know the dependence of secondary electron yield on the charge multiplicity, structure and incident energy of large ions. Further complications loom when one contemplates the very exciting possibilities of MS-MS with multiply charged ions. Upon collisional dissociation a singly charged parent ion is inevitably uniparous but a multiply charged parent can give birth to several daughter ions. Thus, information on composition and structure can be accumulated at a much greater rate from parent ions with multiple charges. Early results including those presented at this meeting are promising but suggest that challenging problems must be solved before MS-MS with multiply charged ions can become a routine procedure. One of them is to find methods for determining z for a fragment ion so that its mass m can be obtained from the m/z information provided by the second analyzer. Another is to develop software capable of processing and interpreting the veritable torrent of data that will result from MS-MS analysis of large multiply charged ions.

Tandem MS of *singly charged* molecular ions greater than ~3,000 dalton is generally precluded due to inefficient ionization and, most importantly, insufficient collisional excitation to promote dissociation on the observational time scale (10^{-6} to 10^{-3} s). Electrospray ionization (ESI) has been shown to efficiently produce multiply charged molecular ions of biopolymers¹ of at least 130 kDa.² Recently, we demonstrated that CID spectra can be obtained for multiply protonated molecular ions of mellitin (Mr 2,846), yielding extensive sequence information.³

We have observed that the internal energy (E_i) of macromolecular ions can be adjusted over a broad range by varying an electric field on the vacuum side of the sampling orifice. Tandem mass spectra were obtained with a triple quadrupole instrument using an atmospheric pressure ESI source.^{2,3} The ($M + 15H$)¹⁵⁺ molecular ions of cytochrome c (m/z 825) were selected. Increasing the bias of the orifice related to the first focusing region results in frequent low energy collisions, allowing molecular ions of $m/z < 1,000$ to be heated to (quasi-thermal) E_i sufficient to result in complete dissociation. Figure 1 shows attenuation ($\log I/I_0$) vs. collision gas thickness (T_g) for internally "cold" and "hot" molecular ions at three different translational energies (E_t). Cold cytochrome c molecular ions require $T_g > 1 \times 10^{14}$ cm⁻² before substantial dissociation (> 1%) is observed; in contrast, at this T_g more than 95% of the "hot" ions have dissociated. CID cross sections for hot ions (from the linear regions of Figure 1) are $\sim 10^{-13}$ cm², while they are negligible for cold ions. Clearly the cold molecular ions require numerous collisions before CID can occur, whereas hot ions (collisionally excited in the interface) require few additional collisions.

Figure 2 compares CID spectra for different E_i and a laboratory frame E_t of 1500 eV, or 4.84 eV center of mass frame. Remarkably, for cold ions a significant peak is observed at $\sim m/z$ 773 (consistent with the 16+ molecular ion), probably due to charge stripping. Negligible fragmentation is observed, consistent with Figure 1. Since only a fraction of the center of mass energy is converted to molecular ion E_i , it appears that no single collision provides sufficient excitation for dissociation until high E_i values are reached. The "warm" and "hot" ions show 80% and 99% dissociation, respectively, with extensive fragmentation observed across the spectra. Noteworthy fragments from hot molecular ions are the iron-porphyrin complex ($m/z \sim 617$) and numerous peaks at low m/z .

The present results have profound implications for the extension of practical tandem MS to large molecules. Multiply charged ions allow relatively high E_t to be obtained, even in quadrupole mass spectrometers. Additionally, the ESI-vacuum interface provides a high pressure region where collisional heating (to arbitrarily large E_i) is obtained without creating a large E_t spread that would degrade spectrometer performance. In light of these developments, we propose that the limitations of tandem MS are more accurately defined by $m/z < 3000$ (rather than $m \leq 3000$ dalton).

Department of Chemistry
College Station, TX. 77843

INTRODUCTION

The specific issue that is being addressed in this study is to determine what factors influence the formation of higher charge gas phase protein molecular ions. In particular, a comparison is made of the conditions for ion formation by the electrospray method vs. the ^{252}Cf -PDMS technique. We shall first look at protein ionization and ion pair interactions in solution and will postulate what happens to the ion pairs when the solution becomes an evaporating aerosol. We then shall then continue the analysis to what happens to the ion pairs when a thin solid film of the protein is formed and subjected to vacuum conditions. Finally, using as a guide, experimental observations from ^{252}Cf -PDMS measurements, we shall determine the fate of the protein ion pairs in the solid state when the matrix is subjected to an intense energy pulse, e.g. the energy deposited by a nuclear fission fragment.

CHARGE STATES OF PROTEINS IN SOLUTION

The degree of protonation of a protein in solution is dependent on pH and the number of charged residues in the protein. For the formation of positively charged species, the three basic amino acids (arginine, lysine, and histidine) are the major sites of protonation. At physiological pH, the more acidic amino acids (aspartic and glutamic acid) are negatively charged so that most proteins have only a small positive or negative charge. Within the vicinity of the charge sites, there is a corresponding counter ion and both the charged site and counter ion are surrounded by a solvation sphere which shields the ion pairs to such an extent that the counter ions are fairly mobile.

CHARGE STATES OF PROTEINS IN THE GAS PHASE (ELECTROSPRAY)

In the process of the formation of a protonated gas phase ion, at least one of the ion pairs associated with the three basic residues must separate as ions rather than as a neutral species. The two competing gas phase reactions: $\text{R-NH}_3^+ \text{X}^- \rightarrow \text{R-NH}_3^+ + \text{X}^-$ and $\text{R-NH}_3^+ \text{X}^- \rightarrow \text{R-NH}_2 + \text{HX}$ determine whether a particular site protonated in solution will also be a protonated site in the gas phase molecular ion contributing to its overall charge. One of the remarkable aspects of the electrospray results is that the final charge state strongly correlates with the number of basic residues in the protein. This means that in the evaporation of the microdroplets, the ion pair dissociation favors the first reaction, the separation into two separated ions even in a sequence of dissociations where the residual protein is gaining a higher charge. This is not the case for ^{252}Cf -PDMS.

CHARGE STATES FOR PROTEINS IN THE GAS PHASE (^{252}Cf -PDMS)

The charge state distributions for protein molecular ions formed by ^{252}Cf -PDMS are in general

much smaller. In the 5000 - 10,000 u region, the singly-protonated ion dominates but there is a small doubly-protonated component. For proteins in the 13,000 -20,000 u range, the singly-charged component is small and the degree of protonation extends to as high as 4 protons. The charge distribution is matrix dependent. Results obtained for insulin adsorbed on polyethylene terephthalate show only the singly-protonated species while the spectrum for insulin adsorbed on nitrocellulose shows a significant doubly-protonated ion.

ROLE OF ION-PAIR DISSOCIATION

We shall now examine some of the reasons as to why there is such a difference in the charge state distributions for the two methods. There are obviously differences in the ion-pair dissociation reactions with the electrospray ionization favoring charge separation to a higher degree of protonation. One of the reasons for this is that in the evaporation of the microdroplet, the ions retain their solvation sphere for a longer period of time which means that the ions are farther apart in the beginning stages of the ion-pair dissociation. It is easier for a solvated ion-pair to dissociate into separated ions. In ^{252}Cf -PDMS, however, the protein is in the solid state. Much of the solvation sphere is lost due to evaporation and the ion-pairs are more tightly bound to each other. It is more difficult to form separated ions and the alternative reaction, proton transfer to the counter ion resulting in the formation of a separated neutral pair, plays a more important role. Thus, the final degree of protonation is much less.

There is also an additional factor relating to the degree of internal excitation of the protein and the instability of higher charge states for excited molecules. For the electrospray ionization, the degree of internal excitation is extremely low whereas for ^{252}Cf -PDMS, the energy dissipation from the fission track can easily transfer energy to the protein molecule. A measure of the stability of multiple charges within a polymer is a property called the Debye shielding length. When the internal excitation of the polymer is low, the Debye shielding length is small and the polymer can accommodate a higher number of charges. The number decreases as the internal energy of the polymer increases. This is another reason why the charge state distribution for protein molecular ions in ^{252}Cf -PDMS is smaller.

ROLE OF MATRIX IN CONTROLLING DEGREE OF INTERNAL EXCITATION IN ^{252}Cf -PDMS

The major way that the degree of internal excitation can be controlled in ^{252}Cf -PDMS is through the modification of the substrate. The crucial feature is the coupling of the substrate to the protein. For a highly hydrophobic surface such as poly(ethylene terephthalate) the protein is strongly bound through the hydrophobic domains that reside on the surface of the protein. When this matrix is excited, a considerable amount of energy is coupled into the protein through the substrate/adsorbate link. This results in a broad spectrum of metastable ions, a weak molecular ion and no doubly charged ion. If a nitrocellulose matrix is used, the metastable component is considerably reduced, the singly-protonated molecular ion intensity increases by a factor of 6 and a doubly protonated species appears. If the substrate is a loose assembly of small molecules, a similar pattern is observed and the internal excitation of the protein is still smaller.

MULTIPLY CHARGED NEGATIVE IONS: A CRITICAL REVIEW

R. N. Compton

Oak Ridge National Laboratory, Oak Ridge, Tennessee, 37831-6125
and The University of Tennessee, Knoxville, Tennessee 37996

Most elements in the periodic chart can accommodate an extra electron to form a stable negative ion. Only a few elements (some exceptions are rare gas atoms, Be and Mg) cannot permanently bind an excess electron. The electron affinities for the great majority of molecules lies in the region between -2 eV (unbound state) to +4 eV. On the other hand, all atoms and molecules can accept an additional electron for fleeting periods of time (milli-sec to femto-sec) in the form of compound states or resonances. For example, an electron can be temporarily bound to an atom via a shape or Feshbach resonance. These states are seen as resonance features in electron-atom scattering cross sections or as autodetaching (metastable) ions in beam experiments. Some of these metastable ions can live for many micro-seconds [e.g. $\text{He}^-(1s2s2p)^4\text{P}$] and have served as useful ionic species in accelerator applications. Much is known and understood about the structure of singly charged negative ions of atoms and small molecules. On the other hand, very little is known about multiply charged negative ions.

The Milliken oil-drop experiment amply demonstrates that multiply charged objects can exist as stable or metastable entities. Thus, it is natural to ask, "How *small* an entity is capable of binding two extra electrons?... can an atom, in particular, form a long-lived doubly charged negative ion?" Doubly-charged atomic negative ions were first reported in 1960.⁽¹⁾ Since that time there have been many claims of observations of multiply-charged atomic and molecular negative ions using a variety of mass spectrometers (omegatron, ICR, magnetic sector, quadrupole, etc.).⁽²⁾ There is considerable evidence for the existence of long-lived ($\gtrsim 1\mu$ sec) or stable multiply charged negative ions of large molecules. Most reports involve large molecular negative ions with electronegative groups as part of the molecule. The conventional wisdom is that electrons can reside in localized "spots" (electronegative groups) at sufficiently large distances within the molecule so as to minimize the Heitler-London repulsion energy. In all cases, the lifetimes of these gas-phase anions must be greater than a few micro-seconds in order to be detected with most mass spectrometers discussed in this talk.

Multiply charged anions are well known to exist in liquids and are stabilized by the surrounding medium. Therefore, it is not surprising that there are reports of doubly charged molecular anions from clusters in nozzles,⁽³⁾ ion spray,⁽⁴⁾ or electrohydrodynamic ionization,⁽⁵⁾ or field ionization from liquid surfaces.⁽⁶⁾ Very recently, doubly charged anions were detected by collisionally induced "ion-pair" formation from singly charged negative ions.⁽⁷⁾ Dissociation of negative ions (e.g. RN_3^-) into ion pairs (e.g. $\text{R}^{2-} + \text{Na}^+$) is also invoked in some electrodynamic studies. The first report of a doubly negative charged "large molecule" (dimer of benzo [cd] pyrene-6-one) is credited to Dougherty.⁽⁸⁾

Thermospray and ion spray mass spectroscopy at atmospheric pressure has proven most effective at producing multiply charged negative ions. The data suggests that multiply charged anions are produced primarily by evaporation in the ion spray and by both evaporation and gas-phase chemical ionization in the thermospray techniques. Covey *et al.*⁽⁴⁾ have used ion-spray mass spectroscopy to produce a synthetic DNA molecule with *eleven* excess electrons.

The evidence for short lived *atomic* negative ions is not so conclusive.⁽⁹⁾ Upper limits on the ratio of X^{2-} to X^- using various ion sources give values ranging from 10^{-7} ,⁽¹⁰⁾ 10^{-12} ,⁽¹¹⁾ to 10^{-16} .⁽¹²⁾ Many of the claims are not reproducible or are known to be flawed. Their possible existence carries the most practical significance since multiply charged atomic ions could be used to greatly extend the energy of tandem accelerators around the world.

Certain classes of hexafluoride molecules are known to possess electron affinities of up to ten electron volts.⁽¹³⁾ There is recent theoretical evidence that stable or perhaps metastable MF_6^{q-} ($q = 2, 3$) ions may exist. One interesting possibility is PtF_6^{2-} . Semi-empirical calculations of the enthalpy of formation of PtF_6^{2-} from a crystal lattice $[K_2PtF_6] \rightleftharpoons 2K^+ + PtF_6^{2-}$ yields an electron affinity for PtF_6^{2-} of 3.9 ± 0.6 eV.⁽¹⁴⁾ Recent SCF-MO and CI calculations⁽¹⁵⁾ on AuF_6^{q-} ($q = 0, 1, 2$, and 3) suggest that AuF_6^{2-} lies lowest [$EA(AuF_6) \simeq 9.6$ eV] in energy; however, the AuF_6^{2-} potential energy surface lies below that of AuF_6^- at the internuclear separation ($Au - F$) of AuF_6^{2-} . This result and other experimental observations suggest that hexafluoride molecules may accept more than one extra electron to form a long-lived or perhaps stable multiply charged negative ion. Aside from the importance to fundamental physics, the existence of stable or long-lived ions such as PtF_6^{2-} , UF_6^{2-} or AuF_6^{2-} would have great practical importance.

LC/MS/MS AND CZE/MS/MS DETERMINATION OF ENVIRONMENTALLY IMPORTANT COMPOUNDS, Jack Henion, and Per Olof Edlund, Drug Testing and Toxicology, Cornell University, 925 Warren Dr., Ithaca, NY 14850.

INTRODUCTION

Environmental samples pose very challenging problems because the analytes are often at trace levels in complex mixtures and cover a wide range of compound types. Historically, the non-polar, more volatile compounds have been targeted because these are amenable to established capillary GC/MS determinations. Capillary gas chromatography is very useful for its high separation efficiencies which facilitate separation of complex mixtures. Electron ionization is useful because it provides structural information which is helpful for characterizing the identity of unknown compounds. However, when the compound is either too polar or involatile to be amenable to GC/MS, serious analytical problems arise.

HPLC is a natural complement to capillary GC because the former can chromatographically separate many of the compounds not amenable to GC. However, without the combined sensitivity and selectivity of mass spectrometry, HPLC does not offer much help for identifying unknown compounds in environmental samples. The obvious answer to this problem is on-line LC/MS. However, most traditional approaches to LC/MS have produced chemical ionization mass spectra which are very simple and do not provide information useful for structural characterization. Tandem mass

spectrometry(MS/MS) can provide this additional structural information.

Typically MS/MS can provide mixture analysis capability and structural information via collision-induced dissociation(CID) of parent or fragment ions. Both of these features of MS/MS complement LC/MS. The mixture analysis capability is useful because HPLC does not provide the high separation efficiency available from capillary GC so HPLC peaks often have co-eluting components. Thus MS/MS mixture analysis in these instances is helpful. In addition, mild ionization conditions characteristic of most LC/MS systems benefits from the CID process which generates fragmentation patterns characteristic of the compound's structure and thus allows structural characterization. Thus it could be said that there is more reason to do LC/MS/MS than GC/MS/MS!

We have applied the technique of MS/MS on an atmospheric pressure ionization mass spectrometer(APIMS) for the study of a variety of polar, involatile compounds of environmental interest. These include, in particular, sulfonated azo dyes and phenoxyacetic acid herbicides. We have found that API LC/MS/MS is a viable, routine approach for detecting and characterizing these compounds in environmental wastewaters.

EXPERIMENTAL

A TAGA 6000E tandem triple quadrupole mass spectrometer (Sciex, Inc., Thornhill, Ontario, Canada) was interfaced to an ion spray LC/MS interface maintained at ambient temperature and -3kV which forms highly charged micro droplets in the vicinity of the API sampling orifice. The HPLC separations were often carried out with a Brownlee Micro Pump equipped with a 1mm x 15 cm microbore HPLC column packed with reversed-phase C18 packing with an eluent flow maintained at 40 microliters per minute through a gradient profile capable of providing a separation of the target compounds. Alternatively, conventional 4.6mm x 10cm columns of similar packing

material were used at one milliliter flow rates, but with a post column "T" which split the effluent about 20:1 to pass about 40-50 microliters per minute to the ion spray interface.

In addition to on-line LC/MS/MS the same ion spray interface may be used to couple capillary zone electrophoresis (CZE) to the mass spectrometer. Typically, 100 μ m x 50-75cm fused-silica capillary columns without a bonded stationary phase inside were used with the anode held at about 30kV and the cathode held at 3kV. The capillary was charged with appropriate aqueous ammonium acetate buffer with either methanol or acetonitrile to accomplish the separation. Both of these separation inlet systems could be used in the MS/MS mode.

RESULTS AND DISCUSSION

A variety of sulfonated azo dyes with as many as six sulfate groups were readily characterized using both LC/MS/MS and CZE/MS/MS. Solid phase extraction of fortified water and municipal wastewater following treatment were analyzed by LC/MS/MS in the negative ion mode. The APIMS system is very sensitive for these compound with 10pg detection limits in the SIM mode. In the single MS mode abundant deprotonated molecular ions are obtained with no evidence for fragment ions. Under LC/MS/MS conditions an abundant fragment ion at m/z 80 is observed in addition to weaker fragment ions at higher mass characteristic of the azo linkage and the parent dye. Quantitative analyses were carried out using an internal standard under LC selected reaction monitoring (SRM) conditions and showed that these compounds could be readily quantified by this approach.

CZE/MS/MS offers the same type of mass spectral information as that described above, but the separation efficiency provided by this inlet system is much greater than that obtained from HPLC. However, the low sample volume (5-15nL) injected in CZE makes it impractical for trace analyses where the sample amount is limited. However, it is possible that CZE could be the premier separation method for complex mixtures where low part per million or greater levels were available.

CONCLUSIONS

LC/MS/MS and CZE/MS/MS are both very useful for providing on-line separation and identification of polar, involatile components in complex environmental samples. The detection limits can be as good or better than typically found for GC/MS, and compounds can be characterized which would be impossible to handle by conventional approaches. There would appear to be a real need and a bright future for tandem mass spectrometry when it is combined with liquid inlet systems and mild ionization conditions applied to environmental problems.

APPLICATIONS OF TRIPLE QUADRUPOLE GC/MS/MS TO THE
DETERMINATION OF CHLORINATED DIBENZO-p-DIOXINS
AND DIBENZOFURANS IN COMPLEX ENVIRONMENTAL SAMPLES

E.J. REINER, D.H. SCHELLENBERG, V.V. TAGUCHI,

The analysis of chlorinated dibenzo-p-dioxins (CDD) and dibenzofurans (CDF) in complex matrices, which oftentimes contain chemical interferences at concentrations several orders of magnitude greater than those of the CDD and CDF, requires extensive sample cleanup prior to instrumental analysis. Limitations in sample cleanup place additional demands on the instrumentation.

The difficulties in the analysis of environmental samples make selectivity and sensitivity important considerations for the method of choice. Capillary column high resolution gas chromatography / high resolution mass spectrometry (HRGC/HRMS) has been the standard method for analyzing CDD and CDF in complex matrices such as sediments, effluents and biological tissues.

Until recently, tandem mass spectrometry (MS/MS) has been able to meet the requirements for selectivity but has been approximately one order of magnitude less sensitive than HRGC/HRMS methods. Optimization of tuning parameters using 1 ug of the analyte of interest in a direct insertion probe (DIP) [1] rather than PFTBA resulted in sensitivities comparable to the HRGC/HRMS technique reported previously [2]. Table 1: compares the limits of detection, reported in 1986, by three manufacturers of triple quadrupole mass spectrometers, using PFTBA or PFK for tuning, to the limits of detection that were obtained when dioxins and furans were used for tuning and to limits of detection obtained by HRMS. Most of the limits of detection obtained by the MS/MS dioxin tune method are between one and two orders of magnitude lower than when PFTBA or PFK is used for tuning and almost as low as those obtained by HRMS.

Collision induced dissociation breakdown graphs were used initially to optimize parameters such as collision energy and collision gas pressure. The breakdown graphs for PFTBA, 2,3,7,8-Cl₄DD and 2,3,7,8-Cl₄DF plotted vs. collision gas pressure are shown in Figure 1. The optimum collision gas pressure for the dioxin and furan was 3.3 mtorr while that for PFTBA was 0.7 mtorr. Figure 2: shows the breakdown graphs of PFTBA and four Cl₄DD congeners. The optimum collision energy for PFTBA was 25 eV while those for the dioxins were between 20 and 28 eV. The variation in optimum collision energy for the four Cl₄DD congeners implies that the relative response factors within a congener group are dependent on collision energy. Figure 3: shows the mass chromatogram of a mixture of three Cl₄DD congeners (1,2,3,4-, 2,3,7,8-, and 1,2,7,8-). Injection A was run with parameters set to optimize 2,3,7,8-Cl₄DD while injection B was set to optimize 1,2,3,4-Cl₄DD. As expected, the signal strength of 2,3,7,8-Cl₄DD was enhanced in injection A and the signal strength of 1,2,3,4-Cl₄DD was enhanced in injection B. In order to obtain reproducible relative response factors, a 2,3,7,8-containing (the most toxic) congener was chosen for each group. These are shown in Table 2.

Each probe sample was prepared by evaporating 1 ug standards of a furan and the corresponding dioxin with the same number of chlorines in the same sample cup. Each of the five cups (Cl₄DF/DD to Cl₈DF/DD) was inserted in turn into the mass spectrometer using the DIP and parameters such as collision gas pressure, collision energy, electron energy, lens voltages, quad offsets, etc. were optimized for both the furan and dioxin.

Another factor that increased the signal strength of the dioxins and furans was elevation of the source temperature to 250°C. This enhanced the signal strength of the congeners of higher chlorine substitution. Also, a high trap current (300 uA) and a Finnigan 4500 ion volume instead of the normal TSQ-70 ion volume was used to increase

the flux of the ionizing electrons into the ion source.

The advantages obtained by using the dioxin tune method include: good sensitivity - less than 1 picogram of dioxins and furans can be detected for all congeners; infrequent tuning - about 3 to 4 times a year @ 200 injections / month with source cleaning every six months; and selectivity - less cleanup is required because of the reduced chemical noise.

Example 1 shows the mass chromatogram of a 500 fg standard injected on a 30m SE-52 capillary column with a split/splitless injector. Note the signal to noise is about 10:1. Example 2 shows 320 fg of 2,3,7,8-Cl₄DD injected on the same column using the "DOW" only cleanup. Example 3 shows a comparison of a fish extract run on both a ZAB-2F and TSQ-70 mass spectrometer. Note that the chromatogram of the sample determined by MS/MS is much cleaner than that determined by HRMS at 12,000RP. Example 4 shows the mass chromatograms of an effluent sample. Note that the relative response factors obtained in the GC/MS/MS mode, when 2,3,7,8- dioxins and furans are used for tuning, are very similar to those obtained in the GC/MS mode.

2. UNC-Chapel Hill, NC 27514

What would you do if asked to analyze small quantities of contaminants in a complex environmental sample? You, as the Analyst, would then appreciate any information pertaining to the type, origin and history of the sample that would facilitate your selection of the analytical methodology. The expected analyte concentration domain also constitutes a useful parameter in the selection process. However, most often, this type of information is not available and the decision on how to process the sample will have to be made almost in an arbitrary manner. What you are looking for in the analytical procedure is its ability to detect with certainty and quantify accurately the trace components in a reasonably short span of time. The approach should be capable of segregating the analyte(s) of interest from the co-extractables, which could be either specific or non-specific interferences, with the highest precision and recoveries as possible.

If a specific type of interference is expected to be present, then you can make an "educated" choice by selecting appropriate fractionation techniques such as the type of chromatographic separations (e.g., gravity flow, HPLC and GC) and the selectivity of the detection system (e.g., HRMS and MS/MS). Of course, you can design the procedure so that these two major aspects (fractionation and analysis) of the analytical scheme can be used in concert to optimize your chances of reaching the goals defined earlier.

Here, we would like to consider more specifically the determination step when a mass spectrometer is used as the detection system. The two facets of the mass spectrometer that are considered below are high-resolution mass spectrometry (HRMS) and tandem mass spectrometry-mass spectrometry (MS/MS). Our objective is not an attempt to demonstrate the general superiority of one approach over the other but to examine specific environmental applications showing the advantages of, what is increasingly becoming the most two common options offered to Analysts for the determination of trace components. Tetrachlorinated dibenzo-*p*-dioxins (TCDD) will serve as the contaminants in this illustration.

The sample introduction can be optimized to allow further separation between the analytes and potential interferences. The combination of gas chromatography with mass spectrometry is particularly powerful during the measurement of polychlorinated dibenzo-*p*-dioxins and dibenzofurans. The mass spectrometer can either be operated in the selected ion monitoring mode (SIM) where ions of a given elemental composition are measured or in the selected reaction monitoring mode (SRM) where the parent (molecular ion) ions are transmitted -- with the help of the double focusing mass analyzer (MS1) -- in the collision cell area. There, collisionally induced daughter ions (i.e., M-COCl) are formed and subsequently mass-analyzed by the quadrupole analyzer (MS2) if a hybrid mass spectrometer (EBQQ configuration) is used.

Unless the Analyst/Operator has knowledge of the type of interferences present in the sample extract, the he/she cannot decide whether one approach is more appropriate than the other. Let's consider the case whereby the sample is known to contain polychlorinated biphenyls (PCB) -- in particular the hexa- and heptachlorinated congeners -- which are

known to interfere with the measurement of TCDDs. If the analysis consists in monitoring the molecular ions of TCDDs (SIM) with the mass spectrometer resolution set at 10,000, one would then expect traces of heptachlorinated PCBs not to interfere during the assay. Indeed, the loss of two ^{35}Cl from the molecular ion of an hexachlorobiphenyl isomer produces a fragment ion that requires a resolving power of 12,500 to distinguish TCDD from the PCB. If however, the Operator is required to monitor, in addition to the molecular ion of TCDD, the fragment ions formed inside the ion source (e.g., $\text{M}-\text{COCl}$), then under SIM conditions this would require impractical resolving powers exceeding 300,000 to segregate TCDDs and the PCBs. In this latter case, SRM would constitute the selection of choice.

Figures 1 and 2 illustrate another example, which was obtained from a paper pulp effluent sample, where severe interferences caused by methyl and ethyl tetrachlorinated dibenzofurans are seen at m/z 320 and 332. Increasing the mass spectrometer resolving power from 10,000 to 18,000 (Figure 1) helps in the elimination of the interferences resulting from the elution of the methylated species. However, as shown in Figure 2, the interferences created by the ethylated compounds are not removed by SIM (note that a resolving power of 85,000 would be necessary) whereas their contributions are substantially minimized in the MS/MS experiment.

In most other situations, the nature of the interferences is unknown. For example, Figure 3 was obtained from a municipal incinerator ash extract under SIM conditions. The figure shows a series of signals, obviously not attributable to tetrachlorinated species, which are eluting in the vicinity of TCDDs. When the chromatograms (Figure 3) generated by analyzing the sample under SIM (at 10,000 and 18,000 resolving powers) and SRM (MS/MS) conditions are compared, the effect of the interferences is significantly reduced by MS/MS analysis whereas no improvements could be noted after increasing the mass spectrometer resolution.

So far the two examples above show that the two techniques are complementary and contribute to improving the quality of the conclusions reached by the Analyst when used in conjunction. This is all fine as long as time is not taken into consideration. Indeed, on numerous occasions, there has been a tendency to overstate the advantages of MS/MS over HRMS in terms of specificity inciting the Analyst to reduce the need for "extensive" sample preparation prior to analysis. We have found that this approach should be reconsidered since, regardless of the instrument configuration (HRMS or MS/MS), the ion source sensitivity can vary with time as large quantities (hundreds of ng per second) of non-specific interferences are eluting of the GC column (Figure 4). These results show that no matter how selective the detection system can be, there will remain a need for adequate fractionation (cleanup) procedures before the determination step when gas chromatographic and mass spectrometric techniques are used [Tondeur et al, Biomedical and Environmental Mass Spectrom. 14, 449-456 (1987); Anal. Chem. 56, 1344-1347, 1984].

DEVELOPMENT OF A MOBILE ION TRAP MASS SPECTROMETER SYSTEM FOR
ENVIRONMENTAL MONITORING

Henk L.C. Meuzelaar, William H. McClennen, Neil S. Arnold,
Wallace Maswadeh, Tim K. Reynolds, Dale T. Urban and Patrick Jones
University of Utah, Center for Micro Analysis & Reaction Chemistry
Salt Lake City, Utah 84112

The objective of the work reported here is to develop a compact, mobile mass spectrometer with EI, CI and MSⁿ capabilities. Moreover, the mobile MS system should be capable of analyzing gases, vapors and aerosols in air at low ppb levels while allowing positive identification of individual components in complex mixtures.

In view of the size and weight restrictions inherent in the mobility requirement, a special miniaturized version of the Finnigan MAT Ion Trap Mass Spectrometer (ITMS®) was constructed in close collaboration with the manufacturer (Figure 1).

This MINITMASS (Miniaturized Ion Trap Mass Spectrometer) system is equipped with automatic gain control [1], automatic reaction control [2], selective mass storage [3] and axial modulation [3] options, in addition to the required EI/CI [4,5] and MSⁿ [5] operating modes.

The 2x2x2 ft MINITMASS module is mounted within a 6 ft high mobile rack together with all gas supplies, pumps, inlet controls and a PC 80386 workstation (Figure 1). The entire system requires approx. 1000 W of ac power. A 6x7x8 ft. self-contained mobile laboratory module, which fits on a standard 3/4 ton pick-up truck (Figure 2), enables operation of the MINITMASS in remote locations and rugged terrain. Also, the MINITMASS system can be remotely controlled from a distance up to several miles using a second PC workstation, and Carbon Copy® software.

A direct air sampling inlet enables repetitive collection of 10⁻⁵ microliter air samples at 15-60 sec intervals. Use of "transfer line chromatography" provides additional resolution and specificity for complex mixtures (Figures 3 and 4). Minimum detectable levels of gases and vapors in air are in the low to medium ppb range without the use of concentration devices (Figure 5). Alternatively, a special automated inlet enables electrostatic precipitation of air particulate matter on a ferromagnetic filament with subsequent analysis by Curie-point pyrolysis (GC)/MSⁿ. An example of the analysis of a simulated biological aerosol (albumen solution) is shown in Figure 6.

The system has been successfully operated in the desert (at temperatures up to 100 F), as well as under a variety of indoor conditions, e.g., for monitoring laboratory-scale combustion reactors.

ANALYSIS OF XENOBIOTIC CONJUGATES BY MS/MS

K. B. Tomer
Laboratory of Molecular Biophysics
National Institute of Environmental Health Sciences
P.O. Box 12233
Research Triangle Park, NC 27709

Tandem mass spectrometry has proven to be very useful for a number of reasons. These reasons include: 1) mixture analysis; 2) increased fragmentation; 3) new information contained in MS/MS spectra not found in MS spectra; and 4) complex molecules often fragment into their constituent building blocks. The advantages of MS/MS over MS are especially useful in conjunction with soft ionization techniques which yield molecular ion species with little fragmentation and, thus, little structural information. With the advent of FAB, the determination of polar pollutants, such as surfactants, has become significantly easier than was the case with ionization techniques such as field desorption.

Surfactants are ideal examples of the utility of combining MS/MS with soft ionization techniques for determining the nature of polar environmental pollutants. They are ubiquitous in modern society and are usually very complex mixtures. The existence of both anion, cationic, amphoteric and nonionic surfactants increases the complexity of their determination.

Arquard 2C-75 is a typical cationic surfactant whose nominal structure is dimethyldidodecylammonium chloride. The FAB/MS spectrum of this surfactant demonstrates the complexity of the surfactant (Fig. 1). Not only is the nominal structure present (m/z 382) but a complex series of homologous compounds are also observed. The MS/MS spectrum of the major species (m/z 382, Fig. 2) contains a series of alkane losses from the molecular cation which can be used to identify the alkyl group in the molecule. The losses of alkanes that are observed are not observed in the MS spectrum and are an example of a new fragmentation. The MS/MS spectra of the homologs, eg. m/z 466, Fig. 3, show a more complex pattern. Losses of C_{12} , C_{14} , C_{16} , and C_{18} chains are observed which indicates that this ion is a mixture of a C_{12} and C_{18} containing quaternary ammonium ion and a C_{14} and C_{16} containing quaternary ammonium ion.

This example demonstrates the ability of the combined techniques of FAB and MS/MS to determine the structures of components of very complex mixtures.

In the environmental sciences there is a need not only to monitor pollutants in the environment, but also a need to determine the fate of the pollutants once it enters living organisms. It is this interaction between xenobiotics, i.e. pollutants, and living organisms which defines our concerns about most of these compounds and is the province of the environmental health sciences. A major key in understanding the effects of xenobiotics on organisms is the determination of the products of the covalent interactions between the xenobiotic and biomolecules.

These xenobiotic-biomolecule adducts are typically isolated as mixtures of polar, often thermally-labile, molecules. The xenobiotics can interact within living organisms in

several ways, including 1) binding to cell constituents and, thereby, modifying the function of the biomolecule, and 2) conjugating with polar molecules as part of the bodies mechanism for excreting xenobiotics. Often the conjugates are also toxic to the cell.

An example of the potential product of the interaction of a xenobiotic with a cell constituent is N⁶[1-(2-hydroxyacenaphthenyl)]adenosine. The FAB/MS/MS spectrum of this modified nucleoside is shown in Fig. 4. The fragmentations observed are characteristic of modified nucleosides, which include formation of the modified base, RBH⁺, by loss of the sugar, formation of the parent nucleoside, BSH⁺, by loss of the modifying group and formation of the ion corresponding to the modifying group, R⁺. A number of ions resulting from water loss from the primary diagnostic fragment ions are also observed. This example illustrates the propensity of complex biomolecules to fragment into their constituent parts which provides information allowing the analyst to determine their structures.

Fig. 4. MS/MS spectrum of hydroxy-acenaphthene and adenosine.

Metabolic activation of molecules to polar metabolites followed by conjugation is a typical mechanism for excretion of xenobiotics from an organism. Both the metabolically activated compound and the final conjugated product can also be toxic. A common mechanism for excretion is conjugation with the tripeptide glutathione followed either by direct excretion or by hydrolysis to the cysteine conjugates or N-acetylcysteine conjugates which are then excreted.

An example is the cysteine conjugate of benzo[a]pyrene epoxide. The FAB/MS/MS spectrum of this compound (Fig. 5) is dominated by an ion attributable to the xenobiotic moiety readily identifying the xenobiotic. The loss of 121 dalton from the molecular ion to form this ion readily identifies the conjugating group as cysteine.

In conclusion, FAB/MS/MS is a powerful tool for both the analysis of pollutants in the environment and for determining the nature of the interactions of pollutants with biomolecules within the body.

ACKNOWLEDGEMENT

The surfactant samples were provided by Dr. P. A. Lyon of the 3M Co. The modified nucleoside was provided by A. Bartoszak and Prof. A. Gold of the University of North Carolina-Chapel Hill. The cysteine adduct was provided by Dr. L. T. Burka of NIEHS - Division of Toxicology Research and Testing.

DETECTION OF LARGE IONS IN FTMS

E. R. Williams, K. D. Henry, B. H. Wang, F. W. McLafferty
Chemistry Department, Cornell University, Ithaca, NY 14853-1301

The multichannel detection capability of Fourier transform mass spectrometry (FTMS) over a wide mass range makes possible enhanced sensitivity for measurements involving high resolution, pulsed ionization, and tandem MS. However, the shorter RF transients obtained with high mass peptide ions reduces both the detection efficiency and resolution for these species. Sensitivity for high mass ions can be substantially improved by remeasuring ions hundreds of times. Measurement of multiply charged ions greatly extends the mass range of FTMS and makes accurate mass measurements of peptides above mass 10,000 possible.

A unique characteristic of FTMS detection which has not previously been taken advantage of is the non-destructive nature of imaging the cyclotron ion current. Elimination of the quench pulse commonly used in an experimental sequence results in substantial increases in sensitivity for high mass ions with multiple signal averaging events. This effect is shown in Figure 1, where molecular ion species of gramicidin S (MW 1141) formed by plasma desorption (1) show a signal-to-noise (S/N) enhancement of 35x with quench off. This enhancement increases with the number of scans such that a S/N improvement of >100x can be obtained with 1000 scans.

This is made possible by x,y collisional deactivation of previously excited ions back to the center of their orbits where they are available for subsequent redetection. The time required for this process decreases with increasing pressure and lower excitation power (corresponding to a smaller ion orbit), consistent with a collisional mechanism. For gramicidin S at $\sim 2 \times 10^{-9}$ torr, the remeasurement efficiency is nearly 100% after 180 s. This high efficiency makes possible the impressive gains in signal observed. For n signal averaged spectra, a S/N gain of $n/2$ is possible. This corresponds to a time savings of $1.59/n^{0.67}$. Thus, 7 spectra measured with quench off produces the same S/N as 100 spectra with quench on.

For only one ionization event, remeasurement can still be used to enhance the signal. Figure 2a shows a mass spectrum of gramicidin S formed by a single laser shot and detected once. Detecting these same ions five more times (without further ion production) results in a S/N enhancement of 3.1x (Figure 2b).

In addition to the sensitivity enhancement possible with remeasurement, the relaxation time provides an indication of the collisional cross section of various ionic species. For example, to obtain a remeasurement efficiency of 97% for Cs_7I_6^+ (m/z 1692) and $(M + \text{Na})^+$ of gramicidin D (m/z 1905) requires 290 s and 32 s respectively at a pressure of 3×10^{-8} torr. While this difference is larger than indicated by their relative physical dimensions, this could explain why high mass CsI clusters have much longer transients (resulting in higher resolution spectra) than peptide ions of comparable mass.

Preliminary results obtained in collaboration with Hunt and Shabanowitz using electrospray ionization (ESI) (2) in a modified QQ-FTMS (3) show abundant multiply charged molecular ions of a variety of peptides up to $\sim 17,000$ MW (Figure 3). Resolution for myoglobin ($M + \text{H}_1^{17}$) is ~ 700 at 10^{-8} torr indicating these high energy multiply charged species do not collisionally dephase and relax faster than a singly charged ion at a comparable m/z ratio. Reduction of pressure to 10^{-8} to 10^{-9} torr should increase sensitivity and greatly extend the lengths of the transients making high resolution, accurate mass measurements of peptide ions >10,000 a.m.u. possible.

**TWO DIMENSIONAL FT-ICR AND ITS
REALIZATION ON A PC BASED INSTRUMENT**

Shenheng Guan and Patrick R. Jones
Chemistry Department
University of the Pacific
Stockton, CA 95211

The technique of two dimensional FT-ICR mass spectrometry was first introduced by Pfandler *et al.* [1]. The techniques of 2D FT-ICR are very new. While its underlying principles have not been fully understood, it has great potential in that, in theory, it allows one to examine all the ion-molecule reactions in a chemical system in one experiment. Future development of the method requires a break-through on theoretical as well as experimental aspects.

This work offers a simple model to interpret the physical significance of the modulation of the ions signals in the additional dimension. According to the model, the additional dimension (which is introduced as the duration between the end of the first excitation pulse and the beginning of the second) determines the velocity of the primary ions just before the reaction period. If the excitation level is sufficiently high, the combination of the 2D excitation pulses will cause ejection of the primary ions at the beginning of the reaction period. Therefore, the primary and the product ions will be modulated with the primary ion's cyclotron frequency in the same phase. Even if the excitation level is low enough to avoid ion ejection, the velocity of the primary ions is still modulated. Starting from assumptions about the ion-packet and assuming negligible phase diffusion during the 2D excitation, a mathematical expression for the velocity modulation can be derived from the Lorentz equation [2]. The expression clearly shows that the velocity modulation is not sinusoidal.

The modulation of ion signals is complicated. It requires information on (1) the ion-loss mechanisms; (2) the ion-velocity dissipation; (3) the ion-molecule reaction kinetics; and, (4) the detection mechanisms for thermally-excited ions. From the examination of a simple chemical system which conserves charge and follows a rigid sphere kinetic model, it can be concluded that the modulation of the primary ion velocity can cause the modulation of ion signals. The ion-signal modulation is essentially not sinusoidal and, therefore, harmonics exist in the 2D spectra.

2D FT-ICR has been implemented on our home-built instrument [3]. According to the model outlined above, the Fourier transformation should be carried out step-wise in order to recover all the information. The instrument is operated at frequencies above the Nyquist frequencies in both dimensions. The spectra (Figure 1 and 2) obtained show the broad-band nature of the 2D technique.

MINIMIZATION OF SPACE CHARGE EFFECTS IN AN FTICR TRAPPED ION CELL

D.A. LAUDE, JR., S. MALEKNIA, AND J. D. HOGAN

DEPARTMENT OF CHEMISTRY, UNIVERSITY OF TEXAS, AUSTIN, TX. 78712.

Suspended trapping pulse sequences provide a convenient mechanism to alleviate space charge effects generated during FTMS detection of poorly controlled, transient, or fluctuating neutral populations. These pulse sequences are distinguished by an event during which trapping voltages are set to ground potential to facilitate longitudinal ion flight along magnet field lines. Although suspended trapping pulse sequences have found some application in FTMS, most notably for ion introduction from external sources, their analytical utility has yet to be exploited. As will be described, manipulation of electrodes along the path of ion formation in the FTMS vacuum chamber accesses an array of experiments which improve mass calibration, increase sensitivity, and extend dynamic range, all with modest changes in hardware and software.

Initial suspended trapping experiments were devoted to an understanding of longitudinal ion motion in the vacuum chamber of the Nicolet FTMS 2000. As indicated in Figure 1, five electrodes placed at right angles to the magnetic field both constrain ions in potentials wells and direct the electron beam. For this electrode configuration in a conventional dual cell experiment, electrode 2 is used as a gate to pass an electron beam which is collected at electrode 5. Electrodes 2, 3, and 4 serve as analyzer trap, conductance limit, and source trap for the dual cell. Trap voltages are maintained throughout the pulse sequence except during the beam event when electrode 3 is grounded to equilibrate ion populations between the analyzer and source trap. An FTMS pulse sequence was written to select any combination of potentials between ± 10 V at electrodes 2 through 5 during the beam and subsequent delay events in the experiment sequence. Among the advantages of suspended trapping observed with this sequence are ion accumulation in a high pressure storage trap to maximize duty cycle for sensitivity gains in chromatographic experiments, a 1000-fold dynamic range improvement for fluctuating neutral populations, and wideband low ppm error mass calibration from a single calibration table independent of ionization conditions.

To gain an appreciation for the flexibility which suspended trapping experiments bring to FTMS experiments, an understanding of longitudinal ion motion between the various electrodes during the pulse sequence is required. In Figure 2, the flight of ions generated by electron ionization from a single section cell established between electrodes 3 and 4 is shown to occur over a several hundred microsecond period. (In an earlier experiment, Dunbar used this approach to determine the kinetic energy of photodissociated fragment ions in the cell (1).) Figure 2 also includes a repeat of the EI ion flight experiment except that a large well between electrodes 4 and 5 is allowed to accumulate ions prior to suspended trapping. This is easily accomplished because electrode 5 is usually biased at +5V during the beam event and can serve a dual role as collector for the electron beam and also as a trap plate for this second reservoir of ions. Note that while ions exit the analyzer cell over several hundred microseconds during the suspended trapping event, ions from the larger well enter the cell and sustain the ion signal for several milliseconds.

Figure 3 provides evidence of the utility of suspended trapping for simplified mass calibration. In the case where trapping potentials are sustained, excess ions

which contribute to a local electric field decrease the measured cyclotron frequency. In contrast, following a several milliseconds suspended trapping time, the identical initial ion population is replaced by a detected population which makes a negligible contribution to the electric field term for the effective cyclotron frequency. In effect, suspended trapping spectra exhibit an invariance to both initial ionization conditions and neutral populations.

Suspended trapping should extend the qualitative dynamic range in which varying neutral populations produce spectra of good quality. Presently, mixture components for GC/FTMS analysis must be within a relative concentration range of 10^2 to ensure detection of low abundance components without space charge distortion in the spectra of large abundance compounds. Figure 4 contrasts conventional and suspended trapping GC/FTMS spectra of naphthalene and methyl naphthalene mixture in the ratio of 1:10,000. To observe a spectrum for 100pg of naphthalene injected on column, a 50 uA, 30 ms electron beam was employed. As expected these ionization conditions yielded grossly distorted spectra of the overloaded methyl naphthalene with sustained trapping. In contrast, the suspended trapping spectrum exhibits no distortion and no frequency shift due to the large initial ion cloud.

These preliminary experiments indicate the potential of suspended trapping to improve the reliability of FTMS as a detector for fluctuating neutral populations. Work continues in the evaluation of its performance for FTMS detection of chromatographic effluent and for detection of transient ion populations generated by laser and thermal desorption.

EXACT AND NEARLY EXACT INTERPOLATION OF APODIZED FT-ICR SPECTRA

Melvin B. Comisarow and C. Dale Keefe; Department of Chemistry, The University of British Columbia, Vancouver, B. C., Canada V6T 1Y6.

All experimental Fourier spectra (FT-NMR, FT-ICR, FT-IR etc.) are defined at only a finite number of points and some sort of data manipulation is required to measure the true peak location/intensity if a spectral peak falls between two points of the discrete spectrum, *as it always does*. Some time ago¹ we developed a simple algorithm for *exactly* interpolating the true peak location from the *unapodized* discrete magnitude Fourier lineshape. This algorithm also extends to the exact interpolation of certain absorption-mode lineshapes². We have now extended this methodology to *apodized* FT-ICR lineshapes. This procedure completely obviates the systematic digital error inherent in apodized discrete Fourier spectra³.

We have also developed a family of interpolating functions, the KCe functions, which provide nearly exact interpolation

$$KC_e = (a\omega^2 + b\omega + c)^e$$

The parabola ($e = 1$) the Lorentzian ($e = -1$) and the magnitude-Lorentzian ($e = -1/2$) functions are members of this family and previously have been used for the approximate interpolation of apodized lineshapes⁴. The optimal KCe function varies with the apodizing window. Compared to the parabola which was shown⁴ to be the best interpolating function for apodized lineshapes, the optimal KCe function is one to two orders of magnitude superior. That is, the optimal KCe function has a *maximum* residual error which is one to two orders of magnitude lower than that of the parabola.

We have also determined the random *frequency* errors which come from the random *amplitude* errors in the spectrum. The efficacy of the KCe functions is so high that for spectra with a signal-to-noise ratio of 100, the residual systematic error is less than the random error. For all intents and purposes then the KCe functions are "exact". We have also shown that the random error increases if the spectra are zero-filled. For the parabola, zero-filling is desirable until it reduces the systematic error to below the random error. For the KCe functions, the residual systematic error is less than the random error and no zero filling gives the lowest total error.

Our recommended interpolating functions are KC5.5 for the Hanning window, KC6.6 for the Hamming window, KC9.5 for the Blackman-Harris window and KC11.5 for the Kaiser-Bessel window. The Kaiser-Bessel window is an estimate based upon extrapolation of the other recommendations. We also recommend *not* zero-filling spectra, prior to KCe interpolation.

An External Ion Source Providing Ion Accumulation and Trapping
of Ions with Broad Energy Range for
Ion Cyclotron Resonance Spectrometry

M. Bamberg and K. P. Wanczek,

Inorganic Chemistry, NW 2, University, D-28 Bremen 33,
West Germany

In ICR spectrometry there are three different possibilities described in the literature to transfer ions generated in an external source outside the room temperature bore of the superconducting magnet. They can be characterized by the average kinetic energy of the transferred ions. Kofel et al. (1) described ion transfer at low kinetic energy of only a few eV for general applications. Alford et al. (2) employed a kinetic energy of a few hundred eV to transfer externally generated metal cluster ions. The deceleration was performed with a pulsed decelerator, which limits the mass range. Kofel and McMahon (3) utilized the same energy range to sample ions from a high pressure source. They used a cylindrical decelerator. The ICR spectrometer manufactured by Spectrospin employs high ion energy of more than 1 kV (4). According to the Lagrange-Helmholtz equation the opening angle, the radius, and the kinetic energy of an ion beam are connected. For a given ion beam radius small opening angles are obtained at high ion energy. On the other hand, the trapping efficiency of externally generated ions is inversely proportional to the kinetic energy distribution.

Best suited as external ion sources are ion sources with a high ion yield like the Extrel ion source for quadrupole mass spectrometers. This source generates ions of a fairly broad energy range and operates best at ion energies around 30 eV.

To trap efficiently ions of a broad energy range and with kinetic energies of up to 100 eV the "screening" of the trapping electrodes of the ICR cell introduced by Marshall (5) was applied to a cylindrical ICR cell.

The experiments were performed with a modified Spectrospin Fourier transform ICR spectrometer (4) with a 7.02 T superconducting magnet. The room temperature bore of the magnet is 89 mm. The instrument is controlled by an Aspect 3000 minicomputer. A differentially pumped vacuum system is used. In the ICR chamber the pressure is kept constant at 2×10^{-9} mbar. In the external source sample pressures between 1×10^{-7} and 8×10^{-6} mbar are utilized. Ions are externally generated with a crossed-beam Extrel ion source, modified for axial beam operation. The source gives best ion yields at ion energies between 10 and 50 eV. The ions are transferred to the ICR cell with this energy with the aid of a guiding lens and deflection system designed for operation at low energies. The ions are trapped in the ICR cell by pulsing the trapping plates between the trapping potential and an optimized potential of a few volts. Trapping potentials of up to 100 V are employed.

With the trapping potentials at 100 V, a mass shift of less than 0.001 amu is generated for nitrogen molecular ion. The mass shift depends linearly on the trapping potential. In the pressure range from 1 to 9×10^{-6} mbar the ICR signal intensity depends linearly on the sample pressure in the external ion source. At higher pressures saturation is observed. The transfer efficiency shows a broad maximum, which depends on the ion kinetic energy as shown in Fig. 1 and the ion density in the beam. The maximum transfer efficiency is at 40 eV ion kinetic energy. The maximum trapping efficiency is found for trapping potentials of 30 - 40 V, correspondingly.

The pulse sequency described above can also be utilized to accumulate ions. The ICR signal intensity increases linearly with accumulation time, as shown in Fig. 2, until the trapping capacity of the ICR cell is exhausted.

In small band mode high resolution of 3×10^6 for the Argon ion at a pressure of 2×10^{-9} mbar has been observed. The performance in broad band mode is not degraded.

SIMION (6) calculations show that the trapping and the ion accumulation are due to oscillations of the ions perpendicular to the magnetic field induced by the grids.

THE EFFECTS OF PRESSURE ON ION EXCITATION IN FOURIER TRANSFORM
ION CYCLOTRON RESONANCE (FT-ICR) SPECTROMETRY

D. H. Russell, E. L. Kerley, C. D. Hanson, and M. E. Castro
Department of Chemistry
Texas A&M University
College Station, Texas 77843

In the past two years we have developed a series of experiments on the TAMU two-section cell FT-ICR to study ion excitation and detection. These experiments involve exciting (rf electric field of discrete frequency, sum of individual frequencies, or by sweeping the rf field over a range of frequencies) the ion population (formed by electron impact ionization) to a radius larger than the aperture in the conductance limit. Ions which are excited to larger radii do not partition to the analyzer cell when the potential applied to the conductance limit is grounded.¹ These types of experiments can be extended to permit high-resolution ion partitioning by phase-specific ion excitation (HIPPIE), which enhances the utility of ion ejection techniques for mass-selective ion chemistry studies.²

The mass-selection methods are most useful for ion molecule reaction chemistry studies and collision-induced dissociation. Because ion chemistry studies require relatively high pressures ($>10^{-7}$ torr), ion excitation can be altered by collisional relaxation (of the translational energy) and the chemistry of a particular system can be altered by collisional excitation (increasing the internal energy of the ion). Another aspect of ion ejection that has been not been evaluated in detail deals with the efficiency of the process. For example, if one ejects ions from the ion cell and then introduces a delay in the experimental sequence to allow ion molecule reactions to occur, the abundance of the mass-selected ion decreases and low abundance ions appear in the ICR spectrum. Oftentimes the ions that "grow" into the spectrum correspond to ions which were ejected. Presumably, the ions "grow" into the spectrum because the ion ejection process is not completely quantitative. That is, a small fraction of the ions are not ejected by the rf excitation, but rather the abundance of the ion is reduced to a value which is below the dynamic range of ion detection.³ *Such considerations become very important for processes such as CID where the efficiency of converting parent ions to fragment ions is low (a few per cent. at best!).*

There are several factors which can strongly influence ion excitation. Two of which are: (i) the extent of ion excitation is greatly influenced by the location of the ion in the ion cell, especially for the cubic ion cell where rf field inhomogeneities are large; (ii) at pressures of 10^{-6} to 10^{-7} torr ion-neutral collisions can lead to collisional relaxation. Collisional relaxation is an important consideration for low power rf excitation where excitation times are long and when ions are excited to high energies (10 eV or greater) and the time between collisions becomes very short ($<10^{-3}$ s).

It is difficult to quantitate the problems described above by performing single cell experiments, but such effects are readily observed in ion partitioning experiments performed on a two-section cell instrument. Figure 1 contains a series of mass spectra obtained on our two-section cell instrument. The region displayed includes m/z 28 (N_2^+) and m/z 29 (background signal). The first mass spectrum was obtained by simply partitioning the ions to the analyzer and detecting. The subsequent spectra were obtained by exciting the m/z 28 by applying an rf signal at the cyclotron frequency for a variable period. Note that the relative abundance of m/z 28 decreases as the rf excitation period is increased (the signal decreases because some fraction of the m/z 28 ions are excited to radii which exceeds the dimensions of the conductance limit aperture), but the m/z 28 signal is not completely eliminated as it should be if all the ions were being uniformly excited. If the pressure of N_2 is reduced (from 10^{-6} to 10^{-7} or 10^{-8}) the signal at m/z 28 is eliminated after the ion has been excited to approximately 4 eV. On the basis of the dimensions of the conductance limit aperture, ion partitioning should cease when the ion has been excited to approximately 4.4 eV.

The results of these experiments clearly illustrate the limitation of rf excitation for quantitative measurements and for enhancement of dynamic range to measure low level signals. Careful attention must be given to any experiment involving ion ejection---ion ejection is not an alternative to quenching the cell by a DC voltage pulse.

The experiment described above points out an important limitation of single section cell experiments for performing CID and mass-selected ion molecule reaction chemistry. Specifically, ion ejection is not an adequate technique for quenching the ion cell of unwanted ions. This problem can be eliminated by performing CID and mass-selected ion molecule chemistry in a two-section ion cell. For instance, by using a two-section ion cell all the ions in one cell can be eliminated by performing a DC voltage quench and ions from the other cell can be selectively partitioned according to mass, energy, and/or phase to the "clean" cell. Once the desired ions are trapped in the "clean" cell the chemistry experiments can be performed.

Figure 1. Partitioning profile for N_2^+ (m/z 28) at 5×10^{-6} torr. N_2^+ ions were irradiated on resonance (110 Vm^{-1}) for 60-500 μs prior to partitioning to an ion free analyzer region.

F. Vedel, Universite de Provence, Marseille, France, 13397

Preliminary findings are presented of a simulation study of resonance excitation of gaseous ions stored within a quadrupole ion trap [1]. The simulation program calculates the trajectories of positively- or negatively-charged ions stored in an ion trap operated in the common mode wherein the end-cap electrodes are grounded. The simulation can be performed for ions of any mass-to-charge ratio either in a collision-free system or in the presence of a chosen collision gas at a selected pressure [2-4]. The output of the simulation is obtained as (i) temporal variations, (averaged usually over one RF cycle), of kinetic energy, axial position, and radial position, (ii) two-dimensional representation of an ion trajectory in the form of axial (z) versus radial (r) position, and (iii) frequency analysis of any chosen time domain of ion trajectory.

The arrangement chosen for computer simulation of resonance excitation allows an excitation signal of any amplitude and frequency to be applied to both end-cap electrodes such that these electrode potentials are in phase with one another. The excitation signal can be initiated at any chosen time and phase. In Figure 1 is shown an example of the temporal variation of ion kinetic energy.

Figure 1. Calculated temporal variation of ion kinetic energy (averaged over one RF cycle) in the presence of neon as collision gas. A delayed auxiliary potential is imposed after 0.3ms of storage time. Working point ($a_z = 0$, $q_z = 0.1955$); m/z 134; $r_0 = 1$ cm; $V = 268$ V; drive frequency 1 MHz; neon pressure = 7 mtorr; initial position, $x = y = z = 5 \times 10^{-6}$ m; initial velocities, $\dot{x} = 1 \times 10^3$ m s $^{-1}$, $\dot{y} = \dot{z} = 0$; auxiliary potential of 3.5 V oscillating at $\Omega_z/2$ (69.6536 kHz); 32 collisions are shown wherein the solid upright and inverted triangles represent, respectively, the instantaneous ion kinetic energies before and after each collision.

Initially, the ion loses kinetic energy from an initial energy of 7 eV in successive momentum-dissipating collisions with neon. While the kinetic energy is averaged over one RF cycle, the instantaneous values of ion kinetic energy upon and immediately following a collision are shown in Figure 1. Collisional focusing of the ion at the ion trap center is concomitant with ion thermalization. At 0.3 ms of the simulation, the excitation signal or tickle is initiated; the tickle voltage, of amplitude (p-p) 3.5 V, is oscillating at the fundamental axial secular frequency. Ion kinetic energy is enhanced gradually in competition with momentum-dissipating collision until at 0.45 ms the ion is ejected. In this example, the ion is ejected radially [5].

The simulation programme permits calculation of ion trajectories over a wide range of conditions and has revealed a variety of features of ion trap behavior. In a collisional system, ion kinetic energy upon ejection is sensibly constant for a given working point within the stability diagram, while the tickle fluence (amplitude x irradiation period) required for ion ejection increases with collision gas pressure. In view of the observation for the experimental conditions of Figure 1, that radial ejection is induced upon axial excitation, attention has been directed to the frequency dependence of ion excitation and the analysis of frequency components of ion motion in collision-free systems.

Results obtained with four ions for which the initial coordinates and velocities are representative of an ensemble indicate that, for the ideal case of a single ion in a trap with infinite electrodes, interpretation of ion motion in terms of a three-dimensional Lissajous figure with independent axial and radial components is incorrect. Ion irradiation at the fundamental axial ($\omega_{z,0}$) and radial ($\omega_{r,0}$) secular frequencies does lead to ion ejection but does not lead exclusively to axial and radial ejection, respectively.

Irradiation at $\omega_{z,0}$ can induce a frequency component of ion motion which is initially of a frequency lower than $\omega_{r,0}$ and increases to the value of $\omega_{r,0}$ upon prolonged irradiation. This frequency component is designated as an *induced* frequency. The higher order secular frequencies are only weakly absorbed. Strong absorption of resonance irradiation was observed with a series of frequencies, $\omega_{u,n}^* = (n + \beta)\Omega$, where $u = r$ and z , $n = 0$ and 1 , β is a function of the working point, and Ω is the RF drive frequency. Of these frequencies, which have been designated as *new* frequencies, $\omega_{z,0}^* = \beta\Omega$ is the most strongly absorbed and absorption of this *new* frequency occurs more readily than that of $\omega_{z,0}$.

Further work is underway in an effort to gain understanding of these observations and to investigate the behavior of trapped ions at working points throughout the stability diagram and in collisional systems.

**NEGATIVE ION CHEMICAL IONIZATION IN AN ION TRAP MASS SPECTROMETER
USING REAGENT ANIONS INJECTED FROM AN EXTERNAL ION SOURCE**

Brian A. Eckenrode, Gary L. Glish, and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-8121

We have been pursuing the analysis of polyatomic anions in an ion trap mass spectrometer (ITMSTM). During the course of this work we have reported on the formation of reagent anions within the ITMS [1], collision-induced dissociation of polyatomic anions in the ion trap [1,2], anion/molecule reactions in the ITMS [2], and the coupling of an external ion source for the injection of anions into the ion trap [3]. We have noted that the number of reagent anions formed within the ion trap by conventional means is roughly 10^3 lower than the positive ions formed from the same reagent gas species [2]. This is due to the fact that electrons are not stored under conditions used to store ions. The slow electron number density is always, therefore, relatively low in the ITMS. For this reason, we have been developing tactics for negative ion analysis which do not rely on the formation of reagent anions or slow electrons within the ITMS.

The interfacing of an external ion source to an ITMS provides two possible approaches to negative ion analysis; i) the formation of **analyte** anions in the ion source followed by injection into the ITMS and ii) formation of **reagent** anions in the ion source, injection of the reagent anions into the ITMS, and formation of **analyte** anions by ion/molecule reactions in the ITMS. We have demonstrated the former approach [2,3] with an atmospheric sampling glow discharge ionization (ASGDI) source [4]. Such an approach is preferred in the real-time analysis for trace compounds in air, particularly for species which capture electrons. The latter approach is demonstrated here. This approach is appropriate when samples can be introduced into the ion trap in a more or less undiluted form, e.g. via a chromatograph or a solids probe. An advantage of this approach is the capability of selecting the reagent anion and therefore having better control over the mechanism and energetics of ionization than is possible in a high pressure chemical ionization source. We have demonstrated the utility of selected reagent cation chemical ionization in an ITMS. We demonstrate selected reagent anion chemical ionization here.

Figure 1 shows the mass spectra of ions injected into the ITMS from a glow discharge source using three different reagent gas mixtures. Note that a variety of anions can be readily created in the glow discharge ion source by changing the gas composition. The ITMS can be operated to mass selectively accept only one of these reagent ions and the ion trap can be "filled" with these ions orders of magnitude faster than by forming the reagent anions in the ITMS. To date, we have concentrated on the reactions of OH^- , O_2^- , and NO_2^- . We find that for 2,4,6-trinitrotoluene (TNT) (admitted via a solids probe) O_2^- reacts primarily by electron transfer, NO_2^- reacts primarily by proton abstraction, and OH^- shows both types of reactions. We have studied the kinetics of the reaction of NO_2^-/TNT in detail to demonstrate the desirability for large reagent ion number densities and long reaction times for low levels of analyte.

To demonstrate the ability to observe low sample concentrations, we admitted the plastic explosive RDX via an unheated solids probe. The saturated head space vapor pressure of this compound at room temperature is roughly 6 pptr. This constitutes an upper limit in number density in the ion trap of $\approx 1 \times 10^8 \text{ cm}^{-3}$. The actual number density within the ITMS is likely to be substantially less since the RDX is not allowed to equilibrate (i.e. the system is pumped at 350 L/s) and the end of the probe was situated several mm away from the ITMS (no teflon inserts were used). Figure 2 (top) shows the mass spectrum obtained when all of the reagent ions from the N_2O , H_2 , He mixture were injected into the ITMS and a reaction period of 1 s was used. A variety of ions appear from the relatively dirty vacuum system (we have

housed the ion trap in an unheated 6" cube). Two of the ions fall at masses known to be formed from RDX, viz. those that appear at m/z 129 and m/z 176. MS/MS confirms that these ions are indeed formed from RDX as the major daughter ions observed (m/z 85 from m/z 129 and m/z 102 from m/z 176) are known from our previous experience with RDX in the ITMS.

A disadvantage to the use of a non-pulsed external ion source, as used in this study, is that reactive neutrals that are formed in the ion source are constantly entering the vacuum system. These reactive neutrals can interfere with the desired reaction chemistry by reacting with the mass-selected reagent anion to form other anions. A pulsed ion source is therefore more appropriate. Nevertheless, the usefulness of the injection of reagent anions into the ITMS from an external ion source is clear from this work and should prove to be an important approach to the analysis of compounds that undergo fast ion/molecule reactions with anions.

DAUGHTER ION FORMULA DETERMINATION BY MSⁿ EXPERIMENTS
ON NATURALLY OCCURRING ISOTOPES

Gary L. Glish, Keiji G. Asano, Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831

Naturally occurring isotopes like ¹³C and ³⁷Cl provide additional information that is useful in the interpretation of a mass spectrum. An MS/MS spectrum of a polyatomic parent ion m⁺ in conjunction with the MS/MS spectrum of the corresponding ¹³C or ¹⁵N containing ion (m+1)⁺ can be used to determine daughter ion elemental compositions.^{1,2} A limitation of this method is that the (m+1)⁺ peak must be composed mainly of the isotopic ion; if it has a significant content due to another ionic species the data is difficult or impossible to interpret.

This limitation can be overcome by the use of high resolution parent ion separation or by using one or more additional stages of mass spectrometry to generate the appropriate isobar for the final stage of MS/MS. The latter method can be carried out with an instrument capable of MSⁿ experiments with good MS/MS efficiency since the initial parent ion will be of small relative intensity when it contains the natural isotopic abundance. The Finnigan Ion Trap Mass Spectrometer (ITMSTM) seemed well suited for this type of experiment since it has been shown to be very efficient in performing MSⁿ experiments.

An example of this utility is described with the compound N,N-dimethylaniline. We have noted that (M-H)⁺, m/z 120, from this compound shows a couple of interesting daughter ions due to loss of 17 and 29 daltons. It cannot be determined by MS/MS alone with the ion trap whether or not these neutral fragments contain the nitrogen atom. The normal experiment of taking the MS/MS spectrum of (m+1)⁺ was not possible since this peak is composed predominantly of the molecular ion. However, the molecular ion fragments efficiently to (M-H)⁺ in the MS/MS spectrum obtained with the ITMS. Thus, an MS³ experiment can be performed to obtain the daughter ion formula from the natural abundance of the isotopes. The left spectrum in Figure 1 is an MS³ spectrum obtained starting with the ¹²C molecular ion and the right spectrum is the corresponding experiment starting with the natural ¹³C isotope of the molecular ion.

The m/z 120 ion in the ¹³C spectrum results from a competing process in the experiment sequence (vide infra) and is not important in the analysis of the data. Looking only at the peaks below m/z 120, the two spectra are almost identical except for the mass shifts. The Table below lists the calculated ¹²C/¹³C ratios for the two possible isobars at each of the main daughter ions along with the experimental results, which have been corrected for contributions from adjacent peaks. This data shows that the neutral lost in each of these reactions contains the nitrogen. While this is not unexpected for the m/z 77 ion which can be formed by a simple cleavage, a rather complex rearrangement must occur for the formation of m/z 103 (loss of NH₂) and m/z 91 (loss of CH₂NH). We are continuing to study this system to determine the reaction mechanism and product ion structure.

Besides the ¹²C/¹³C ratio of the daughter ion peaks of interest, there are other features of these spectra to be noted. First, it is desirable to obtain both daughter ion spectra under identical conditions so that appropriate corrections can be made when there are adjacent peaks. To get the initial parent ion intensities of m⁺ and (m+1)⁺ to be equal in their respective experiments, it is necessary to ionize for approximately eleven times longer in the (m+1)⁺ experiment. However, increasing the ionization time increases the relative contribution of other reactions taking place. In this case a competing reaction to electron ionization is self-protonation to give an isobaric species to the ¹³C containing molecular ion. The MS/MS spectrum of this species is different from that of the molecular ion because of the additional dissociation pathways from the protonated species (e.g. a base peak at m/z 107). Also, this competing reaction makes it difficult to obtain an initial intensity of the ¹³C containing parent ion that is equal to the ¹²C parent ion in the complementary MS/MS spectrum.

Another feature of the data is the large m/z 120 peak in the ^{13}C spectrum. This peak provides evidence of another reaction taking place during the first stage of MS/MS in the experimental sequence, charge exchange. This is a potential problem in any trapping instrument when the neutral analyte is continuously present in the reaction region. The result here is that the m/z 121 selected for the second stage of MS/MS contains isobaric ions, the ^{12}C molecular ion along with the ^{13}C (M-H) $^+$. The charge exchange reaction is not readily apparent in the first stage of the ^{12}C experimental sequence since it mainly produces (91.2%) the same ion, along with some (8.8%) ^{13}C molecular ion.

Looking only at the MS^3 spectrum of the ^{12}C ion, it might be deduced that the m/z 120 ion undergoes charge exchange and proton transfer with the neutral to give the ions at m/z 121 and 122, respectively. However, looking at the MS^3 spectrum of the ^{13}C ion, it can be seen that the respective ions formed are m/z 122 and 123. This suggests that the ^{13}C species retains the charge in the ion/molecule reaction and that one and two hydrogens are transferred to it from a neutral reactant.

A limitation to this procedure is that it will be applicable, for the most part, only to peaks that have a significant abundance in the final MS/MS spectrum or peaks that do not have adjacent peaks. This is due to the statistical considerations associated with the fact that a limited number of ions can be stored in the ion trap (10^3 - 10^6). Thus small peaks in MS^3 or higher spectra will consist of a few hundred to few thousand ions. Therefore, statistical fluctuations in ion signal will be relatively large and determining accurate $^{12}\text{C}/^{13}\text{C}$ ratios will be difficult.

In conclusion, the use of multiple stages of mass spectrometry (greater than two) should prove useful in many cases in which isobaric or possibly isomeric interference precludes the use of the conventional MS/MS approach. Such circumstance is likely for the ITMS which typically affords unit mass resolution for both parent ion selection and daughter ion measurement.

HOW TO USE A STANDARD QUADRUPOLE FILTER AS A TWO DIMENSIONAL ION-TRAP

Claude Beaugrand and Gérard Devant,
Nermag, 49 quai du Halage, 92500 Rueil-Malmaison, France

Brahim Elabbassi, Daniel Jaouen, Hélène Mestdagh and Christian Rolando,
Ecole Normale Supérieure, 24 rue Lhomond, 75231 Paris Cedex 05, France

Ion confinement in the RF-only collision cell of a tandem quadrupole instrument, using the entrance and exit lenses as electrostatic mirrors is very efficient (1). With trapping Collisionally Activated Dissociation (CAD) efficiency is proportionnal only to the number of collisions (which is proportional to the product of target gas pressure by confinement time) between reactant ions and the collision gas, independently of the value of each parameters. Furthermore the absence of an added buffer gas allows to observe reactions at room temperature since the kinetic energy of ions near the quadrupole axe is low in comparison of thermal energy. An important application of this device is the access to thermodynamic equilibrium in ion molecule reaction (2). We have also demonstrated that selective ion rejection from the collision cell can be effected using an auxiliary radiofrequency field characteristic of the considered ion (3).

We wish to report here the use of a single quadrupole analyzer (scheme 1) fitted with prefilter at the front and at the rear of the filter and with an annular detector in order to perform ion selection and confinement process. In this instrument the mass selection for parent or daughter ion and the reaction or CAD steps are realized at consecutive time instead of being done at different place as in a tandem MS/MS instrument (scheme 2).

A typical experiment for ion-molecule reaction is described below: (i) filling of the trap (RF-only), (ii) parent ion selection (resolving quadrupole), (iii) reaction step (RF-only, and auxiliary field), (iv) daughter ion selection (resolving quadrupole), (v) ion detection.

Preliminary experiments show that resolution of the analyser increases with trapping time and that good kinetic data can also be obtained with this instrument although the reaction time is less precisely defined than when using the RF-only collision cell of a MS/MS instrument.

INJECTION OF IONS INTO A QUADRUPOLE ION TRAP FROM A CHEMICAL IONIZATION SOURCE USING A DC QUADRUPOLE DEFLECTOR

Randall E. Pedder and Richard A. Yost
Department of Chemistry, University of Florida
Gainesville, FL 32611

Michael Weber-Grabau
Finnigan MAT, 355 River Oaks Parkway
San Jose, CA 95134

Commercially available quadrupole ion trap mass spectrometers (Finnigan ITD, ITS, and ITMS) are currently designed to permit ionization only within the ion trap by either electron ionization (EI) or low-pressure chemical ionization (CI). The ability to inject ions from an external ion source into an ion trap with simple line-of-sight (on-axis) ion optics has recently been reported (1-2).

In this work, off-axis injection of ions into an ion trap is demonstrated from a high-pressure CI ion source through a DC quadrupole deflector (3). Design criteria for this system were: non-differentially pumped system for instrumental simplicity, ion optics which are open to gas flow to minimize collisions of ions with neutral gas molecules; no line-of-sight between the ion source and the detector, to minimize neutral noise problems as well as to minimize resolution and sensitivity problems, and to preclude ion-molecule reactions inherent to operating an ion trap under high pressure conditions; exclusive pulsed injection of either positive ions or negative ions; ability to inject ions of low kinetic energy.

The quadrupole deflector ion injection system (Figure 1) was designed through the use of the SIMION ion optics modeling program. Since the quadrupole deflector is an energy analyzer, it would be expected to discriminate against ions created outside the ion source through collision-induced dissociation, CID, as they pass through the injection system. The quadrupole deflector does suffer from the lack of focusing in the direction parallel to the quadrupole rods. Through SIMION modeling, it was determined that the quadrupole deflector system offers excellent positional and angular acceptance in addition to its inherent energy filtering. Pulsed injection was effected by gating the voltages applied to the quadrupole deflector rods, thereby deflecting the ions 180° from the trap when injection is gated off.

Representative EI and methane electron-capture negative CI spectra of injected perfluorotributylamine ions with a nominal injected kinetic energy of 5 eV are shown in Figure 2. The ion at m/z 219 in the EI mass spectrum, not present in previous experiments, suggests minimal fragmentation for this low-energy ion injection experiment. The ion at m/z 197 is the result of an ion/molecule reaction of m/z 219 with water.

Experimentally determined transmission efficiencies were: 98% of ions which entered the quadrupole deflector could be deflected to the second tube lens, 60 to 70% of deflected ions are transferred through that tube lens to the entrance endcap, and 25% of deflected ions are actually transferred into the ion trap analyzer. The poor transmission through the endcap aperture is due to the defocusing of the ion beam which accompanies the sharp reduction in ion kinetic energy just prior to injection.

Detection efficiency can be defined as that percentage of total injected ions which are collected, stored, and ultimately detected. Figure 3 shows the detection efficiency of ion injection for argon 40^+ ions with various kinetic energies. Also shown is the multiplicative effect of detection efficiency with the transmission efficiency through the entrance endcap, illustrating the sensitivity advantage of low ion kinetic energies during injection.

Distortions in the quadrupolar field inside the quadrupole ion trap can result in non-linear resonances (4-5), experimentally seen as losses in sensitivity for certain combinations of RF and DC voltages. Relative minima for injected ions for various RF and DC voltages applied to the ring during ionization are found to correspond with theoretical third- and fourth-order distortions in the quadrupole field. The effects of non-linear resonances on injected ion spectra are shown in Figure 4: intensities of Br^- ions from bromobenzene and the resulting isotopic ratios are plotted as a function of RF voltage applied to the ring during injection (1 DAC $\sim 4 \text{ V}_{pp}$). These effects could be minimized by ramping the RF voltage applied to the ring during the ion injection pulse. Similar effects were seen using two different ion trap analyzers. Such non-linear resonances may result from field imperfections due to the holes drilled in the center of the ion trap endcaps for ion injection and detection. Optimal collection efficiency for injected higher mass ions ($m/z > 200$) occurs with applied RF trapping voltages corresponding to lower values of the Mathieu parameter q , where non-linear resonances are less prevalent; thus, injected higher mass ions do not suffer from this phenomenon.

This work demonstrates the utility of using a quadrupole deflector to separate a high pressure ion source from a mass spectrometer both in space and orientation, thus alleviating the need for differential pumping, as well as minimizing problems inherent to having a line-of-sight relationship between a high-pressure ion source and a mass spectrometer. Injection of ions from an external ion source opens up the possibilities for a wide range of new ionization and sample introduction techniques, including positive CI, electron-capture negative CI, fast atom bombardment (FAB), and any of numerous interfaces for liquid chromatography (LC/MS).

A Historical Review of the On-line Combination
of Chromatography with Mass Spectrometry

W H. McFadden
Finnigan Corporation
355 River Oaks Parkway
San Jose, CA 95134

During the decade of the 50's, two important developments were taking place. One of these was the introduction of gas-liquid-partition-chromatography by James and Martin; the other was the development of mass spectrometry for a broader range of organic compounds (McLafferty, Meyerson, Sharkey, *et al*). Looking back 30 years later, it is easy to say that the on-line combination of the two instruments was obvious.

In actuality, the combination was not obvious. Gas chromatographs of that period usually ran at carrier gas levels of 25 to 50 cc/min. Mass spectrometers at that time were designed for analysis of petroleum fractions using a batch inlet. Vacuum systems were not optimized and scan mechanisms were deliberately slow to achieve maximum stability and precision. Thus, the suggestion that a mass spectrometer could be opened up to a gas chromatograph was modestly audacious to say the least, and required significant hardware modifications and operational compromises before the first crude experiments could be demonstrated.

In 1956, J.C. Holmes and F.A. Morrell presented a paper at the ASTM E14 meeting describing changes they had made to a consolidated 21-103B mass spectrometer. The inlet system was adopted to permit "an aliquot of the output of the column into the mass spectrometer"; the scan circuit was modified to give "a scan from approximately mass 12 to mass 100 in six seconds"; and the amplifier output was "fed to the Y input of the oscilloscope ... to present mass 28 to mass 44 in a single 13 second sweep".

Although today's sophisticated users might scorn this humble start, a small cadre of research workers foresaw the potential of the combination and in the next 2-4 years, several laboratories modified their magnetic mass spectrometers in a similar manner. In addition, the Bendix Time-of-Flight on the market at that time was immediately recognized as an instrument with certain built-in features that facilitated the combination, namely, a large, reasonable efficient pumping system and an electron multiplier (which was not standard in magnetic instruments of that period). Roland Gohlke at Dow was one of the first Bendix TOF users and his pioneering work demonstrated clearly that GCMS (as we now call it) was very practical for many real life problems.

Although instrument manufacturers were slow to respond to the need of larger pumping systems, several research groups were attacking the problem from two angles. Use of capillary columns for the GC separations provided carrier levels of 1-2 cc/min or less and thus improved efficiency of sample transfer. For packed column systems, a variety of enrichment devices, the so-called separators, were being developed in many laboratories. These were primarily of 3 types; jet separators (Ryhage-Stenhagen), effusion separators (Watson-Biemann) and membrane (Llewellyn-Littlejohn) separators. The first two of these performed the task of removing carrier helium from the GC effluent without significantly decreasing the quantity of sample in the flow. The membrane separator performed the task of enriching sample through a thin silicone rubber membrane due to the higher permeability of organic materials over the helium carrier gas.

Typical separator yields to the mass spectrometer were in the range 20-70% depending upon the GC flow conditions and mass spectrometer pumping systems. Considerable controversy occurred during the 60's over which separator was the best and occasionally, erroneous data was cited in an attempt to prove superiority. In the end, as is very evident today, the jet separator has been shown to have acceptable enrichment with minimal sample decomposition and is the only survivor in common usage.

Of course, use of capillary columns in the flow range of 1 cc/min. automatically results in a higher sample/carrier ratio. Even with the older pumping systems in use in the early 60's, 20 to 100% of the flow could be directed to the mass spectrometer so that use of separators was unnecessary.

By the end of the 1960 decade, most of the problems of GCMS interfacing were reasonably well understood. Electron multipliers were standard on all organic mass spectrometers, thus facilitating fast scanning. Some compromise was necessary for magnetic scanning, but this was not serious except for high resolution studies. Most commercial spectrometers had well designed differential pumping systems that would accept a gas flow in the range 10-30 cc/min. Future developments were to involve computerization, adaptation to special ionization methods, improvement of column technology, and of course, acceptance of the quadrupole. It was clear to everyone by 1970 that GCMS had arrived.

Wonderful! So now what about LCMS? Although liquid chromatography in several of its many forms had preceded gas chromatography by many years, it was not until the decade of the 60's that the technology was developed to permit what we now call high performance liquid chromatography (HPLC). Since most of the problems of GCMS had been resolved, it might be anticipated that LCMS should follow naturally. But nothing could be further from the truth.

The flow problems of GCMS involved handling 1-20 cc/min of gas into the spectrometer. In HPLC, a typical flow is 1 cc/min. of liquid but this amount will generate around 1000 cc/min. of gas (1244 for H₂O at STP). Furthermore, one important raison d'être for liquid chromatography is the separation of nonvolatile compounds. If a compound cannot be vaporized for separation in a GC column without decomposition, then it is highly probable that the same adverse fate will result if the compound is vaporized into a mass spectrometer. For LCMS, the problems of GCMS are exacerbated by one or two orders of magnitude. This is virtually a whole new ballgame.

The first published account of LCMS was by Tal'Rose, et al in 1968. In this work, a very small fraction of the LC effluent was leaked into a general purpose EI mass spectrometer with no special modifications. Benzene, biphenyl, and naphthalene were separated using heptane as the mobile phase. Aside from historical interest, the experiment caused little excitement due to the very small fraction of solute that was sampled and due to the volatile nature of the selected samples.

In 1974, 3 separate groups published results on 3 separate LCMS interface methods. Arpino, et al, modified an AEI MS-902 mass spectrometer with increased pumping capacity to accept 10-12 microliters/min. of LC effluent and showed an LCMS chromatogram of several steroids. Scott, et al, adopted a wire transport detector so that the wire passed through two vacuum locks into the ion source of a Finnigan 1015 quadrupole mass spectrometer and exited through similar vacuum locks on the other side. In spite of the limited amount of material that can be deposited on the wire, impressive results were shown for a fermentation extract sample. Horning, et al, used an API source to obtain spectra of MTH aminoacids. In their apparatus, the LC flow was

vaporized in an evaporation chamber prior to entering the API source where ionization occurred by either corona discharge or ^{63}Ni beta radiation.

Commercial adaptation of the wire transport and the direct introduction system followed in the latter half of the 70 decade. The wire transport was modified into a belt transport system to permit efficient transfer of solute into the ion source (Finnigan Corporation). The McLafferty DLI system was modified and marketed by Hewlett-Packard. These two commercial units were the basis of most LCMS studies up to the early 1980's.

Of course, other developments were concurrently in progress. A dimethylsiloxane membrane system was demonstrated by Jones and Yang (1975), but showed little promise due to low selective leverage between solute and solvent. Furthermore, tailing of relatively easy samples such as anthracene was excessive and presaged significant problems for less volatile materials. More important, several laboratories were actively searching for other methods, particularly methods involving nebulization of the solvent flow. Vestec investigated several processes for producing thermal nebulization; Futrell, using a similar apparatus, demonstrated mass spectra using sonic nebulization; Takeuchi used micro LC with pneumatic nebulization; and Iribarne and Thomson were showing direct ion evaporation using a pneumatic nebulizer with an atmospheric pressure induction electrode to enhance charging of spray droplets.

In 1980, a very important event occurred; thermospray ionization was discovered. Although this remarkable serendipity was anticipated by the theoretical studies on ion evaporation, it was first discovered in Vestal's laboratory when the filament of an experimental system failed and ion current was still observed. It was soon apparent that this was a soft ionization process that would produce ions from low volatility compounds. Equally important, the discovery stimulated the basic understanding of soft ionization processes and the realization that many of these occur through a similar mechanism, namely ion evaporation from aerosol droplets.

Within 2-4 years, thermospray was commercially available from several manufacturers and rapidly became the most popular LCMS interface. Further development of the belt transport system continued with significant interest in laser and ion bombardment. The data obtained by these desorption processes was quite acceptable but the sensitivity achieved was about 2 orders of magnitude less than acceptable. The DLI system lost much of its popularity to thermospray but continues to be used, particularly with micro LC which achieves a significant increase in sample utilization. But undoubtedly, an equally important development taking place in the early eighties, alongside thermospray, was the emergence of the various atmospheric ionization sources (Tsuchiya, liquid ionization; Fenn, Whitehouse, electrospray; Thomson, Iribarne, ion evaporation; Thomson, Danylewych-May, heated pneumatic nebulizer; Covey, Henion, ion spray). These atmospheric pressure techniques all have in common some form of nebulization and an electrode to assist in aerosol formation and sample ionization. They all give excellent soft ionization of a wide variety of samples with high sensitivity. Some of the operational modes, especially electrospray, have been shown to produce multiply protonated ions on high molecular weight materials. These multiply charged ions can be used to extend the molecular weight range of analytes above 15,000 Daltons even though the m/z range of the spectrometer is less than 2000 Daltons. The practical limit of this technique is not known at this time but is expected to possibly exceed 100,000 Daltons.

On the other end of the molecular weight scale, there has been renewed interest in obtaining electron impact data on compounds in the range 100-500 Daltons, particularly for environmental samples. Although the belt interface has performed this service for over

12 years with subnanogram quantities, the mechanical system is still perceived as a dinosaur lumbering through a delicate ion source and has never received widespread acceptance. Recent developments in the field of particle beam generation, as pioneered by Browner and co-workers at Georgia Institute of Technology, have been commercialized by Extrel (Willoughby) and Hewlett-Packard (Apffel) and offer an alternative interface method for obtaining EI spectra. These systems have demonstrated useful EI spectra for a wide variety of compounds, usually on samples in the range of 1-50 nanograms. Current trends show a strong orientation toward the particle beam system for environmental samples. As another alternative, there has been some effort toward generation of EI spectra using low flow columns (500 nanoliters/min. to 10 microliters/min.) in a DLI mode. These systems work satisfactorily but the paucity of commercial support for microliquid chromatography has discouraged any significant move toward this methodology.

GCMS started during the mid-50's, most problems were understood by the late 60's, and today it is almost a household word (at least it is in my house). LCMS started 15 years later, about 1970, but due to the very difficult obstacles that had to be overcome, has only started to be widely accepted in the past 3-4 years. But another very encouraging trend has been occurring concurrently during this decade of the 80's, namely, the interfacing of other chromatographic techniques to the mass spectrometer. The most dramatic of these new combinations has been the interfacing of capillary zone electrophoresis (CZE) and isotacophoresis by Smith and co-workers at the Battelle Pacific Northwest Laboratory. This group modified the capillary electrophoretic system so that the terminal end of the capillary was biased at 3-4KV rather than the conventional ground potential. Electro-osmotic flow provides a bulk liquid transfer of approximately 1 microliter/min. to the tip which is interfaced to the mass spectrometer in the configuration of an electrospray ion source (following Fenn, *et al*). Preliminary data show a real potential for analysis of complex biochemicals as well as other simpler molecules, especially salts.

Other separation systems that are being successfully interfaced to the mass spectrometer are super critical fluid chromatography, thin lay chromatography, ion chromatography, and yes, even countercurrent chromatography. The degree of interest in these various methodologies varies considerably, but an important message is being revealed. Even though interfacing a liquid separation system to a mass spectrometer will always be fraught with obstacles, there is now a clear demonstration that it is practical in many forms and that we have conquered our fear of these difficulties. The developments of the next decade will be spectacularly inspiring!

The Development of Selective Methods of Ionization

Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware
Newark, Delaware 19716

Perhaps the first selective method of ionization in mass spectrometry was the technique of low voltage electron ionization, LVEI. The technique was first applied for the determination of low molecular weight inorganic gases.¹ However, the first substantial amount of work on the application of LVEI/MS to the analysis of complex mixtures was reported in 1956 for the analysis of unsaturated hydrocarbons in complex petroleum mixtures. The electron energy is adjusted to a compromise value sufficiently low to eliminate most (if not all) of the ionization from paraffins and sufficiently high to allow reasonable sensitivities for the unsaturated hydrocarbons.² Quantitative analyses on the compositions of synthetic mixtures agreed well with values from synthesis. The analyses of individual compounds and compound types agreed well with the much more time consuming analytical procedures then available.

One of the main problems in the analysis of complex mixtures is the absence of standards for the determination of calibration factors. It was shown in subsequent work that the sensitivities as molecular ions, M^+ , for aromatic hydrocarbons depended on the compound type, the number and length of the side chains, and the actual value of the electron energy.³

The combination of high resolution mass spectrometry with low electron energy ionization increased the selectivity of the analyses and provided much more detailed information about the composition of complex mixtures. The initial procedures required the manual recording of the peak heights for each component of every multiplet for hundreds of masses from the oscillographic paper from a high resolution mass spectrum.⁴ Improvements in the stabilities of the scan functions and the development of appropriate computer algorithms eliminated much of the spectacularly tedious work and while still allowing the identification of at least septuplets at the same nominal mass.⁵

Recently low voltage EIMS has been successfully combined with gas chromatography.⁶ Good agreement has been reported between the conventional batch introduction and gas chromatographic introduction using low voltage EIMS. The gas chromatographic separation enhances the interpretative capabilities of low voltage EIMS in general. A combination of low and high voltage GC/EIMS allows the differentiation between alkenes and cycloalkanes of the same molecular weight.

In chemical ionization mass spectrometry, CIMS, the sample ions are formed by chemical reactions of ions from the reagent gas with the sample molecules. Selective detection in CIMS involves changing the ionic chemistry (by changing the reagent ions) to be able to identify compounds with certain functional groups in the presence of other compound types. Perhaps the earliest reported example of selectivity in CIMS was the use of water as a reagent, H_3O^+ or $H(H_2O)^+$, as the reagent ion, to ionize only decanol in an equimolar mixture of decane and decanol.⁷

Since the sample ions are produced by gas phase ionic reactions, the rate constants for the ion/molecule reactions between the reagent ions and the sample molecules are the determining factors in the selectivity (if any) of a chemical ionization reagent gas system. The original CI reagent gas (and one that is still widely used) is methane, a non-selective reagent gas because of the large rate constants for the reactions of the two reagent ions, CH_4^+ and $C_2H_5^+$, with most molecules or classes of compounds. Using methane as an example, one may readily show the dependence of total

sample ionization (or sensitivity) on the rate constants for the ion/molecule reactions.

Under normal CI conditions, when the pressure of the sample is less than a few tenths of a percent of the pressure of the methane reagent gas and the extent of conversion of the reagent ions to product ions is no more than approximately 25%, one may write the differential rate equation for the formation of sample ions,

$$d\Sigma I_i^+ / dt = \alpha (k_{i+}[CH_5^+] + k_{is}[C_2H_5^+]) [Sample] \quad (1)$$

which may be solved with the usual approximations for a small extent of conversion to give

$$\Sigma I_i^+ = \alpha (k_{i+}[CH_5^+] + k_{is}[C_2H_5^+]) [Sample] \Delta t \quad (2)$$

The symbols in these equations have relatively standard definitions: I_i^+ = detected ion current for each product ion; α = proportionality constant between detected ion current and ion concentration in the source of the mass spectrometer, which is presumed (and generally appears) to be the same for all ions; k_i = rate constant for reaction of ion, i , with the sample; $[X]$ = molar concentration of X ; and t = ionic reaction time. From equation (2), one can see that the total sample ionization, ΣI_i^+ (for positive ions), is proportional to the sample concentration, the ionic reaction time, the concentration of reagent ions, and the rate constants for the reagent ion/sample molecule reactions. An analogous equation can be developed for the production of sample ions from reactions of negative CI reagent ions.

It is one of the generally accepted tenets of ion/molecule chemistry that endothermic reactions are slow and seldom observed, whereas exothermic reactions are at least probable. For simple reactions, like proton transfer and charge exchange, it is generally agreed that the exothermic reactions will occur rapidly to give product ions and the endothermic reactions will not occur, and hence no product ions will be detected. Consequently, one uses a thermochemical basis to identify selective CI reagents.

Some of the most commonly used CI reagent ions react by proton transfer,

or by charge exchange,

The heat of reaction for reaction (3) is

$$\Delta H = PA(X) - PA(SH) \quad (5)$$

that is, the proton affinity (or basicity) of the sample minus the proton affinity (or basicity) of the reagent (which may not always be the reagent gas itself). If ΔH is positive, the proton transfer reaction from the reagent ion, XH^+ , to the sample, SH , will not occur and no sample ions will be detected. Reagent ions, XH^+ , which are formed from strongly basic compounds (high proton affinities), X , will not produce sample ions from compounds, SH , that are less basic than X . If the sample, SH , is a stronger base than X , then the proton transfer reaction is exothermic and it is likely that the proton transfer reaction from XH^+ to SH will be fast and abundant sample ions, SH_2^+ or fragment ions, will be produced.

One of the first selective CI reagent gases was isobutane, because the dominant CI reagent ion, $t\text{-C}_4\text{H}_9^+$, is a weaker acid than the CH_4^+ reagent ion in methane; that is, isobutene is a stronger base than methane. The methane CI mass spectra of alcohols contain virtually no ROH^+ ions, and it was expected that the isobutane CI spectra of aliphatic alcohols would give more abundant ROH^+ ions than the methane CI spectra.⁹ Although the extent of fragmentation in the isobutane CI mass spectra of aliphatic alcohols is less than in the methane CI mass spectra, virtually no protonated molecules were observed for the higher alcohols. Although moderately abundant $(\text{M} - \text{H})^+$ ions are observed (which are useful for molecular weight determination), the dominant ions are the alkyl ions, R^+ . The sensitivities appear to be somewhat low for the alkanols in general and for the 1-alkanols in particular. It was similarly noted that the isobutane CI spectra of DDT and related compounds did not contain abundant protonated molecules, MH^+ .⁹

The heats of formation of many of the basic ionic structures needed to determine (or estimate) the heats of reaction with many reasonably complex molecules are not well known. Dissociative proton transfer from the t -butyl ions to the alcohols to produce alkyl ions, isobutene, and water is clearly endothermic. It is likely that proton transfer from the t -butyl ion to these types of compounds is endothermic and that the sample ionization is formed by X^+ abstraction,

One can show, however, a selectivity of the t -butyl ion for polar compounds over hydrocarbons, when compared with the isomeric s -butyl ion (formed from n -butane as a reagent gas), or the propyl ions (from propane as a CI reagent gas). The rate constants for reaction of propyl and butyl ions with hydrocarbons and with simple polar compounds are approximately the same (within a factor of approximately two); however, the rate constants for the reaction of the t -butyl ion with simple polar compounds are some twenty or so times larger than the rate constants for reactions with hydrocarbons containing tertiary hydrogens, and perhaps one thousand times as large as the rate constants for reactions of t -butyl ions with n -alkanes.¹⁰

Another widely used and highly selective reagent gas is ammonia. Early work indicated that strongly basic (nitrogen-containing) compounds and not non-polar hydrocarbons would be selectively ionized in ammonia CIMS.¹¹ The reactions are not exclusively proton transfer, since adduct ions, $(\text{M} + \text{NH}_3)^+$, are formed with some polar compounds. The ratio of intensities for the two major species, $(\text{M} + \text{NH}_3)^+/\text{MH}^+$, depend strongly on the experimental conditions, as well as the proton affinities of the samples being ionized.¹² The low sensitivity as adduct ions for simple polar molecules appears to result from a displacement reaction,

Another complicating factor in ammonia CI mass spectra is the variable abundance of substitution ions, $(\text{M} + \text{NH}_3 - \text{H}_2\text{O})^+$. Di-isopropyl ether (DIPE) has a proton affinity very close to that of ammonia, but DIPE should be less reactive and less strongly solvating than ammonia. A few experiments have been done using DIPE as a reagent gas which give CI spectra which contain predominantly $(\text{M} + \text{H})^+$ ions and virtually no adduct ions.¹³

Negative ions have been observed in mass spectrometers under conventional electron ionization conditions for many years, but the low sensitivities and frequently uninformative spectra for small molecules discouraged most applications.¹⁴

One of the problems with negative ion mass spectrometry under the low pressure conditions of conventional EI mass spectrometry is the low electron capture cross section for the high energy electrons. The electron energies can be reduced by collisions with molecules under CI conditions and early experiments showed significant abundances of negative ions under high pressure conditions. The mechanisms for the formation of the negative ions are not always clearly defined and frequently involve both electron capture and ion/molecule reactions. The "methane-enhanced" negative ion mass spectra of chlorinated pesticides showed multiple modes of negative ion production and the sensitivity of these negative ion spectra to oxygen as an impurity in methane (analogous to the strong sensitivity to water as an impurity in methane positive ion CI spectra).¹⁸

A very high sensitivity has been demonstrated for negative ion mass spectrometry at high pressures for compounds which have high electron capture cross sections for low energy electrons (highly electronegative compounds containing multiple functional groups with high electronegativities). These spectra are very simple, containing predominantly only the negative molecule ions, M^- . However, the relative abundances of these M^- ions are strongly temperature dependent and the experimental conditions must be carefully controlled to maintain the selectivity, sensitivity, and quantitative reproducibility.¹⁹

The selectivity of negative ion molecule reactions in CIMS was demonstrated for the analysis of TCDD (tetrachlorodibenzodioxin). Ions from the polychlorobiphenyls frequently overlap the M^- region of the dioxins; however, the negative ion spectrum of TCDD (O_2 as the reagent gas) contains characteristic fragment ions which are in an interference free region of the mass range.²⁰ These fragment ions were postulated to involve a reaction of a sample ion with the reagent gas (oxygen, in this case). Other examples have been shown for the reactions of sample negative ions with the reagent gas in the case of $(M-H)^-$ ions of alkyl aromatic molecules with nitrous oxide. However, these reactions were not sufficient to prevent the selective analysis of alkyl aromatic hydrocarbons in complex mixtures using OH^- as the negative CI reagent ion, with a relatively low pressure of a nitrous oxide/hexane mixture as the reagent gas.²¹

There are several other types of selective ionization, such as Field Ionization, Field Desorption, Photoionization, and Penning Ionization which will not be discussed at this time.

Historical Developments in Quadrupole Mass Spectrometry

P.H. Dawson, Laboratory for Microstructural Sciences,
National Research Council, Ottawa K1A 0R6, Canada

Introduction

The three members of the quadrupole family of instruments, that is, the mass filter, the ion trap and the monopole have very different histories. The first two ideas originated in 1953 but the monopole was not described until 1963 and had a short life as a widely used instrument. In this brief history, the flow of ideas and concepts will be described with less attention to exact dates and to acknowledging all the myriad of contributions to the development of quadrupoles as the dominant class of mass spectrometers. Inevitably some individuals' contributions may not be adequately recognised in such an approach and I offer a blanket apology to anyone thus neglected. However, in classical history, I find the history of ideas more interesting than the recitation of the lists of kings and queens and the dates of their reigns!

Another difficult factor is that I have been myself a participant in the field for about 24 years and so this history naturally reveals all my personal biases and particular interests. I will therefore concentrate on instrument performance and design rather than application and I will permit myself the luxury of some reminiscence about my own early involvement. My involvement in the three types of instrument was in opposite order to their sequence of development, beginning with the monopole in 1965, the ion trap in 1966 and the mass filter not until 1971. I will describe the development in this sequence but first I will begin with a description of how the foundations for the whole field were laid by the group of workers at the University of Bonn. Rarely has a new field been so dominated by the initial concepts developed by one group. In fact, looking back with today's knowledge, the experimental achievements in the initial years were really quite limited — but almost every concept exploited later was explored conceptually.

Table I simply lists the early published works leading to the proposal of the instruments. The principles of the use of radiofrequency quadrupole electric field for separation according to M/Q ratio were recognised at about the same time by R.F. Post at the University of California and by W. Paul and H. Steinwedel at the University of Bonn. However, the first years of exploitation and the eventual successful development can clearly be attributed to the latter group. Published results were few in the early years and the Bonn group had the luxury of five years of study before publication of the now classic paper of Paul, Reinhard and von Zahn on the mass filter (see Tables II and III). In the meantime, the quadrupole ion trap was the subject of at least two theses before the publication of Fischer's work in 1959. Significant North American effort on quadrupoles only began about that time but grew to a high level in the mid-1960's driven and funded in large part by the requirements of the space program. With the invention of the monopole in 1963 and its rapid commercialisation, the mass filter and the monopole became great rivals in the residual gas analyser market. A 1971 review, could find little difference in commercial specifications although there were some indications that in practicality and ease of use, the mass filter was beginning to win out. In fact, after that time, the monopole rapidly waned in popularity and has now almost disappeared.

My own involvement began with the monopole while I was working at the General Electric R&D center in Schenectady. The company's Vacuum Products Groups had rapidly introduced a commercial instrument based on a design reported by J. Hudson¹⁴ of RPI in 1964. Von Zahn¹³ had first described the monopole only in 1963 and it appeared to have some length advantages over the quadrupole. The G.E. product was initially successful and gained customer acceptance. Then disaster struck. In a sequence since well known to all

TABLE I: IN THE BEGINNING

- Static magnetic multipole field to focus neutral atoms (Friedburg and Paul 1951)¹
- Strong-focussing alternating gradient principle of accelerator design - a quadrupole magnetic field with spatial periodicity (Courant, Livingston & Synder 1952)²
- Use of alternating electric fields for focussing (Blewitt 1952)³
 - Mass selection 1953
- R.F. Post, University of California Laboratory Report⁴
W. Paul and H. Steinwedel, Z. Naturforsch.⁵

TABLE II: CONTRIBUTIONS FROM THE BONN GROUP

- General principle - Paul & Steinwedel 1953⁶
(Mass filter first & second regions)
- U.S. Patent Application 1954⁷ (Mass filter & Ion trap)
- Experimental results on the mass filter (Paul & Raether 1955)⁸
 - Frequency scanning, Measurement of efficiency
 - Effect of field errors on peak shape
- Detailed characterisation of the mass filter plus an isotope separator (Paul Reinhard & von Zahn 1958)⁹

- Detailed report on the ion trap¹⁰ (Fischer 1959)
- Field fault analysis¹¹ (von Busch & Paul 1961)
- Large scale isotope separator¹² (von Zahn et al 1960)
- The monopole¹³ (von Zahn 1963)

TABLE III: THE MASS FILTER

- The "Bible"; Paul, Reinhard & von Zahn⁹ Z. Phys. 152, 143 (1958)
- Stability diagram with iso-beta lines using analytical calculations
 - "Acceptance ellipses" (Fischer)¹⁰ & amplitude calculations
- *Two regions of operation using parallel ion entry (a) flat-topped-relative abundance depends on source & detector not the analyser (b) triangular peaks-transmission restricted by the analyser
 - Resolution = $n^2/12.25$

- Discussed demands on accuracy & uniformity
- $r_{rod}/r_{field} = 1.16$ (from Dayton, Shoemaker & Mosley¹⁵: should have been 1.148)
- Problems of the "transition field" discussed
 - Effect of high pressures discussed
 - Source position was transversely adjustable
- Experimental result - resolution 1500 at mass 16 using 1m. quadrupole, 4MHz frequency and 75eV ions.

TABLE IV: THE "AGES" OF ION TRAPPING

- (taken from J.F.J. Todd's introduction to "Quadrupole Storage Mass Spectrometry" by R.E. March and R.J. Hughes)
- Mass selective ion detection e.g. Fischer 1959¹⁰; Rettinghaus 1967²¹
- Mass selective ion storage e.g. Dawson & Whetten 1968¹⁸; Dawson, Whetten & Hedman 1969²²
- Mass selective ion ejection e.g. *Stafford, Kelley, Reynolds & Syka 1983²³

quadrupole manufacturers, specifications could suddenly no longer be met. Deliveries were delayed. The Vacuum Products Group appealed to the R&D center mass spectrometrists for help. As an added inducement, they offered free one monopole. I accepted this gift horse (definitely the worst spectrometer I've seen before or since). In the meantime, R.P. Lever¹⁶, a customer at IBM awaiting a monopole delivery began some numerical calculations of ion trajectories in a quadrupole field. The results, published in 1966, did not explain the performance of the conventional monopole as then used but referred to a proposed high resolution monopole using simultaneous focussing in the x and y directions. Lever's calculations remain beautiful examples of trajectory simulations and set the stage for all the future computation. With the interest and encouragement of my colleague Rey Whetten, I began the then tedious and expensive process of simulating trajectories in the monopole operated conventionally. After a great deal of effort, and to the justifiable chagrin of our colleagues in the Vacuum Products Group we demonstrated that the monopole was not able to give good performance and was bound to produce poor peak shapes. The answer to this conundrum only came when the effects of fringing fields¹⁷ were taken into account in 1971. The importance of the fringing fields was also confirmed by indirect experimental evidence. However, by now, the monopole was already in decline even though the manufacturing group had long since solved their production problems.

Sensitized by our monopole experience, Rey Whetten and I stumbled across the ion trap principle in J.B. Hasted's book on the "Physics of Atomic Collisions". Intrigued by this, we examined Fischer's paper but decided that it might be superior to store the ions mass selectively and eject them into an electron multiplier to be detected as a pulse. We coupled a study by ion trajectory simulation with an experimental program.^{18,19}

In J.F.J. Todd's introduction to the recent book²⁰ "Quadrupole Storage Mass Spectrometry" by R.E. March and R.J. Hughes ion trapping has been characterised in terms of 3 "ages" as shown in Table IV. The initial "age" was one of storing a range of different ions and selectively detecting them by some electronic property related to their frequency of oscillation. The main problems were due to interference effects between species and to ion molecule reactions if storage times were too long. Mass selective ion storage was much more straightforward and the ion trap almost reached commercialisation as a residual gas analyser in a very simple form.²² However, the real breakthrough did not come until the use of nonselective storage but mass selective ion ejection by Stafford et al²³ coupled with stabilisation of ion trajectories by collision with helium. This latter factor meant an ideal application to GC/MS. The rest of the exciting story is very recent history and does not need to be repeated here.

The key point of collisional stabilisation had been known for some time (see Table V) but not exploited. Particularly intriguing is the work on producing "frozen" arrays of particles — originally macroscopic charges dust particles as early as 1957²⁴ and very recently of atomic ions.^{31,32}

The experience with the ion trap led Rey Whetten and I to study the effect of field faults in quadrupole fields. This activity has continued to the present day with increasing levels of sophistication (Table VI) with the main applications to the mass filter.

For the mass filter, the contributions of the classic paper by Paul, Reinhard and von Zahn⁹ have been listed in Table III. The theoretical work is all the more impressive when one remembers that it was all carried out by calculations using the analytic theory — numerical simulation by computer was not yet feasible. One interesting feature of the paper was the description of acceptance ellipses (based on Fischer's work). Many years later, these became the basis for the modern ion optical theory of quadrupoles (Table VII). However, the full significance does not seem to have been realised in the original work.

TABLE V: COLLISIONAL STABILISATION

- *Wuerker, Shelton & Langmuir 1959²⁴ Trapping of macroscopic charged particles. (work first reported in 1957)
 - Effect of elastic collisions²⁵ (Major & Dehmelt 1968)
- *Dawson & Whetten (1969)²⁶ Heavy ion stabilisation by a light gas
 - Collisional focussing of ions (Bonner, March & Durup 1976)²⁷
 - Phase-space Theory for Dawson (1977)²⁸

- Confirmation of (Neuhauser, Hohenstatt, Toschek & Dehmelt 1978)²⁹
 - Application to Mass Spectrometry (Stafford, Kelley, Reynolds & Syka 1983)³⁰
- *Ionic arrays and phase transitions (Diedrich, Peik, Chen³¹, Quint & Walther 1988)³²

TABLE VI: FIELD FAULTS

- von Busch & Paul 1961 General analytic theory Errors in field geometry & harmonics in the rf¹¹
 - Dawson & Whetten 1969³³
- Experimental & computer simulation for the ion trap
- Full analytical examination - Halbach (1969) for accelerators³⁴
 - Applied to quadrupoles by Pocek 1978³⁵
- Limits to performance of the mass filter, Dawson & Meunier 1979³⁶
 - Diverging, converging, bent & bowed rods, Dawson 1988³⁷
 - Electrical drive errors much less studied

TABLE VII: APPLICATION OF PHASE SPACE METHODS

- Fischer (1959) calculated ellipses for the ion trap
- Matrix methods - Richards et al (1973) for square-wave³⁸
- Phase space concept for the ion trap - Baril & Septier (1974)³⁹
 - Similar ideas - Sheretov & Kolotilin 1975⁴⁰
- Detailed application to the mass filter including fringing fields Dawson 1975⁴¹
- Direct experimental measurements, Henniquin & Inglebert 1978⁴²

TABLE VIII: THE SPREAD OF APPLICATIONS

- 1960s - The mass filter & monopole as RGAs (Isotope separation)
 - Application to upper atmosphere & space
- 1970s - The mass filter in GC/MS SIMS systems
 - 1978 The tandem quadrupole for MS/MS
 - 1983 The ion trap detector for GC/MS
 - 1983 ICP/MS & Glow-Discharge MS
 - 1986 LC/MS/MS
 - 1987 Ion Spray/Thermospray LC/MS

TABLE IX: RF-ONLY QUADRUPOLES

- 1959 The ion trap
- 1972 Weaver et al; Differentiation of Mass Filter signal⁴³
 - 1972 Brinkmann; Retarding geometry at the collector⁴⁴
 - 1978 Holme, Sayyid & Leck Improved collector⁴⁵
- 1980 Dawson, Meunier & Tam; Annular collection system⁴⁶
 - Plus various refinements since

The classic paper also described an isotope separator — a mass filter on a larger scale operated with an auxiliary rf field to remove ions at resonance. The ultimate separator was an 8.2 m long instrument (in the stairwell at the University of Bonn in a vertical position).³⁸ The instrument was vertical and the electrodes formed by a large number of weighted piano wires. A resolution of 10,000 was reported.

The performance of the mass filter gradually improved over the years. The perfection of the fields was a significant factor. Ion source design became more appropriate, allowing the use of lower energy ions. Mass range was extended and new applications opened up (Table VIII). However, there has been no significant departure in basic design — just the steady technological improvement. After the contributions of the Bonn group, the body of work of greatest significance was that of Wilson Brubaker and various colleagues. He began by exploring the application of the mass filter to direct ion sampling in the upper atmosphere and studied in detail both experimentally and theoretically³⁹ transmission of ions as a function of transverse position, transverse angle and rf frequency. This led to the first detailed understanding of the importance of fringing fields at the entrance. Eventually, they proposed the concept of the "delayed d.c. ramp" with an rf only section to mitigate fringing field effects. Another classic study was the only detailed attempt to directly compare round and hyperbolic cross-section rods in the same system.⁴⁰

Some novel developments of the mass filter still unexploited in a practical way are the use of higher stability regions (originally recognised by both Post and Paul and Steinwedel) and of the rf only concept (Table IX). Other ideas remaining unexploited are the use of exact focussing, the quadrupole time-of-flight, resonant detection, the use of gas collisions in the mass filter and ion bunching at the mass filter entrance. One would expect therefore that history is not yet concluded and the future could continue to be exciting.

A HISTORY OF GC/MS INTERFACES

Michael A. Grayson
McDonnell Douglas Research Laboratories
St Louis, MO 63166

During the initial development period of combined gas chromatography and mass spectrometry, a great deal of effort went into the design of interfaces to accommodate the drastically different pneumatics of these analytical instruments. Subsequent improvements in the technologies of each instrument removed the need for interfaces to combine them. This history covers work on molecular interfaces for the combination of gas chromatography with mass spectrometry during the period between the late 1950s and the early 1970s.

The complementary analytical capabilities of gas chromatography and mass spectrometry were noted by early users of the two instruments. For samples of identical size, mass spectrometry could provide accurate identification of compounds whereas gas chromatography could only provide approximate identification based on retention indices. On the other hand gas chromatography was clearly superior to mass spectrometry in quantitatively analyzing samples. Both techniques required the sample be in the gas phase for analysis. Combining the two was an intriguing prospect; however, the combination was thwarted by the incompatibility of the large mass-flow rate of carrier gas required by the gas chromatograph and the static vacuum systems of the mass spectrometer. Nevertheless, because the potential power of a combined instrument was viewed as limitless, a number of workers focused their attention on solving the problem of the incompatible mass-flow rate requirements of the two instruments by means of some kind of interface.

Most researchers cite the work of Gohlke (Ref. 1) as the beginning of the age of combined GC/MS, even though Holmes and Morrell (Ref. 2) reported a combined instrument using a magnetic sector machine several years earlier. The work of Holmes and Morrell was done on a Consolidated Engineering Corporation Model 21-103B magnetic sector instrument which required nearly a minute to scan the mass range from 12 to 100 daltons. Holmes and Morrell devoted the bulk of their paper to the description of an oscilloscopic display system which permitted the operator to continuously scan a 16-mass-unit-wide portion of the spectrum to ascertain that a compound had entered the ion source, thus allowing the spectrum to be recorded with an oscillograph. However, no information was given about the manner of connecting the chromatograph to the mass spectrometer! This oversight is particularly disconcerting today since the 103B instrument had a vacuum system capable of a miniscule gas load.

Gohlke devoted more attention to a description of chromatographic instrumentation than to interfacing the instruments. Towards the end of his paper, he describes how a portion of the column effluent was split to the mass spectrometer by means of a fine needle valve. This work was done with a time-of-flight mass spectrometer which had the advantage that oscilloscopic monitoring of the mass spectrum was an intrinsic feature of the instrument. It is also noteworthy that the time-of-flight had an open ion-source and that the conductance between the ion-source housing and the vacuum system was high. Thus, in 1959, Gohlke's time-of-flight mass spectrometer had one of the most dynamic vacuum systems of any such analytical instrument. Even so, Gohlke reported that "... the mass spectrometer is consuming the effluent vapor from the chromatographic column at a rate of about 0.003 cc. [-atm] per second ... " (Ref. 1).

Quite obviously, split interfaces meant diverting a large fraction of sample molecules away from the mass spectrometer. Although Gohlke does not state the carrier gas mass flow rate, conditions of pressure (10 psig) and column

*This work was conducted under the McDonnell Douglas Independent Research and Development program.

size (10 foot x 1/4 inch) suggest that it was in the tens of mL-atm/min. Thus, probably less than 1% of the analyte reached the mass spectrometer.

In the ensuing years, attempts to enrich the analyte in the carrier gas entering the mass spectrometer proceeded along two different lines: sample-trapping interfaces, and enrichment interfaces. Typical of the sample-trapping approach is the work of Ebert in 1961 (Ref. 3), and Miller in 1963 (Ref. 4). These workers attacked the problem by modifying the static inlet system of the mass spectrometer. They were quite successful in enriching the chromatographic effluent, but for only a few components in an analysis. The alternative approach, enrichment interfaces, was also being explored by other workers and this latter technique soon dominated.

A variety of techniques for enriching the chromatographic effluent in a dynamic fashion were reported in the mid-1960s. These enrichment interface techniques can be divided into three fundamental categories:

- 1) Molecular Effusion Interfaces
- 2) Molecular Jet Interfaces
- 3) Permselective Barrier Interfaces

MOLECULAR EFFUSION ENRICHMENT INTERFACES

In the molecular effusion interface (Fig. 1), the effluent from the chromatograph enters an effusion chamber having one or more porous walls with a well-defined pore size. Flow restrictions between the chromatograph and the effusion chamber, between the effusion chamber and the mass spectrometer, and a pump evacuating the envelope surrounding the chamber allow control of the pressure to create conditions for molecular effusion. Specifically, the mean free-path of the carrier-gas molecules in the effusion chamber should be ten times greater than the pore size of the porous walls (Ref. 5). Under these conditions, the lighter molecules of carrier gas, usually helium, preferentially diffuse through the porous walls thus enriching the concentration of sample gas entering the mass spectrometer.

Watson and Biemann (Ref. 6) were the first to report a molecular effusion device for interfacing the two instruments. The problem of obtaining a mass spectrum during the relatively short time the chromatographic peak is eluted was solved by using an integrating detector, the photoplate, in a high-resolution instrument of Mattauch-Herzog geometry. This elegant solution had the advantage that the detection limit for low-concentration chromatographic peaks was improved while at the same time high-resolution mass spectra could be obtained.

Figure 1. Molecular effusion GC/MS interface.

Immediately following this work, a number of molecular effusion devices in which different materials were used for the controlled-pore-size walls of the molecular effusion chamber were reported in the literature. Cree (Ref. 7) used porous silver membranes for the walls of the effusion chamber. His idea was followed by Blumer (Ref. 8), Grayson and Levy (Ref. 9), and a commercial company (Ref. 10). Krueger and McCloskey described an interface using a porous stainless steel tube (Ref. 11). Lipsky and co-workers (Ref. 12) reported the use of a thin-wall Teflon tube as a molecular effusion barrier. Brunée et al. (Ref. 13, 14) described a "variable slit" interface which operated on the principle of molecular effusion. Markey (Ref. 15) reported an improved glass-frit device suitable for use in biomedical applications. The performance of single- and double-stage molecular effusion interfaces was compared by ten Noever de Brauw and Brunée (Ref. 16).

Thus, in the five or six years following the introduction of the molecular effusion enrichment interface, a large number of variants on this basic concept were developed and placed at the disposal of the venturesome mass spectroscopist.

MOLECULAR JET ENRICHMENT INTERFACES

In the molecular jet interface (Fig. 2), the effluent from the chromatograph flows through a constricted orifice, thus forming an expansion plume in the evacuated envelope (Ref. 17). The core of the plume is rich in analyte; thus, a skimming orifice placed opposite the expansion orifice will extract the enriched core for sampling by the mass spectrometer. An advantage of this approach is that the analyte molecules undergo minimal contact with the surfaces of the interface and thus labile molecules have a greater chance of surviving the enrichment process without degradation--an important consideration in biological applications.

Figure 2. Molecular jet GC/MS interface.

Ryhage (Ref. 18) describes the application of the molecular jet technique in a two-stage interface which was the culmination of four years of work on the enrichment problem. In this work, the scan speed of the single-stage mass spectrometer was reduced from tens of seconds to several seconds over the mass range from 12 to 500 daltons. Ryhage (Ref. 19) later described details of the optimization of the molecular jet as an enrichment device for combined GC/MS, and the comparative performance of single- and dual-stage separators.

Devices based on the molecular jet principle also flourished after Ryhage's initial work. Wikstrom and Waller collaborated with Ryhage (Ref. 20) in extending the interface to use with capillary columns. Novotny (Ref. 21) later described the use of this interface with support-coated-open-tubular columns. In 1966, a report (Ref. 22) described a commercial instrument employing the two-stage molecular jet separator. This latter instrument dominated the commercial market for combined GC/MS instruments for several years.

PERMSELECTIVE MEMBRANE ENRICHMENT INTERFACES

In this type of GC/MS interface, a barrier with widely differing permeabilities to the analyte and carrier gas is used to enrich that portion of the effluent entering the mass spectrometer. Not surprisingly, GC/MS interfaces have been developed for barriers which selectively pass analyte molecules and barriers which selectively pass carrier-gas molecules.

Analyte-permeable barriers are based on organosilicone membranes (Fig. 3) which Llewellyn and Littlejohn (Ref. 23) were the first to exploit for their permselective properties (Ref. 24) as an enrichment device. Unlike other interface technologies, which initially were developed in the academic sphere, analyte-permeable barriers were developed by an instrument manufacturer; thus most early information is found in the commercial and patent literature (Ref. 25). Commercial interfaces were originally two-stage devices because of the vacuum technology used in the mass spectrometer. However, since the membranes were readily available from other commercial sources, single-stage variations soon appeared in the literature (Refs. 26, 27, 28).

89-221-177a

Figure 3. Permselective membrane interface.
(Barrier selectively permeable to organic Cpd's)

Lucero and Haley (Ref. 29) reviewed the theory of permselective membrane devices in general and then applied it to a device based on a palladium/silver alloy as a barrier. In this device, hydrogen is used as the carrier gas. Depending upon the temperature of a palladium/silver alloy tube through which the GC effluent passes, hydrogen will preferentially diffuse out of the tube, leaving the enriched sample stream to enter the mass spectrometer. Several years later, Simmonds et al. (Ref. 30) described such a device and its operating characteristics. Catalysis of the analyte was a concern with this interface.

NON-ENRICHMENT INTERFACES

Despite developments in enrichment devices, work continued on refining and improving the utility of split-connections between the chromatograph and mass spectrometer. Lindeman and Annis (Ref. 31) extended Gohlke's work to a cycloidal mass spectrometer and reported continuous monitoring of selected ions characteristic of specific compounds in the analyte. Henneberg and co-workers (Refs. 32, 33, 34), Dorsey et al. (Ref. 35), and Brunée et al. (Ref. 36) all took advantage of chromatographic columns which used lower mass-flow rates, thus increasing the sample mass delivered to the mass spectrometer with the split-connection.

As early as 1962, other workers, notably McFadden and Teranishi (Ref. 37, 38), took advantage of the efficient pumping system of the time-of-flight mass spectrometer to directly connect the column outlet to the mass spectrometer without benefit of split or pressure reduction. Merritt and coworkers (Ref. 39) demonstrated the utility of direct connections for a variety of mass spectrometers with support-coated-open-tubular columns. Improvements in vacuum-system design (Ref. 40) made use of a direct connection practical for columns with flow rates in excess of 5 mL-atm/min.

SUMMARY

By the early 1970s, improvements in both column technology and vacuum systems for mass spectrometers set the stage for direct connection of the two instruments to dominate combined GC/MS. A polemic in *Nuclide Spectra* (Ref. 41) succinctly summarizes the arguments for direct connection of the two instruments. Today, almost all commercial instruments have direct connections for the GC/MS interface. Where higher column flow rates are required, the molecular jet is the most widely used enrichment device. Thus, a field of intense interest with many exciting developments over a short period of time was deserted when improvements in the fundamental technologies of chromatography and mass spectrometry were made. In a sense, the analytical power of combined gas chromatography/mass spectrometry was demonstrated with enrichment interfaces; these interfaces were then rendered unnecessary with the development of low mass-flow-rate chromatographic columns and dynamic mass-spectrometer vacuum systems.

THE DEVELOPMENT OF METHANE CHEMICAL IONIZATION MASS SPECTROMETRY

Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware
Newark, Delaware 19716

Chemical ionization mass spectrometry was an outgrowth of fundamental studies of ion/molecule reactions at increasingly higher pressures.

The first mass spectrometers which were specifically designed for high pressure operation, in the range of 0.1 torr, were reported around 1960. One of these instruments was the the Humble chemical physics mass spectrometer, designed by Frank Field to study ion/molecule reactions. The first publication from work on this instrument showed ionic products as high as C, from ion/molecule reactions in ethylene at 0.2 torr.¹ Another high pressure mass spectrometer had been developed a little earlier and had been used for the study of collisionally induced decompositions.²

Relatively minor modifications were made to the Humble (then Esso, and eventually Rockefeller) mass spectrometer in 1965 to allow operation at pressures as high as 1 - 2 torr. These modifications were the relatively minor ones of decreasing the sizes of the electron entrance and ion exit slits of the source. We re-discovered that the distributions of ions in methane at these pressures were very sensitive to very low levels of impurities and painstaking efforts were needed to remove traces of water from the reagent gas, the inlet system, the transfer lines, and the mass spectrometer. The very low levels of water as an impurity could easily be detected as ions at m/z 19. We never seriously considered CH₅⁺ as an ionic species, but it was very frustrating to observe large and variable amounts of m/z 19 in research grade methane in what was presumed to be a very clean vacuum system. It was eventually established that CH₅⁺ and C₂H₅⁺ did not react with methane to any significant extent under these experimental conditions.³

A series of experiments were then done with mixtures of methane and small amounts of various simple molecules to understand the then completely unknown ion/molecule chemistry of CH₅⁺, and to a lesser extent the ionic chemistry of C₂H₅⁺. These ions react with almost, but not quite everything, and the dominant reactions were dissociative and non-dissociative proton and hydride transfer. CH₅⁺ could be considered as a strong Bronsted acid, and C₂H₅⁺ could be considered as a Bronsted or a Lewis acid.⁴ Reactions of the methane ions, CH₅⁺ and C₂H₅⁺, with two isomeric hexanes showed ionic product distributions which were independent of pressure, similar enough that one could identify both compounds as hexanes, and sufficiently different that one could differentiate between the structures of the two isomers. The ionic distributions for mixtures of methane with small amounts of other isomeric hydrocarbons showed similar features: sufficient (M - H)⁺ ions to obtain the molecular weights of the compounds and sufficiently different distributions of fragment ions that the compounds could be distinguished. At that time, it occurred to us (to Frank Field, first, I believe) that we had a potentially useful analytical procedure.

A patent application was filed in 1965, which was disallowed because of a prior patent of Fite, et al (#3,254,209, May, 1966). There is no new thing under the sun. However, the lawyers persevered and a revised patent application was submitted in 1968 which was granted in 1971 -- my only patent and one of Frank Field's three.

The first non-company presentation on chemical ionization (not to be confused with chemi-ionization, which refers to the reactions of excited state ions with neutral molecules to form an ion and an electron) mass spectrometry (CIMS -- the initials look better in caps) was given at the Eastern Analytical Conference in New York, in November, 1965.

The first paper on CIMS was published in 1966. The review of the first version of the paper was not favorable, to say the least.

"This is a very carelessly written paper and a serious waste of a reviewer's time. ... I cannot argue with the author's [sic, there were two authors] conjectures regarding the origin of the spectra. However, despite occasional references to heats of formation and exothermic reactions, conjecture is all that it is. When some observations (e. g. p. 31 [in the original draft]) are "explained by the use of impure materials [sic, closing " and , were omitted] I think one should give serious consideration to the value of the work and the usefulness of the publication."

I thought that the originally submitted version was not that bad; however, I may be prejudiced. We persevered and the first paper was accepted, without an excessive delay.'

In the early work, comparisons were made between the methane CI mass spectra and EI mass spectra, which showed generally abundant ($M \pm H$)⁺ ions as well as structurally useful fragment ions, whose formation could be relatively easily explained by proton or hydride transfer reactions followed by simple cleavages or rearrangement decompositions from the excited ($M \pm H$)⁺ ions. Comparisons were generally made for relatively simple compounds for which the EI spectra contained little or no M^{+} ions.'

Two things greatly aided the general acceptance of methane CIMS as a routine analytical tool around 1970. One was the development by Marvin Vestal at Scientific Research Instruments of a high pressure source which could be fitted to existing mass spectrometers. The other was a series of papers by Fales and others which showed that methane CI was useful for "real" molecules of interest to organic and biomedical mass spectrometrists.' Since the 70's CIMS with methane and other reagent gases has been routinely used for mass spectrometric quantitation and characterization.

CHEMICAL IONIZATION WITH TETRAMETHYLSILANE, PAST AND PRESENT

or

A HISTORY OF GAS PHASE TRIMETHYLSILATION

Ron Orlando and Burnaby Munson

Department of Chemistry and Biochemistry

Newark, Delaware 19711

Chemical ionization mass spectrometry (CIMS) has become a routine analytical technique which gives information complementary to that obtained by electron ionization (EI). A major advantage of CIMS is that a lower quantity of energy is imparted to the sample ions compared with EI. Because of this lower energy, CIMS frequently yields molecular weight information for compounds which give only fragment ions in EIMS. Also, an additional degree of selectivity can be added to an analysis by the use of a reagent gas which will selectively ionize only chosen classes of compounds.

In CIMS, the amount of fragmentation is dependent on the heat of the reaction, which can be altered by changing the reagent ion. Methane, the traditional and most widely used reagent gas, gives only fragment ions for several classes of compounds.¹ Because the reagent ion from iso-butane, $t\text{-C}_4\text{H}_9^+$, is a weaker acid than the reagent ions found in methane, CH_5^+ and C_2H_5^+ , this reagent increases the amount of $(\text{M}+\text{H})^+$ or $(\text{M}-\text{H})^+$ and causes a decreased extent of fragmentation when compared to methane.² Ammonia is even more basic than CH_4 , C_2H_4 , or $i\text{-C}_4\text{H}_8$; consequently, proton transfer from the ammonium ion is less energetic than proton transfer from either CH_5^+ , C_2H_5^+ , or $t\text{-C}_4\text{H}_9^+$.^{3,4} Resulting in primarily $(\text{M}+\text{H})^+$ ions being observed with very little, if any, fragmentation when NH_3 is used as a reagent gas. A second ion which is formed in NH_3 CI is the ammonium adduct ion, $(\text{M}+\text{NH}_4)^+$, which can cause problems in the molecular weight assignment of the sample. Ammonia has a very low sensitivity for compounds which are less basic than itself.^{5,6}

The lack of a reagent gas having a high sensitivity for a wide range of compounds while imparting a minimal amount of energy upon reaction has caused a search for an alternative reagent gas. One such reagent which has been used is tetramethylsilane (TMS). The major reactant ion found when TMS is used as a CI gas is the trimethylsilyl ion, $(\text{CH}_3)_3\text{Si}^+$, at $m/z = 73$. In the early work employing TMS as a CI reagent gas, the base peaks for several compounds with a variety of functional groups were the $(\text{M}+73)^+$ adduct ions, which were presumed to be formed by direct addition of the trimethylsilyl ion to the sample.⁷ Additional sample ions have been reported at $(\text{M}+131)^+$ and $(\text{M}+145)^+$, formed by the addition of other reagent ions in the high pressure mass spectrum of TMS to the sample.^{7,8,9} Mixtures of TMS and d_{12} -TMS were used with desorption CI to simplify the recognition of the trimethylsilyl adduct ions with a number of biologically important molecules.¹⁰ The formation of $(\text{M}+73)^+$ adducts has been reported recently for a large number of oxygen-, nitrogen- and sulfur-containing compounds.¹¹

The presence of $(M+H)^+$ ions were also reported in the early work with TMS as a reagent gas for a number of compounds. Because the proton affinity of 1,2-dimethylsilaethylene (the conjugate base of the trimethylsilyl ion) is much higher than the proton affinities of these compounds, proton transfer from the trimethylsilyl ion is endothermic and therefore should be very slow.¹² It has been suggested that these $(M+H)^+$ ions were formed by proton transfer from protonated trimethylsilanol, $(CH_3)_3SiOH_2^+$ at $m/z = 91$, present in the reagent spectrum from the addition of the trimethylsilyl ion to trace amounts of water, an impurity in the system.¹³

The trimethylsilyl ion acts as a Lewis acid, rapidly forming adduct ions with compounds containing non-bonding electron pairs.⁷ The gas phase Lewis basicities of ketones, alcohols, aldehydes, and esters have been studied by obtaining their relative trimethylsilyl ion affinities in an ICR spectrometer.^{14,15,16} These values were found by the bracketing technique: the presence or absence of the trimethylsilyl cation transfer reaction is observed between base pairs.

The study of trimethylsilyl ion affinities suggests the use of ternary mixtures (methane, TMS, and much smaller amounts of a Lewis base) as a CI reagent system.¹⁷ With these systems, the major reactant ion is the adduct of the Lewis base, this ion will transfer the trimethylsilyl ion to samples which are stronger Lewis bases. Because adduct ions formed by displacement reactions are expected to have lower energies than the adduct ions formed by direct addition, less decomposition of the adduct ion should be seen when ternary mixtures are used. Along with increasing the gentleness of the trimethylsilyl ion transfer, the selectivity was enhanced because only a stronger base will displace the one present in the original mixture. These mixtures can consequently be used to ionize selectively compounds based on their trimethylsilyl ion affinity.

Several kinetic studies of the gas phase reactions between the trimethylsilyl ion and oxygenated compounds have been made using an ion cyclotron resonance (ICR) spectrometer.^{18,19,20,21,22} These experiments showed adduct ion formation, $(M + 73)^+$, as well as fragmentation reactions under ICR conditions. The product ions from the reactions of $(CH_3)_3Si^+$ with alcohols under ICR conditions²⁰ were different from the ions reported in the high pressure CI mass spectra¹³. More recently, the reactions of the trimethylsilyl ion with aliphatic alcohols²³ and ethers,²⁴ have been studied under both ICR and CI conditions.

Two very different mechanisms have been found to lead to the formation of the $(M+73)^+$ adduct ions. The first involves the formation of a stable intermediate by dissociative addition, which then reacts with a second sample molecule to form the adduct ion. When this two step process is not possible because of the lack of an exothermic dissociative addition reaction, the adduct ion is formed by direct addition of the trimethylsilyl ion.

Studies of the proton affinities of trimethylsilanol, trimethylsilyl alkyl ethers, and trimethylsilyl alkyl sulfides have recently been performed.²⁵ Possibly eliminating the discrepancy in the literature values for the proton affinity of trimethylsilanol.^{17,26} Also, the value for the heat of formation of the trimethylsilyl ion, which has been disputed recently in the literature,²⁷ can be obtained from the value of the proton affinity for trimethylsilanol. The values for the proton affinity of trimethylsilanol and the trimethylsilyl alkyl ethers are of interest because of their use in determining trends in proton affinities, as well as comparisons between the silicon compounds

and their carbon analogues. Several improvements have been made in the bracketing technique which is used to determine proton affinities. These improvements have led to an increase in the accuracy of the values obtained for the proton affinities and a decrease in the time needed for these measurements. Also, with this technique, the proton affinity is determined for compounds whose neutral species are not present, allowing the determination of the proton affinity for unstable compounds.

Finally, the selectivity of the trimethylsilyl ion has been used to decrease the demands on the chromatographic separation in the analysis of complex mixtures. The selectivity of this reagent allowed the quantitation of oxygenated blending components in gasoline with relatively little sample preparation, and a simple separation.²⁸

TANDEM MASS SPECTROMETERS FOR FUN, NOT PROFIT: Jean Futrell; Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716.

This paper attempts to review briefly the history of the development of tandem mass spectrometers from their origin as a gleam in the eye of several investigators interested in fundamentals of mass spectrometry to the present day. Emphasis is placed on three instrument configurations developed in the author's laboratories at Wright-Patterson Air Force Base, the University of Utah, and the University of Delaware and shown in Figures 1, 2, and 3. Figure 1 is immediately recognized as the tandem combination of two double-focusing mass spectrometers. Figure 2 is similarly recognizable as a triple quadrupole instrument while figure 3 is a tandem hybrid mass spectrometer. In 1989 most mass spectroscopists would grasp the significance of these instruments as powerful tools for analytical mass spectrometry. The interesting story of the evolution of MS^2 and MS^n for chemical analysis is told separately at this Symposium. This is not the thrust of this paper.

Our story traces another pathway and emphasizes the applications of tandem mass spectrometry to fundaments of ion reaction mechanisms and dynamics. The story is told from the biased perspective of the author with the intent of being historically accurate without attempting to write a comprehensive review. As a minimum it is hoped that the newest members of our Society will be intrigued by the dates associated with these instruments and their direct ancestors, cousins and descendants.

Studies of ion molecule reaction kinetics in the 1950's determined reaction mechanisms, branching ratios and rate coefficients primarily by relating appearance potential curves for reactants and products and on ion source pressure and using simple electrostatics to calculate residence times. It was always obvious that the study of elementary reactions could best be accomplished by selecting a reactant ion and colliding it with the reactant molecule under controlled conditions. Once the instrumentation for carrying out these kinds of measurements became available, it was a frequent source of astonishment to the author that the deductions for complex reaction schemes based on appearance potential measurements so often proved to be correct!

TRANSVERSE GEOMETRY INSTRUMENTS The first example of a technically sophisticated tandem mass spectrometer was the instrument designed by Einar Lindholm and constructed at Stockholm in 1954. This instrument consisted of two 180° mass spectrometers arranged so that the ion beam of the mass selector instrument was shot through a collision cell at right angles to the ion path for the second stage mass spectrometer. The focus of Lindholm's reactions at was charge exchange reactions at relatively high energy (100 eV to kilovolt energies initially, later extended to several eV). In this geometry the charge transfer product is formed at thermal energy and extracted at right angles while the primary ion projectile is shot through the cell and not observed. A relatively elaborate deceleration lens developed by Lindholm and collaborators allowed the observation of some ion molecule reaction products in addition to charge transfer product ions. This apparatus clearly pointed the way to the development of subsequent instruments designed specially for the study of ion molecule reactions.

When Professor Lindholm retired, one of his students, Professor Imre Szabo of the University of Lund, inherited the most sophisticated version of this apparatus and has continued to develop this technique. In its present three-stage configuration it provides state selection of reactant ions plus the capability of following second and higher order reactions quantitatively. The instrument is obviously capable of extension to higher order and Szabo has investigated and described mass-resolving and non-mass-resolving RF ion pipes for this purpose.

Other relatively sophisticated transverse geometry tandem spectrometers

were constructed by Tal'roze and co-workers in the Soviet Union and by Fite, Brackman and Snow at General Dynamics in the United States. [Wade Fite and Ted Brackman dropped this line of work when Wade became Professor of Physics at the University of Pittsburgh; they started Extranuclear Labs (now Extrel) shortly thereafter.] A rather different but conceptually similar system which utilized a time-of-flight second state analyzer was constructed in England about the same time. A simpler version with a 1" radius first stage mass selector was constructed by Koski and co-workers at Johns Hopkins. In Koski's apparatus the small radius and low accelerating voltage of the ion selector spectrometer facilitated turning the ion beam in the direction of the exit slit of the collision chamber for the investigation of ion molecule reactions.

COLLINEAR GEOMETRY INSTRUMENTS. Ion molecule reactions other than charge transfer (or hydride transfer) frequently impart forward momentum to product ions. This is intrinsic to proton transfer, condensation and pick-up reactions. In addition, all reactions which proceed via the formation of an intermediate complex will generate product ions which are forward scattered in the laboratory frame at 1 eV or higher ion kinetic energies. Severe discrimination effects are therefore anticipated.

The first tandem mass spectrometer specifically designed for studying ion molecule reactions involving momentum transfer was constructed by Clayton Geise when he was at the University of Chicago in 1963. This apparatus replaced the ion source of a large sector mass spectrometer with a 1" radius mass selector mass spectrometer and a complex deceleration/acceleration lens and collision chamber. This design was further elaborated by his student, William B. Meyer II who constructed an improved version at the Los Alamos Laboratory. Other instruments of in-line geometry were constructed in the 1960's in Professor Bailey's laboratory at the University of Florida, at General Dynamics by Turner, Fineman and Stebbings and at the Aerospace Research Laboratories in Dayton, OH, by the author and his collaborators.

The instrument shown in Fig. 1 was conceptually designed in 1962 and completed in 1965. It contained a number of ideas which were quite sophisticated for its day and enabled it to be applied quite extensively to the study of ion molecule reaction kinematics. It also has many features, evident in Fig. 1, which qualify it for current day MS² kinds of experiments.

The first stage reagent ion selector is a Nier-Johnson geometry double-focusing mass spectrometer consisting of a 90° electric sector and a 60° magnetic sector. An energy slit at the intermediate focal point established the energy band pass of the electric sector at 0.2 eV. It also served as an object slit for the 3" radius, 60° magnetic sector and as a detector for tuning the ion source and electric sector optics.

The acceleration voltage for the first-stage mass spectrometer is 169.8 volts and the collision chamber is at 3 KV, fixing the ion source voltage at 3.1698 K.V. The magnetic field coils of both electromagnets are at ground. Soft ion field plates for the ion gun magnetic field placed inside the flight tube were separated electrically (and physically) from field plates outside the vacuum envelope. Both the magnetic sector and ESA fields were terminated by Herzog shunts.

The ion beam at the mass resolving slit has a width of 0.003" and a half angle of divergence of 0.0152 radians. The mass resolving slit is the object for the 60° turning electric sector whose image forms the object of the deceleration lens system. This plate also serves as a beam monitor and, when the sector voltages are unbalanced, serves as a total beam detector for the first stage mass spectrometer. Einzel lenses placed between the source and electric sector and inside the electric sector provide vertical and horizontal focusing, increasing both transmission and resolution by a 0.25" gap.

The deceleration lens system is undoubtedly the most critical element of tandem mass spectrometers intended for the study of low energy ion-neutral interactions. The lens in the Fig. 1 instrument was designed in collaboration with Chris Kuyatt and J. A. Simpson of the NBS (now NIST). We called it a "slot" lens because it had slit geometry but considerable thickness. This lens design has subsequently been utilized in several ion collision apparatuses. Its currently accepted name is a "rectangular tube lens" and its optical properties have been thoroughly described. Remarkably enough, our design--based on the assumption that its strength as a focusing element was twice that of a slit lens because it is a 2D rather than a 3D lens--matches almost exactly the dimensions deduced from recent, accurate calculation. Two stages of deceleration, each with a retardation ratio of 9 and demagnification factor by 2 were used for our design.

For the reacceleration lens a standard lens originated by Soa was selected. Both the deceleration and reacceleration lens systems are high transmission devices optical elements. At the design retardation final energy of 2.1 eV and for all higher energies essentially 100% of the ion beam entering the lens is transmitted through the image slit (collision chamber). The (space-charge-limited) transmission was of the order of 70% at 1 eV and 30% at 0.3 eV, making the instrument a useful tool for investigating low energy ion-molecule reactions. These characteristics constituted a significant "breakthrough" in beam techniques for studying ion-neutral collision phenomena, decreasing the energy range accessible to quantitative measurements by nearly two orders of magnitude.

The second stage mass spectrometer was constructed from components of a Mattauch-Herzog geometry Consolidated model 21-110 mass spectrometer. To make the two mass spectrometers compatible, the object slit and ESA slits were enlarged. A quadrupole lens scaled down by a factor of 0.8 from the design of Giese was placed approximately mid-way between the object slit and the entrance slit of the electric sector to convert a tall, narrow beam of product ions to a square cross-section beam which is transmitted with high efficiency by the electric sector and the rather narrow magnet gap. Beam deflectors and intermediate ion collectors were installed at several points to monitor the primary ion beam.

As a parenthetical note, this second stage instrument was used to demonstrate the "decoupling" (our word) or "defocusing" (everybody else) technique for studying metastable ion decompositions in double-focusing mass spectrometers. This technique was developed independently and contemporaneously by Jennings and Elliott utilizing an AEI MS-9 spectrometer. This utilized the second state ESA as an energy selector for the magnet mass analyzer. It was intended, but never implemented, that this energy analysis capability be utilized to measure the energy distribution of product ions from ion molecule reactions. Analogously, the planned feature of comparing product distributions at 60° and 0° by locating a second collision chamber at the focal point of the first stage spectrometer (e.g., replacing the 60° turning sector by a collision chamber) was never implemented.

A most important collaborator in developing the Fig. 1 instrument was Dean Miller, coauthor on the Review of Scientific Instruments paper that described the characteristics of the instrument. Miller was an electronics technician who worked with the author during the frantic days of testing components, modifying designs, rebuilding and converging on the final configuration of the instrument. His many ingenious contributions made it possible for us to learn together enough about ion optics, vacuum techniques, and signal processing to exceed a signal-to-noise ratio of unity within about six months of our initial assault on the machine. Standing in the wings and eager to carry out measurements on the instrument as soon as it became available was Postdoctoral Fellow Fred Abramson, whose chemical insight and ambition moved the early experiments forward quite rapidly. Lieutenant Wayne Sieck, Ph.D., joined the research team shortly thereafter and also made major contributions in the early measurements.

Captain Larry Bone carried out his Ph.D. thesis research on this apparatus. Tom Tiernan, already a research collaborator for a few years, was away at graduate school completing his Ph.D. at the time that the instrument came on stream. He joined the tandem mass spectrometer research team on his return from Carnegie-Mellon University. Postdoctoral Fellow Mason Hughes joined the team shortly thereafter. To my regret, his arrival preceded by only a few months my becoming the team dropout when I left Air Force employment to join the University of Utah.

Having deserted this elegant tandem mass spectrometer and the research team that used it effectively for many years for a lower budget environment at the University of Utah in 1967, I turned my attention to a new technique for the study of ion-molecule reactions. This technique was ion cyclotron resonance mass spectrometry developed especially by Peter Llewellyn and John BaldeSchweiler. It eventually assumed the central role in the investigation of ion molecule reaction kinetics. Developments in this field, under its current designation as Fourier Transform mass spectrometry (FTMS), continues to evolve as one of the key developments of mass spectrometry. Our contributions to ICR emphasized mechanisms of ion molecule reactions and their dependence on ion kinetic energy. Not surprisingly, we soon turned our attention to the development of the tandem ion cyclotron resonance mass spectrometer. We utilized a 180° mass analyzer as the ion injector for this new tandem replacing the ion source of a standard drift cell ICR. This was based on the principle discussed by Dempster years earlier that the ion source and detector occupy symmetric positions at 180° within a uniform magnetic field. Consequently provided the optics are equivalent, the properties of the ion beam presented to the detector are identical to those presented at the ion source end. Mass selection of low energy ion beams with a resolution of several hundred is trivially simple. The injection of mass-selected ions also proved to be rather simple in that the ion projectories curl up on themselves as the ion is slowed to near thermal energies. We demonstrated that moderate mass resolution and low energy ion selection were simultaneously achieved using a relatively simple retardation lens geometry. Use for about seven years at Utah, this spectrometer has recently been rejuvenated by Professor John Wronka at Northeastern University. A similar version is currently a primary research tool in Professor Mike Bowers' laboratory at the University of California at Santa Barbara.

ANGLE RESOLVED INSTRUMENTS. In 1989 most mass spectroscopists have some familiarity with the topic of angle resolved mass spectrometry (ARMS). Our colleagues who care about the details of disposal of energy and the dynamics of ion reactions--as distinguished from reaction kinetics and mechanisms--have long understood that the precise description of how these reactions occur requires a knowledge of both scattering angles and the post-collision kinetic energy of product ions. In fact, the velocity vectors of the reactants and products before and after collisions and the internal energy states need to be measured to achieve a full description of ion reactions at the most fundamental level. From an instrumentalist's perspective this requires that the experiment be carried out using the technique of crossed molecular beams. This technology was first developed for neutral beams and only a few laboratories have developed the technology for working with low velocity (and variable velocity) ion beams, crossing them with molecular beams and analyzing the products with respect to energy, identity, and scattering angle.

The grandfather of all such apparatuses was developed by Zdenek Herman and Richard Wolfgang at Yale University. This instrument provided the first definitive information on the detailed mechanism of proton stripping reactions. It consisted of a permanent magnet first stage mass analyzer which mass selected (with resolution of about 50) ions generated by electron impact. The entire first stage apparatus--ion source, mass selector and neutral beam source--was mounted on the lid of a scattering chamber which is sealed with a rubber "O" ring. This lid and the attached apparatus are mechanically rotated about the object slit of a sector mass

analyzer. A more elaborate version of the same apparatus is in Dr. Herman's laboratory at the Heyrovsky Institute in Prague, Czechoslovakia.

The coincidence in time that a remarkable graduate student named Marvin Vestal arrived in Salt Lake City, that the author was awarded an Alfred P. Sloan Fellowship which provided enough money to construct a new instrument and the availability of Postdoctoral Fellow Calvin Blakley encouraged us to proceed with the construction at Utah of a rather more elaborate version of a tandem crossed beam apparatus. A talented graduate student, Philip Ryan, also appeared in my office one day to say that his current thesis problem was too easy and he would like to join the Vestal and Blakley team. Together they managed to construct a fairly formidable research instrument.

The new features of this tandem crossed beam apparatus were the inclusion of a high pressure, or chemical ionization, ion source which permitted (in favorable cases) the specification of the internal energy state distribution for the reactant ion, a higher resolution (to m/m 200) first stage mass analyzer, a new design for the deceleration lens which permits the deceleration of ions from 750 eV to below 1 eV laboratory energy, the inclusion of a supersonic jet which provides accurate specification of the neutral reactant velocity vector, and the addition of a high resolution energy analyzer for product ions. With moderate improvement in most of these features, refurbishment of components, and several subsequent generations of computer equipment for data acquisition and data reduction, this instrument is currently in use in the author's laboratory at the University of Delaware. A contributed paper at this Conference presents new data on quantum-state specific angular scattering in charge transfer reactions.

A frequent visitor at Utah during this period was Professor James D. Morrison of LaTrobe University. We engaged in many discussions of quadrupole mass filters and various experiments that could be designed if several of these instruments could be stacked in series (Morrison is now up to five). An apparatus which was constructed in our laboratory by Marvin Vestal and Gerard Mauclair (an exchange visitor from Orsay) is shown in Fig. 2. It was designed for and utilized in laser photolysis of ions. The first stage quadrupole was used as a mass selector, the second stage quadrupole was used as a strong focusing device to hold the ions in the light path of the laser, and the third quadrupole was used as a mass selector to distinguish the photolysis products from that experiment.

One of the major experimental artifacts plaguing the laser photolysis experiment was "ion noise" caused by metastable ions and collision induced dissociation (plus the collisional loss of electrons in negative ion experiments) which occurred in the central quadrupole of the apparatus. This clearly suggested that the apparatus might be useful for studying ion molecule reactions and collision induced dissociations. This was independently discovered and exploited very effectively by Enke and Yost and not exploited at all by us. A similar triple quadrupole constructed in Jim Morrison's laboratory served as the prototype for the triple quadrupole at Michigan State which now has many descendants. This story is told elsewhere at this Symposium.

The author's love affair with tandem mass spectrometers is far from over. Our most recent entry is shown schematically in figure 3, which utilizes a commercial double focusing mass spectrometer as the ion gun. An elaborate lensing system, which is a lineal descendant of the lenses first conceived for the Fig. 1 apparatus, serves to decelerate positive or negative ion beams generated in the first stage mass spectrometer to energies as low as 1 eV. The upper energy limit is currently 3000 eV. This ion beam is crossed at right angles by a supersonic jet molecular beam. Products are analyzed by a hemispherical energy analyzer and quadrupole mass filter which rotate about the scattering center. A full description of the apparatus and its characteristics has recently been

published and three contributed papers describing some of our first exciting results were presented elsewhere at this Conference. The key collaborators who have contributed to the development of this machine are the listed coauthors on these papers.

This apparatus was designed explicitly for the investigation of the reaction dynamics of collision-induced dissociation of polyatomic ions--e.g., the fundamental mechanism of MS^2 and MS^n types of experiments. This contemporary instrument utilizes a number of technologies developed for other purposes during the last 25 years. These include the use of lasers as aligning devices, the use of optical tables and rotators and choppers, digitally driven power supplies throughout, computer control of experiments and much more sophisticated signal averaging techniques than were possible in the Fig. 1 device. It also has many of the characteristics that have been exploited in earlier instruments developed in the author's laboratories. The motivation is unchanged and these remarkable devices still have a lot to teach us about the properties of ions in low, moderate and high energy collisions.

Tracing the History
of Analytical MS/MS

Kenneth L. Busch
Department of Chemistry, Indiana University
Bloomington, IN 47405

Mass spectrometry/mass spectrometry (MS/MS) as an analytical tool developed almost inevitably from the extensive work of thirty years on the origins and reactions of metastable ions. The border between the study of metastable ions occurring as a result of unimolecular dissociations of gas-phase ions in transit through a mass spectrometer, and the explicit collection of daughter ions formed as a result of purposeful collision-induced dissociations is a nebulous one. No singular new experiment or instrument heralded the beginning of analytical MS/MS. Rather, the development of analytical MS/MS was essentially a conceptual one; the instruments for MS/MS experiments were completed long before chemists realized the extent of the information that could be drawn from them. The development of the intellectual framework of MS/MS continues even today. Analytical chemists who use MS/MS today should by all rights appreciate the efforts (often unheralded) expended in the development of the technique, and should conscientiously explore both its advantages as well as its shortcomings.

Mass spectrometry/mass spectrometry involves the measurement of the mass-to-charge ratios of ions before and after some reaction that occurs within the confines of the instrument. Such reactions have been known since the earliest mass spectrometers were constructed; the poor vacuums of the time made the occurrence of ion/molecule reactions inevitable. In retrospect, recognition of the true natures of these reactions was an extraordinary achievement. An equally important achievement was the recognition of the analytical value of MS/MS reactions. Experiments in analytical MS/MS were initially described about 1976, given the definition of analytical MS/MS as the use of MS/MS for determination of the presence or levels of particular compounds in a mixture of compounds. After several prototype instruments were fielded by manufacturers, MS/MS with commercially available hardware was introduced in the early 1980s. Widespread availability of the commercial instruments, coupled with the intrinsic analytical capabilities of the MS/MS method and ten years of continued interest and development, has culminated in today's breadth of MS/MS research and applications. This presentation provides a retrospective on some of the significant instrumental and experimental developments in analytical MS/MS.

Instrumentation

Multi-sector instruments were first developed for other purposes, but were also one of the first instrumental configurations to be used for analytical MS/MS. Inghram and Gomer assembled a BB instrument in 1954, and White et al. developed a number of multi-sector instruments from 1954 through 1972, including BB, BBB, BBE, and EBBE. These instruments were used for isotope measurements in which high abundance sensitivities were required, in the generation of high purity atomic ion beams, and in energy loss and charge exchange experiments. Molecular dissociation experiments were carried out for small molecular ions. Investigators at Oak Ridge National Laboratories assembled a number of multi-sector instruments used for isotope work. The construction of multiple sector instruments by Futrell and Todd and McLafferty, among others, was pursued in increasingly sophisticated studies of fundamentals in ion chemistry.

Both EB and BE geometry sector instruments can provide solutions to the double focussing equations, but the BE instrument offers the ability to mass select parent ions by momentum analysis through the magnet, and to use the electric sector for kinetic energy (and therefore mass) analysis of daughter ions formed in an inter-sector collision cell. Beynon, Cooks, Amy, Baitinger, and Ridley at Purdue University described the reverse-geometry MIKES instrument in the A pages of Analytical Chemistry in 1976, with the express purpose of using the instrument for mixture analysis with analytical MS/MS experiments. Construction of the instrument literally involved reversing the normal order of sectors in an MS9 instrument. Such a project could only be possible with the involvement of an excellent machinist and instrument builder, and Tom Ridley's involvement with mass spectrometric instrumentation was both long and productive. The

MIKES instrument survived several source, vacuum, and electronic updates, and several generations of graduate students, and as of this date, is still producing data. The popularity of ZAB instruments (VG Instruments) is derived in no small part from the capability of 'reverse' geometry instruments for MS/MS. Triple- and four-sector instruments of various geometries were developed to provide higher resolution for either the parent or the daughter ions, at the expense of added size, cost, and complexity.

The first multi-quadrupole instruments were described by Vestal and Futrell, and by McGilvery and Morrison, and were used for photodissociation research. A multi-quadrupole instrument developed expressly for MS/MS applications was described in 1978 by Yost and Enke at Michigan State University with the contributions of machinists Russ Geyer and Len Eisele. A patent in 1980 described the basic attributes of a 'tandem quadrupole' instrument for CID MS/MS. Early prototypes of triple quadrupole MS/MS systems were placed in research laboratories around the country. The research group of Hunt at the University of Virginia was especially active in demonstrating the power of the triple quadrupole instrument for analytical MS/MS. By 1982, sales for commercial triple quadrupole MS/MS instruments had entered the high growth period that continues today. Combination of relatively low price with relative ease of operation provided the impetus for the success of the triple quadrupole instrument. These attributes are exactly those that characterize the use of ion trapping spectrometers for MS/MS as demonstrated in the last few years.

Triple quadrupole instruments provided unit mass resolution for both parent and daughter ions in MS/MS experiments. BE sector instruments could provide better than unit resolution for selection of parent ions, but less-than-unit resolution of daughter ions due to the kinetic energy release measured by the electric sector. The stage was set for hybrid instruments (combinations of sectors and mass-analyzing quadrupoles) to be developed. A BQ was first described in 1974 for studies of the structures of organic ions, and a BQ combination instrument assembled by Armentrout and Beauchamp was used in 1980 for studies in studies of organic ion/molecule reactions and metal ion/organic ion interactions. A hybrid BQQ instrument for analytical MS/MS was first described by Glush et al. in 1982. This work led to a prototype BEQQ instrument in the same laboratory, and then to commercial EBQQ and BEQQ instruments.

Experiments

Studies of metastable ions are studies of daughter ions formed by unimolecular dissociations of parent ions. With the purposeful introduction of collision gas into a reaction region of a mass spectrometer, either through a leak valve or through the simple expedient of loosening a bolt on a vacuum flange, product ions resulting from collision-induced dissociations could be increased in relative abundances. As such studies continued on multi-sector instruments, equations that described the masses of the parent and the daughter ions reacting in various regions of the mass spectrometer were derived. A conceptual advance occurred when the study of metastable ions and CID products drifted from careful studies of ion structure to the examination of ions from various component molecules present in the source of the mass spectrometer at the same time, and then moved to studies in which the presence or absence of a particular metastable or daughter ion MS/MS spectrum was interpreted to reflect the presence or absence of a particular compound in a mixture of components in the source.

The study of daughter ions produced by collision induced dissociation has a long history in the study of ion structure, drawing upon the extensive studies in metastable ion dissociations. Careful studies by a number of workers, including McLafferty, Levsen, Beynon, and others, showed that the daughter ion MS/MS spectrum could be interpreted to yield structural information just as could the electron ionization mass spectrum, and that the method could be extended to the study of components in unseparated mixtures. The early work extending the concept to the determination of components in mixtures appeared in 1976 and 1977. Levsen and Schulzen in 1976 reported the use of daughter ion MS/MS spectra to identify six major components in the mixture of pyrolysis products of DNA. Using the MIKES instrument, analysis of simple mixtures of organic compounds was demonstrated by Cooks et al. in 1976. A series of papers starting in 1977 from Cooks' laboratory highlighted the use of daughter ion MS/MS for the direct analysis of trace components in crude extracts derived from natural products. It was the figures that accompanied these papers that captured the interest of those who saw the possibility of

direct mixture analysis without separation. The work could be extended to levels of trace components at a few percent in the original sample, and 0.1 to several micrograms in the source of the mass spectrometer. Matrix effects exert significant effects below this level, and are a complex function of the nature of the sample and the chemical matrix. Retention of at least a rudimentary sample clean up or chromatography step is used to minimize these matrix effects.

Linked field scanning of sector instruments for the acquisition of parent ion MS/MS spectra was described by Boyd and Beynon, and Evers et al. in 1977. It was the introduction of the triple quadrupole mass spectrometer, with its ease of calibration and scanning, that made both the parent ion and the neutral loss experiment more accessible. The parent ion scan was not mentioned in the first Yost and Enke paper on the triple quadrupole mass spectrometer, but appears as part of the three modes of operation (daughter, parent, and constant neutral loss scans) in the 1979 review in the A pages of Analytical Chemistry. The use of parent ion scans highlights the ability of MS/MS to provide different sorts of information than normal mass spectrometry. One of the more common uses of parent ion MS/MS is in the determination of the number of structurally related compounds in a mixture. In the case of drug metabolites, for example, most of the metabolites retain the bulk of the structure of the original drug. If a daughter ion characteristic of that original structure is established, then a parent ion MS/MS spectrum can be used to establish the number of precursors to that ion. Similarly, classes of related natural compounds can be linked via the appearance of a common ion in each of their daughter ion MS/MS spectra.

In 1979, neutral loss scans (in which the selected masses of parent and daughter ions are simultaneously varied to maintain a constant mass offset between them) were described for sector instruments (Zakett et al.) and for triple quadrupole MS/MS instruments (Yost and Enke). The neutral loss scan provides specific information on the chemical reactivity of the ions studied. In one of the first examples, it was shown that anions formed from carboxylic acids typically undergo loss of 44 daltons (neutral carbon dioxide) in the CID daughter ion MS/MS spectrum. Other functional groups also exhibit their characteristic neutral losses, so that the MS/MS experiment can provide functional group information on the various components in a mixture. More importantly, as demonstrated originally by Hunt in his work on environmental MS/MS, derivatizations of the mixture can provide both functional group specificity in the derivatization reaction, with the ability to design an MS/MS constant neutral loss experiment tied to that derivatization label. The use of derivatization labels is all the more significant since compounds of higher mass tend to contain several different functional groups, and their gas phase CID fragmentations are dominated by one functional group over the other. Derivatization occurs in solution under conditions designed for more complete reaction, and the gas phase dissociations of the labels are more independent of the remainder of the ionic structure. In the past decade, neutral loss scans specific for sulfur-containing aromatics, sulfonated dyes, and nitro-group-containing compounds, among many others, have been described in the literature.

MS/MS instruments can be manipulated to provide information other than the usual daughter ion, parent ion, and neutral loss MS/MS spectra. Energy-resolved MS/MS experiments were introduced in 1981 by McLuckey et al. These have mostly been used for ion structural studies, but a few analytical applications have been reported. Despite the 'nodes' in transmission through the rf-only collision quadrupole, the collision energy can be related to the internal energy deposited in the parent ion. Charge permutation reactions, once thought to be entirely within the domain of sector instruments and high collision energies, have been demonstrated on multi-quadrupole instruments. With low collision energies in the triple quadrupole instrument, ion/molecule association reactions can be studied; the first reports in 1980 have been followed by many other examples, but the intrinsic selectivity of the associative reaction has not yet been exploited in analytical applications. Consecutive reactions (MS/MS/MS) on a triple sector instrument were reported by Burinsky et al. in 1982. A few pentaquadrupoles have been assembled in research laboratories, and MS/MS/MS for studies of ion structure have been reported. Trapping mass spectrometers excel at MS/MS/MS/... within the limits of ion trapping and dissociation efficiencies; whether analytical problems exist to justify the regular use of these extended sequences is still unknown. Finally, the conjunction of MS scans of various types to yield new variants such as the

'familial' scans and the 'reaction intermediate' scans, is, in concept, already three years old, but these new means of extracting information about ion chemistry through MS/MS are just now being explored.

The initial excitement for MS/MS focussed on its abilities to identify components in complex mixtures without separation. Debate then, as now, pitted a separations method that could resolve any component of any mixture against a detection method so selective that no separation of the mixture would be necessary. The development of the selective detection of MS/MS came at a time when new developments in separations methods were sparse, adding to the debate. The early discussions of MS/MS were somewhat mis-directed, the result of errors in judging the long range potential and areas of strength of the analytical method. The broad scope of uses of MS/MS today were not envisioned fifteen years ago when analytical MS/MS was first demonstrated, not by the initial workers in the field, nor by those who stood up to declare MS/MS to be without merit, but who are now practitioners. The best insurance against the inability to judge strengths and potentials is a willingness to investigate high risk but high return research areas, and to support those who do the same. Almost all of the researchers involved in the original developments of MS/MS are still active in the field, and have been joined by those who use the approximately 500 instruments worldwide. The outlook for continued development is secure.

THE DETECTION AND RECORDING OF ION BEAMS: FROM THE GOLD-LEAF ELECTROSCOPE TO THE INTERACTIVE GRAPHICS WORKSTATION.

Alan Hogg, Dept. of Chemistry, Univ. of Alberta, Edmonton, Alberta, CANADA
T6G 2G

Objective

The mass spectrometer consists of many parts all of which must work correctly and simultaneously if useful information is to be obtained. Achieving this is not as difficult now as it was in the early days.

Much of our present concern is to produce ions in the most appropriate way and to separate them with the best compromise between sensitivity and resolution, but we tend to take for granted that they can be detected and measured and the output displayed in an easily handled format. The earliest pioneers in the field did not have even basic electronics available to them, let alone computers, and detecting and recording the ions they produced was a far from simple task

This poster reviews some of the important developments which led to our present demand for ever faster and more intelligent workstations to examine the vast quantities of data routinely produced by modern mass spectrometers.

Historical Development

Mass spectrometry predates the science of electronics and the first methods for the detection and recording of ion beams used such devices as scintillators, photographic plates and mechanical electroscopes. J.J. Thompson's spectrograph produced parabolas on a scintillating screen or a photographic plate, but no useful intensity measurements were possible until he replaced the plate with a parabolic slit and collected the beam on a Wilson gold-leaf electroscope. Dempster achieved the first really quantitative recording of a mass spectrum also using a gold leaf electroscope. In his apparatus the positive charge deposited by the ion beam caused the leaf to deflect and this could be balanced by allowing beta particles from a radioactive source to fall on another detector attached to the electroscope. A mechanical shutter with a graduated scale controlled the amount of beta particles reaching the collector and so the intensity of the original ion beam could be quantified in units of the graduated scale.

The ability of ion beams to darken photographic emulsion was used from the earliest days as a means of both detecting and recording for mass spectrometry and this has only recently disappeared from use. There are no longer any commercial mass spectrometers available with photoplate detection although there may still be laboratories which use the technique on older instruments. The biggest drawback of photoplate recording was the nonlinearity of the darkening process and its lack of dynamic range but this could be overcome with multiple exposures and by making plates of uniform quality which were carefully calibrated with a good microdensitometer. The biggest advantage was the ability to integrate weak or unstable signals for as long as necessary to obtain a good record. Thus photoplate recording reached its greatest popularity in recording complete high resolution spectra and also the fluctuating output of spark sources.

MASS SPECTROMETRY PREDATES ELECTRONICS. DEMPSTER'S INSTRUMENT WITH CALIBRATED ELECTROSCOPE.

NIER'S WHEATSTONE BRIDGE CIRCUIT UTILISING A VACUUM TETRODE.

The advent of the thermionic valve, or vacuum tube, made the first electronic detection of ion beams possible. If the beam was allowed to hit a Faraday cup which was attached to ground via a high value resistor, a voltage could be generated which was proportional to the ion current and this could be applied to the grid of a vacuum tube. In an early circuit described by Nier a tetrode is used in a battery operated Wheatstone bridge network where the filament to screen and filament to cathode spaces form two segments of the bridge. A galvanometer measures the unbalance bridge current which is proportional to the original ion current. Such circuits were capable of measuring beams as low as 10^{-15} A but were very unstable, slow reacting and had no means of recording other than noting the galvanometer deflection by hand.

As electronics developed and negative feedback circuitry was invented, tube type amplifiers became common and the first commercial mass spectrometers used them typically with a 954 or ME1403 electrometer tube followed by a multi-tube d.c. amplifier. Great pains had to be taken to reduce noise and drift and the electrometer tube was enclosed in an evacuated, light-tight and magnetically shielded enclosure. Some of the d.c. amplifiers used dry cell battery coupling between stages and, if the batteries were not enclosed in thermally insulated boxes, they were a major source of drift at high gains.

VACUUM PENTODES. THE 954 "ACORN" HAD AN INDIRECTLY HEATED CATHODE. THE ME1403 WAS DIRECTLY HEATED.

THE VIBRON VIBRATING REED ELECTROMETER. THE REED IS IN THE ALUMINUM CYLINDER.

It was known that a.c. amplifiers were inherently drift free and in the 1940s vibrating reed electrometers were developed which incorporated a capacitor with one plate fixed and the other, the reed, connected to a stable mechanical oscillator run at a frequency of about 1000Hz. The input from a Faraday cup was attached to the reed and also via a high megohm resistor to ground. This produced an ac signal which could be stably amplified with little drift. These electrometers found use in isotope ratio instruments but were not widely used in more conventional mass spectrometers because electron multipliers were developed around the same time. These had many advantages. Because high drift-free gain could be achieved in the multiplier, a dc electrometer using a much smaller resistor could be employed and this minimised drift in the amplifier and also increased its speed. The drawbacks of the early multipliers were unstable gain (which made them unsuitable for isotope ratio work) and susceptibility to magnetic fields. These problems were solved and a number of different dynode structures were developed, each with its proponents and claimed advantages.

THE BENDIX CONTINUOUS DYNODE MULTIPLIER USED A MAGNETIC FIELD TO CAUSE ELECTRONS TO STRIKE THE DYNODE REPEATEDLY.

ELECTRON MULTIPLIERS OF BOTH DISCRETE DYNODE AND CHANNEL DESIGN IN A VARIETY OF CONFIGURATIONS.

When solid state electronics began to replace vacuum tubes in the 1960s some hybrid electrometers were used where the very high input impedance of the vacuum pentode was combined with the stability of a transistorized amplifier but eventually the high impedance MOSFET (metal oxide silicon field effect transistor) replaced even the electrometer tube and totally solid state electrometers became standard on all mass spectrometers. This progressed to the FET input integrated circuit amplifiers which we use today.

AN EARLY KEITHLEY DISCRETE COMPONENT FET INPUT ELECTROMETER. BESIDE IT IS A MODERN IC FET INPUT OPERATIONAL AMPLIFIER IN A TO99 CAN.

THE SCINTILLATOR USED BY J.J. THOMPSON REAPPEARED IN 1960 IN THE DALY DETECTOR AND IS ALSO USED IN SOME MODERN SYSTEMS.

For some special low signal applications the electron multiplier, usually of the channel type, was run in the saturated mode so that pulses produced by individual ions could be counted using fast digital electronics thus preserving the inherently digital nature of the ion beam rather than converting it to an analog signal.

HEINTZ BOETTGER DESCRIBED AN "ELECTRIC PHOTOPATE" AT THE 1973 ASMS CONFERENCE. MODERN MICROCHANNEL ARRAYS DEVELOPED FROM THIS.

The Daly detector and some later developments of it returned almost to Thompson's original design by using a scintillator which was followed by a photomultiplier although in this modern system the original ions strike a conversion dynode to produce secondary electrons and these strike the scintillator rather than the ions. The multichannel array detector, which is one of the most promising new devices in our field was first discussed in the early 1970s when it was expected to combine the merits of electrical and photographic recording and was dubbed "The Electric Photoplate".

LARGE MOVING-COIL GALVANOMETERS DISPLAYED ELECTROMETER OUTPUT ON EARLY COMMERCIAL INSTRUMENTS LIKE THE METROPOLITAN-VICKERS MS2. THE MINIATURE MIRRORED GALVO WAS USED IN A UV OSCILLOGRAPHIC RECORDER.

Recording the output of electrometer amplifiers began with moving coil galvanometers whose deflection could be noted, but for a continuous record either long arm recording galvanometers or self balancing potentiometric recorders writing with ink on paper were necessary. The long arm galvanometers did not give a very linear response but had the advantage that several overlapping arms with different attenuations could be used to extend the dynamic range. They were not used to a great extent in mass spectrometry. Potentiometric recorders were accurate and reliable (except for the ink feed which was always the weakest point) but to provide good dynamic range an automatic range changer was desirable. Some imaginative designs evolved which sometimes required repeatedly backstepping the scan generator until a peak could be recorded on scale while the range was reset to maximum sensitivity when the signal dropped back to baseline. These recorders had a response time of about one second at best but were very widely used until electron multipliers became common.

OPERATING PRINCIPLE OF THE OSCILLOGRAPHIC RECORDER.

6. A high speed MULTI-CHANNEL OSCILLOGRAPH and its 36" scanning automatically driven wide chart strip - allows continuous recording after calibration and allows the operator to mark any mass peak with a recording spectrum

PHOTOGRAPHIC DARK ROOM

Learn to those who make use of a dark room: a dark room should be provided for processing the oscillograph chart. Even with a direct writing oscillograph recorder like the Haverhill 1000, the glass protection is still required for permanent display. For the Haverhill 1000, the light source should be dark red. Connections may vary, see 10" x 14" for details and 10" x 14" for the dark room. A quartz type oscillograph recorder and a dark room safety light 10" x 14" are recommended.

THE EARLIEST UV OSCILLOGRAPHS USED SEALED CASSETTES AND REQUIRED A DARK ROOM FOR PROCESSING.

Because a multiplier detector can operate at both high gain and high bandwidth, recording systems with bandwidths in the kilohertz range became necessary. Oscilloscopes were suitable but had to be photographed for a permanent record. High speed miniature mirrored galvanometers could be used to reflect a beam of UV light onto photographic chart paper and multiple channels could be used to provide dynamic range. The first systems used paper which moved in a light-tight cassette and the record had to be developed in a dark room. This was far from satisfactory but soon direct print paper became available which developed in room light and was reasonably permanent in the absence of UV. These oscillographic recorders were very widely used and are still available today although the cost of paper can be daunting. They remain one of the few ways of examining the analog output from a scan complete with "metastable" peaks, noise spike and assorted glitches - features which are usually lost when the signal is digitized, massaged and replotted through a computer. Some ink-jet and electrostatic recorders could also operate in the high bandwidth range but never became common in mass spectrometry.

The Present Day

In the early 1970s, dedicated minicomputers became generally available for use on mass spectrometers. Since then the recording systems previously used were rapidly displaced by the analog to digital converter, on-line minicomputer and printer/plotter. Electron multipliers, scintillator/photomultipliers and multichannel arrays are still the state of the art but, with the current trend towards closed-loop design where detectors are controlled by software or even by feedback from the output, the operator may be unaware of precisely what components are being used. This was never the case with earlier mass spectrometrists.

ARTIFICIAL INTELLIGENCE IN MASS SPECTROMETRY

by Robert W. Kiser, Department of Chemistry
University of Kentucky, Lexington, Kentucky 40506

This presentation outlines some important milestones in the history of the applications of mass spectrometry in artificial intelligence, and of artificial intelligence in mass spectrometry, for the 50 year period 1939-1989.

C. E. BERRY

For half a century - from the conceptualization and construction of the first electronic digital computer, the Atanasoff-Berry Computer of 1939-1941, to the present microcomputers, minicomputers, mainframes, and supercomputers - mass spectrometry has been intimately intertwined with computers in serving as a focus for a wide variety of applications. One of the first applications in what today might be regarded as artificial intelligence was in mass spectrometry - Berry's CEC MASCOT for multicomponent analysis based on mass spectral data.

Definitions of artificial intelligence, such as Minsky's "the science of making machines do things that would require intelligence if done by men," Rich's "the study of how to make computers do things at which, at the moment, people are better," Winston's "the study of ideas which enable computers to do the things that make people seem intelligent," and Boden's "the use of computer programs and programming techniques to cast light on the principles of intelligence in general and human thought in particular," are appropriate to the applications of artificial intelligence in mass spectrometry.

Expert systems, robotics, planning and decision-making, and other component areas of artificial intelligence have been and are directly involved in the development of mass spectrometry; still other areas, such as natural language processing, automatic programming, and intelligent computer-assisted instruction also impact our efforts in mass spectrometry.

It is significant, of course, that some schools recognized as leaders in artificial intelligence also are recognized as leaders in mass spectrometry; possibly the most important of these schools are MIT and Stanford. Some early Biemann papers (with Hertz, Hites, and others) considered photoplate data conversion, data acquisition systems, and the determination of amino acid sequences in small peptides in computer-aided interpretation of high resolution mass spectra. And the Stanford DENDRAL program (Feigenbaum,

Lederberg, Djerassi, Buchanan, Smith, *et al.*) for computing structural descriptions of complex organic compounds from their mass spectra and related data, together with related contributions, continue to be cited in nearly all artificial intelligence publications.

Some of the visionary early work of the ASTM Committee E-14 in inaugurating a collection of mass spectra, the establishment of the Uncertified Mass Spectra, and the early work of Grotch and others in encoding mass spectral data, provided one of the best scientific databases to use in searches, and to apply logic and heuristics to in the development of expert systems. The interpretation of mass spectra to provide identification and library searches, such as done by McLafferty, Venkataraghavan, and others (NIST, NIH, NBS, etc.) with PBM and STIRS, etc., and the early work of Jurs, Isehour, and Kowalski in artificial intelligence, particularly pattern recognition, factor analysis, and graph theoretical methods, have all had an important effect upon mass spectrometry.

It is clear that a statement made in 1953, "It would not be practicable at the present time to associate such a machine [computer] with *each* mass spectrometer, and the necessity for speed in analysis may prohibit the transmission of data and answers to and from a central organization," indicated much foresight for the needs that were to be experienced and the development that was to come.

The following provides a chronological synopsis, albeit likely incomplete, of some of the major developments in artificial intelligence and mass spectrometry in the past fifty years.

- 1939 Atanasoff and Berry develop the first automatic electronic digital computer.
- 1942 First commercial mass spectrometer delivered by CEC to Atlantic Refining.
- 1943 British Colossus used to decipher the German Enigma code.
- 1944 Aiken and IBM develop ASCC, an electromechanical machine to solve polynomial equations.
- 1945 Von Neumann conceives "stored program" design for serial digital computers.
- 1946 Berry describes a computer (early MASCOT) for solving linear simultaneous equations for mass spectrometric analyses.
- 1946 ENIAC dedicated at the University of Pennsylvania.
- 1950 Turing describes his test for machine intelligence.
- 1950 Shannon speculates on the prospects for computer chess.

- 1952 Formation of ASTM Committee E-14 on Mass Spectrometry.
- 1953 First ASTM Committee E-14 meeting (jointly with Pittsburgh Analytical Chemistry Conference).
- 1954 Production of FORTRAN by team headed by John W. Backus initiated.
- 1955 Bernstein develops the first working chess program using heuristic techniques.
- 1956 McCarthy, Minsky, Rochester, and Shannon organize the Dartmouth Conference.
- 1956 McCarthy coins the term Artificial Intelligence.
- 1956 Newell, Shaw, and Simon develop the *Logic Theorist*, the first successful AI program.
- 1957 McCarthy invents LISP, the first popular AI programming language.
- 1957 Samuel develops a champion-play checkers program using learning routines.
- 1958 FORTRAN-II, the first widely-used scientific programming language is made available.
- 1962 Quasi-Equilibrium Theory computer calculations by Vestal, Wahrhaftig and Johnston.
- 1962 FORTRAN-IV becomes available.
- 1964 Abrahamsson, Stenhagen-Stallberg, and Stenhagen publish proposal to use a computer to search mass spectra.
- 1965 Feigenbaum develops heuristic *DENDRAL*, the first expert system, for analysis based on mass spectral data and predictions of molecular structure.
- 1965 BASIC created by Kemeny and Kurtz at Dartmouth College.
- 1966 Biemann, *et al.*, use computer to determine amino acid sequence in oligopeptides.
- 1966 Weizenbaum develops ELIZA at MIT.
- 1966 Quillian invents the semantic network.
- 1967 Hites and Biemann describe completely automated data collection system for mass spectra.
- 1967 Greenblatt develops MacHack, the first competent chess program.
- 1968 Crawford and Morrison identify unknowns via catalog search.
- 1969 Charter and formation of ASMS.

- 1969 Jurs, Kowalksi and Isenhour apply pattern recognition to mass spectrometric analyses.
- 1969 Extensive DENDRAL applications begun by Djerassi, *et al.*
- 1970 Computer-operated mass spectrometer systems developed by Lederberg, *et al.*, and by Sweeley, *et al.*
- 1970 Colmerauer and Roussel at the University of Marseille begin development of the PROLOG language.
- 1971 Graph theoretical applications to mass spectra made by Jurs.
- 1972 Computer identification of mass spectra by Grotch using highly compressed code.
- 1972 MYCIN, first practical expert system to use production rules, developed by Buchanan and Shortliffe.
- 1972 Winograd completes SHRDLU, a natural language processing program.
- 1973 Self-training interpretative and retrieval system (STIRS) developed by McLafferty, *et al.*, for interpretation of mass spectra.
- 1974 Minsky publishes "A Framework for Representing Knowledge" paper.
- 1975 McLafferty, *et al.*, establish network availability for mass spectral interpretation.
- 1975 Factor analysis applied to mass spectral analyses by Isenhour and Rozett.
- 1975 The Lisp Machine, the first specialized AI computer, invented at MIT.
- 1975 The first personal computers begin to become available.
- 1976 Automatic rule formation applied to mass spectral data using meta-DENDRAL.
- 1976 McLafferty, *et al.*, develop probability-based matching (PBM) system for mass spectral identification.
- 1977 FORTRAN-77 standards are defined.
- 1981 Japanese launch "Fifth Generation" AI research effort.
- 1982 Clark and McCabe argue for PROLOG use in building expert systems.
- 1986 Berliner's HiTech is first chess computer to receive Senior Master title.

Most of the above interfaces of mass spectrometry and artificial intelligence has involved electron impact mass spectral data. It is expected that LV/MS, FAB/MS, CA/MS, FI/FD/MS, *etc.*, will play a significant role in the future as the databases for these and other (new) mass spectrometric techniques are established more fully.

From the above digest, it is observed that in the past decade relatively few significant innovations have occurred. Interestingly, contributions to the area of artificial intelligence in mass spectrometry from scientists in China and the Soviet Union appears to be on the increase. These features provide a hint that this interesting area in mass spectrometry may now be poised on the threshold for further significant advances.

Dare we envision mass spectrometer systems with fully-developed robotic features and planning/decision support, augmented with expert systems for analysis and interpretation, that will replace (some/many/most/all) human mass spectrometrists in the next fifty years ?

A RESOURCE FOR BIOMEDICAL MASS SPECTROMETRY

William R. Sherman* and Dennis M. Bier**
Departments of Psychiatry* and Medicine**
Washington University School of Medicine
St. Louis, MO 63110

The Washington University Mass Spectrometry Facility began with the acquisition of an LKB-9000 in 1969. The decision to obtain a GC/MS instrument at Washington University at the School of Medicine was largely based on the report, in 1968 by Hites and Biemann (1), that using an IBM 1800 it was possible to acquire and process mass spectra in times compatible with the elution periods of gas chromatography and store them at disk for later retrieval. The decision to buy the LKB was made following experiments performed with the help of Chuck Sweeley on the University of Pittsburgh LKB-9000 and because of the outpouring of results on the LKB instrument from the laboratories of Elliot, Holmstedt, the Hornings, Ryhage, Sweely, Waller and others. The instrument was received in 1968.

William F. Holmes, then a joint appointee in the Departments of Biological Chemistry and the University Biomedical Computer Laboratory, agreed to design a data system for the LKB. Bill was experienced with the LINC, a "small" (refrigerator-size) display-oriented computer. At that time DEC was manufacturing the LINC as their PDP-12. As we obtained the system it had two LINC-tapes as storage devices. These were ~4 inch diameter, large-hub 3/4 inch wide magnetic tapes each of which could store 225,000 12-bit words. The system used a 10-bit analog to digital converter and 8K (!) of magnetic core memory. The PDP-12 cost \$36,500 and the plotter \$3500, (cf. the ratio of cost of the mass spectrometer, for the LKB about \$60,000, to the computer then and now as well as today's prices for a PC with 80 times the computer memory). During this period several other GC/MS-computer systems were under development around the world (see references in [1] and [3] which include then-current developments in the Sweeley/Jack Holland lab and in Sandy Markey's lab). Of these the PDP-12 approach was unique with respect to the large display which was the user interface of the system.

During the computer development period the LKB was used by a small group of individuals that were willing to work with the light beam oscillographic output. Among the users was Denny Bier, a pediatrician, who performed his first experiments using stable isotope-labeled substrates as metabolic tracers in patients for whom exposure to radiotracers was unacceptable. While far from optimal analytical conditions, without the advantages of signal averaging that later became available with ion monitoring, these early studies showed the feasibility of doing the experiments using doses of the labeled species that were small enough so as to not disturb the pool size of the metabolite and thus complicate the interpretation of the results. It was also shown that blood samples for these studies could be small enough to carry out experiments on newborns.

Using the techniques developed on the LKB-9000, Denny performed the first measurements of glucose production and alanine kinetics in young children in 1972 and subsequently described the developmental changes in glucose production rates throughout childhood (14). Perhaps the ultimate flattery is that these numbers are now incorporated into pediatric textbooks as established fact without refering the source. Subsequently, using similar GC/MS techniques and stable isotope tracer infusions, Denny described the onset of gluconeogenesis in the human infant immediately after birth (15), the source of gluconeogenic carbons in these infants (15,16), and the turnover and uptake of fatty acid and ketone body fuels in human neonates (16,17).

Another early user was Bill Sherman who began cataloging spectra of carbohydrates and other biological substrates and their phosphate esters as the trimethylsilyl and boronate derivatives. Some of these spectra became part of the catalog of "Mass Spectra of Compounds of Biological Interest" compiled by Sandy Markey and others and printed by the, then, Atomic Energy Commission. Another early published effort done without the data system was a study which showed that, in the enzymatic conversion of glucose-6-phosphate to *myo*-inositol-1-phosphate, the intermediate molecular species never left the enzyme molecule. This was done by carrying the transformation out with an equimolar mixture of perdeuterated

and undeuterated glucose-6-phosphate. The inositol-forming process occurs by transfer of a hydrogen atom from glucose-6-P to the cofactor NAD^+ . This same hydrogen was postulated to be returned to the incipient inositol-1-P. If the NADH (or the hydrogen abstracted by the NAD^+), or the oxidized glucose-6-P, or the incipient inositol-1-P, dissociated from the enzyme complex, any of these intermediates could carry a hydrogen to a deuterium-labeled species (or vice versa) which would be evident from the isotopic composition of the product. The only products that were formed were found to be the fully deuterium-labeled and completely unlabeled inositol phosphate proving that the hydrogen removed was the same one returned and that all of the intermediates in the reaction remained enzyme-bound until the product dissociated from the enzyme (2). This kind of experiment could not have been performed with radioisotope-labeled substrates, it uniquely requires a mass spectrometric solution.

The LKB-9000/PDP-12 system was described in 1971 (3). The system acquired data and presented mass calibrated spectra in bar graph form on the PDP-12's 12 inch display oscilloscope in GC real time. The mass marker used was the Hall effect device designed by Ryhage, the squared analog output of which, when digitized, was the equivalent of a 14-bit ADC. Maximum scan rates were from 20-500 u in 4.2 seconds, 20-1000 u in 12 seconds, mainly slowed by the magnetic field collapse time. These rates were seldom incompatible with packed column gas chromatography. The data were stored on LINC magnetic tape for review, listing or plotting. The maximum size spectrum was limited to 850 peaks by core size. Over 200 spectra of 200 peaks each could be stored on one tape, while the second tape carried most of the programs. Sequential spectra could be recovered from tape and displayed at 2 second intervals.

A useful feature of the PDP-12 system was a variable mass range scan which resembled oscillographic output in that the actual peak profiles including metastable ions were displayed in real time. Another feature was a display that used data that could be stored with every spectrum that gave the deviation of an assigned mass from the nearest mass calibration value. For example a spectrum that was acquired and stored with a user-assigned mass defect per 1000 u, and containing mass assignment data in 0.1 u increments, could be displayed with the stored mass assignments as made with perfluorokerosene. Any incorrectly assigned peaks (e.g. misassigned because they fell close to 0.5 u from a nominal mass) were evident by their deviation from continuity within a 1 u window established by the PFK. Thus each spectrum could be viewed retrospectively to verify the mass assignment for any ion.

The choice of the PDP-12 computer was based on the philosophy of the University Biomedical Computer Laboratory that the user interface with the computer should be what is termed today as "friendly". The interactive display has, of course, now become standard but then it was common to enter instructions on many computers by switches and obtain results via printer. The alphanumeric and graphic displays of the PDP-12, as used with Bill Holmes' system, allowed users to set up experimental conditions by filling out questionnaires and presented the mass spectral data in an essentially "publishable" format that was intuitively understandable. This philosophy became one of the underpinnings of the "hands-on" aspect of the Facility. Most individuals learned how to use the LKB for their own experiments thus freeing the Facility staff for other activities.

By early 1973 Bill Holmes had developed computer controlled ion monitoring programs and hardware (4). This and J. T. Watson's PDP-12 based system (5) were the first fully digitally-controlled ion monitoring hardware and programs, precursors to what are today routinely employed techniques for quantitative analysis. These devices were a logical extension of the relay-switched three channel Accelerating Voltage Alternator (AVA) of Sweeley et al., the first practical device for selected ion monitoring of gas chromatographic effluents (6) which was improved on by Holland et al. (7) by interfacing the AVA to a computer. At about the same time Klein et al. (8) had designed a two channel AVA that used a multichannel analyzer for storage. The Holmes device generated a variable accelerating voltage that was calculated by the computer and added to the accelerating voltage to bring up to eight ions into focus with a fixed magnetic field. A feature of the system was a 0.5 u scan around any ion selected. This ion profile was used with PFK for source tuning and slit adjustment to establish the desired ion peak shape, resolution and maximum intensity. Since this display was available in what is now referred to foreground-background mode it was also used during data collection to insure that the analyte ion was in mass focus (i.e., was the correct mass defect chosen? had the magnetic field drifted?). This was done in real time using 0.2 seconds of the total

1 second of sampling time, with the rest of the time divided between the other ions selected, which could be eight in number. Thus the system could be monitored while data was collected and stored and the mass focus could be corrected at any time by adjusting the magnetic field. This monitoring feature was of especially great importance to us when we began to use quadrupole instruments which are subject to mass drift. The complete PDP-12 system with ion monitoring capabilities was duplicated and used successfully in 8 different locations including the Karolinska Institute.

The ion monitoring capabilities opened many doors for us as it did for many other laboratories. Since there was a strong focus at Washington University on stable isotope tracer studies in humans, and because the precision of isotope enrichment measurements with the new equipment was so great, this area literally took off.

An illustration of the power of the system was the ability to combine ion monitoring GC/MS with analyses of tissue samples obtained using techniques for dissecting and weighing single cells or extremely small and anatomically well-defined tissue sections. In collaboration with a group which practiced that art we obtained, and analyzed for myo-inositol, tissues weighing as little as 3 nanograms dry weight (9). The weighing technique used "fishpole" balances: made from a quartz fiber drawn and fixed in a horizontal position and calibrated with quinine crystals which are placed on the tip of the balance and the amount of deflection measured. The quinine is then dissolved in water and the fluorescence of the solution measured and thus the mass of the weighed material determined. The balance used had a deflection of 1 mm with 33 picograms. For analysis the entire dried and weighed tissue was immersed in 10 of trimethylsilylating reagent. When derivatization was complete the entire sample was injected onto a packed GC column for analysis. Only myo-inositol was evident using m/z 305, a three carbon fragment ion characteristic of TMS-inoitol, and m/z 318 for validation.

Another "first" for the Facility was the development of an electron ionization GC/MS method for measuring all of the then-used tricyclic antidepressants in plasma samples from patients under treatment (10). The need for the method was, and is, due to the extremely variable blood levels achieved by patients on a given dose, leading to a lack of therapeutic effectiveness in patients with high metabolic rates. Because of the fragmentation characteristics of some of the drugs, which produces mainly an ion at m/z 58, the method was criticized as impractical because drug levels are so low (25 to 300 ng/ml) and because interferences would probably interfere with the analyses. Nevertheless, the method is still in use and is still run on a quad that is shared by Facility users.

The success of the PDP-12, and especially the power of the ion monitoring method, increased the demand for instrument time as individuals recognized the potential of GC/MS. Increased demand was met by the purchase of a quadrupole instrument in 1975 and by the development of a less expensive (~\$20,000) and smaller (file-cabinet-size) data system by Bill Holmes, Phil Berger and Peter Norberg (the latter two individuals subsequently formed the Teknivent Corporation). This quad data system centered on an extremely fast, flicker-free display generator that they designed and a Computer Automation LSI-2 CPU for which mass spectrometer control and data processing programs were written (11, 12). Those programs followed the general philosophy of the PDP-12 software and added extended capabilities that resulted from the ability to digitally control all aspects of the scanning and data collection as well as processing.

The precision with which ion monitoring data could be collected was improved by the design and construction of digitally coupled wide dynamic range device consisting of an electrometer, an integrator, an autoranging amplifier (gain X1, X4, X16, X64) and an ADC optically coupled to the computer. This device, known with affection as "the Rempel", (13) allowed measurements of 0.3 - 0.5% precision to be made at 1/256 of full scale if necessary.

During 1975 and 1976 we added another EI quadrupole and two CI quads to the Facility. The "user-friendliness" of the computer and a few safeguards on the instruments made the Facility almost completely into a hands-on operation.

While the Facility had been heavily involved in stable isotope tracer studies using GC/MS to follow isotopes in amino acids and in glucose from patient blood samples there was a need for analysis of ^{15}N and ^{13}C in the metabolic end products CO_2 and urea. In 1979 Dwight Matthews joined the Facility and shortly began to build an automated isotope ratio instrument using a commercial 3 inch 60° sector magnetic mass spectrometer, a home-built gas sampling and handling apparatus and a DEC PDP 11/23-based home-built and programmed system for controlling the analytical process and handling the data. When completed, the automated IRMS was completely under computer control, sampling breath samples from blood collection tubes (Vacutainer tubes) in which samples from investigators all over the world were sent. Tubes set in a fraction collector were sampled in sequence, processed and transferred to the mass spectrometer where they were analyzed and the results automatically printed out. Since being built the system has analyzed over 10^4 samples, quantifying $^{13}\text{CO}_2$ generated from the oxidation of amino acid, lipid and carbohydrate tracers of substrate inter-organ fuel transport in man. Also capable of analyzing $^{15}\text{N}/^{14}\text{N}$ ratios by the hypobromite method, the system remains in active use today for measuring body protein nitrogen turnover using various ^{15}N -labelled amino acid tracers. Working together, Denny Bier and Dwight Matthews developed many of the stable isotope tracer techniques now regularly used throughout the biomedical field to determine amino acid kinetics and oxidation and to estimate body protein flux, synthesis and breakdown. In this regard, Dr. Matthews published two seminal papers (18,19) describing the use of $[1\text{-}^{13}\text{C}]$ leucine and $[1\text{-}^{13}\text{C},^{15}\text{N}]$ leucine to measure body protein/amino acid dynamics which are now classics in the field and widespread in their application. Using approaches developed in the resource, Drs. Bier and Matthews in collaboration with many resource users, but in particular with Dr. Vernon Young's group at MIT, have published a long series of investigations on the role of dietary protein and energy intake on amino acid and body protein kinetics in man (20-45). These studies form a significant fraction of the currently available information on essential and non-essential amino acid kinetics in the human.

When FAB came on the scene we found that either a saddle field or a capillaritron gas gun could be used with our CI GC/MS systems by directing the beam at right angles to the analyzer axis through the high pressure reagent gas exhaust of the source thus allowing us to use the instrument for GC/MS or FAB without any mechanical changes. This system served us until 1985 when the Facility received funds from the University and from the NIH Shared Instrument Program to purchase an extended mass range high resolution instrument which was acquired and installed in 1986.

Gradually, by user preference, the LKB was used less and less and ultimately was replaced, in 1987, with heavy hearts, by a thermospray quad. As the original GC/MS quads have aged they have become greater maintenance problems. Recently, through the NIH Shared Instrument Program, we were able to replace two of the originals with two new EI/CI quads. It is interesting to note that, in positive ion CI mode, the original dedicated CI systems are more sensitive, and retain that sensitivity longer, than the new quadrupole instruments.

The Facility now has 10 instruments that provide a full range of services. A measure of the usefulness of the Facility to the scientific community is that over 10,000 hours of instrument time were logged by over 100 investigators in 1988. Much of the growth, development, research and sustenance of the Facility has been supported by NIH through two grants, RR-00954 and AM-20579 as well as by University support and by grants from the NIH Shared Instrument Program.

MINNEAPOLIS, MN AND CHEMEX INTERNATIONAL INC., FT. COLLINS, CO.

Mass spectrometry has played an important role in our investigation of space. A first detailed picture of the chemistry in the earth's atmosphere was revealed by mass spectrometers flown on both rockets and high altitude balloons. Often these instruments were fitted with ion sources that could measure both existing ionic species and neutral atoms and molecules along the flight path. Data from these flights have provided atmospheric scientists with the insight they needed to formulate a unified explanation of the complex chemical and physical interactions of earth's atmosphere today (Nier, 1985). It was a natural extension of the investigation of the earth's atmosphere that has led to the use of mass spectrometry in our planetary probes.

The Viking mission to Mars carried two mass spectrometers on each of two spacecrafts. The aeroshell which was used to protect each spacecraft during entry into the atmosphere of the planet had an instrument in its outer surface. The sensitivity of this instrument was enhanced by the ram effect produced as a result of the high speed of the spacecraft. The instrument was of the Mattauch-Herzog geometry and had two collectors. The design was very similar to the instrument flown on the Atmospheric Explorer C, D and E (Nier, 1973; see Figure 1 for schematic drawing). This instrument had two collectors in the focal plane. One covered a mass range of m/z 1-7 and the other m/z 7-49. Before the entry vehicle encountered the more dense portion of the Martian atmosphere (above 100 km) this "neutral mass spectrometer" was able to make some important measurements of the planet's temperature and atmospheric mixing (Nier, 1977).

Using data taken from the height of 200 km down to 100 km, the atmospheric science team was able to report that: the Martian atmosphere consists mainly of CO_2 , with traces of N_2 , Ar, O_2 , CO and O. Some evidence for NO in the upper atmosphere was also observed (Nier, 1977). A more detailed study of the singly charged CO_2 peak cluster at m/z 44-46 indicated an $^{18}\text{O}/^{16}\text{O}$ isotope ratio of 0.0020 ± 0.0001 . The doubly charged CO_2 peaks gave a very similar ratio (e.g. 0.0021). Using the peak heights at m/z 12 and 13 and m/z 44 and 45, a $^{13}\text{C}/^{12}\text{C}$ isotope ratio of 0.0115 ± 0.0004 was determined. These values for carbon and oxygen are very close to values for terrestrial measurements. In contrast, the isotope ratio for $^{15}\text{N}/^{14}\text{N}$ was found to be 75% greater on Mars 0.0064 ± 0.001 . This data has been used to estimate the nitrogen content of the Martian atmosphere over the planet's geological past (McElroy, 1976).

Each of the Viking landers was fitted with a gas chromatograph/mass spectrometer (GC/MS) that had been designed to study both the soil and the atmosphere at the surface of the planet. The mass spectrometer (see Figure 2) was a Nier-Johnson configuration fitted with a permanent magnet (6326 G). The ion source was differentially pumped with selectable 45 or 70 eV energies for EI ionization. Individual mass spectra could be obtained at the rate of 1 every 10 sec by scanning the accelerating potential from 2350 to 125 volts.

FIGURE 1

FIGURE 2

This covered a mass range of 12 to 220 amu. Vacuum was maintained by a sputter ion pump (500 ml/sec) that shared the magnetic sector magnet.

Atmospheric measurements were made through a molecular leak into the ion source. Since CO_2 was expected to be the most abundant molecular species in the atmosphere, an additional system was added to the inlet before the molecular leak. This chemical absorption unit was attached to the volume adjacent to the molecular leak through a series of valves. In one chamber, CO was oxidized to CO_2 by silver oxide and all the CO_2 was removed by reaction with LiOH . This process removed 99.98% of the CO_2 and 99% of the CO and released H_2O . In a second chamber, all atmospheric H_2O including the H_2O produced during

the removal of CO_2 was absorbed onto $\text{Mg}(\text{ClO}_4)_2$. One cycle of chemical absorption took 1 hour. By repeated cycles, one could "enrich" the atmosphere in the chamber with those natural constituents that were unaffected by the chemical absorption system (e.g. N_2 , Ar, Xe etc.).

The GC/MS system on each lander presented some interesting engineering problems. Not that it wasn't enough to manufacture a complete gas chromatograph/mass spectrometer and data system that would fit into one cubic foot (excluding size consideration for the soil processor) a system had to be designed that would maintain a sufficient low pressure in the mass spectrometer while sampling the pyrolysis products of a soil sample. Power and weight were also extremely limited. These requirements led to the development of a unique system capable of withstanding large overloads of H_2O and CO_2 , while detecting part per billion (ppb) levels of organic molecules released from heated soil samples. The solution to this problem was a five stage effluent divider, controlled by the mass spectrometer's ion pump current, that would open or close a parallel series of valves and their associated flow restrictors (Rushneck, 1978). A second unique feature of the GC/MS system was the use of a pressure reduction GC interface that did not require a vacuum pump. Hydrogen gas was used as a carrier gas and was removed with a heated palladium alloy separator (Dencker, 1972).

Results from the lander atmospheric experiments confirmed the isotopic ratios reported during the entry phase of the mission. Namely, the abundance of ^{18}O and ^{13}C were similar to those found on earth but ^{15}N was between 50 & 75% more abundant compared to earth's atmosphere. In addition, argon isotopes at m/z 36, 38 and 40 were detected and their ratios measured. Using the chemical absorption unit to remove CO_2 and CO and repeating the enrichment cycles 15 and 30 times, krypton and xenon were detected and their isotope ratios measured. Krypton ratios were very similar to terrestrial values but the xenon 129 to 132 ratio is enhanced (Owen, 1976). The noble gas abundances indicate that at least 10 times the present atmosphere amount of N_2 and 20 times the CO_2 abundance were released by the planet during geologic time; the outgassing of a large amount of water must also have taken place (Owen, 1977; McElroy, 1976).

Martian soil samples released only a small amount of water and carbon dioxide when heated to 350 or 500°C. The water was thought to be present in the form of mineral hydrates, from which it is released at these temperatures. The total ion chromatogram shown in Figure 3, for a complete experiment sequence carried out with an empty oven during flight to Mars, indicates a small amount of terrestrial contamination. The presence of these contaminants was a fortunate circumstance because they proved that the system operated reliably. The same signal was obtained when heating soil taken from the Martian surface (peaks A -> D are identified as acetone, methyl fluorosiloxane, benzene and C_1 to C_3 alkylbenzenes respectively). A detailed inspection of individual mass chromatograms from each soil sample at 200, 350 and 500°C from m/z 12 thru m/z 220 did not reveal additional organic constituents in these samples. The limit of detection for organic compounds in soil was in the 0.01-1 ppb range. The absence of organic molecules at these levels significantly reduced the possibility that life exists or existed on Mars (Biemann, 1977).

POTASSIUM ION IONIZATION OF DESORBED SPECIES (K^+ IDS)-BY-FAB:
A USEFUL METHOD FOR PROBING THE SELVEDGE REGION, AND FOR
OBTAINING MOLECULAR WEIGHT INFORMATION

Gary Schultz and John Allison, Department of Chemistry
Michigan State University, East Lansing, MI 48824

We have reported previously a desorption/ionization technique that we call K^+ IDS, K^+ ionization of Desorbed Species (1). It utilizes rapid heating, which generates intact molecules and simple thermal degradation products in the gas phase from a thermally labile/nonvolatile analyte, followed by K^+ attachment to the desorbed neutrals. The K^+ ions are formed by thermionic emission from a heated filament coated with a silico-aluminate glass containing K_2O (" K^+ -glass"). We investigate here a split FAB probe that supports the conventional glycerol matrix/analyte mixture, and K^+ glass, the two being physically separated to prohibit interaction. Upon fast atom bombardment, glycerol and analyte molecules are desorbed, presumably creating a high pressure "selvedge" region above the target. Fast atom bombardment of the glass yields copious amounts of K^+ ions, which are "injected" into the selvedge region. The goal is to use K^+ ions, which attach to neutral molecules without inducing fragmentation, to "sample" the neutrals formed in FAB. Figure 1 shows the results when glycerol and the K^+ glass are subjected to FAB. If the ions from glycerol - fragment ions and proton-bound clusters (G_nH^+) - were desorbed directly from the matrix, one might expect to see only one additional ion in this experiment at m/z 39, K^+ . However, a G_nK^+ series is observed. The similarities between the proton-bound clusters and K^+ -bound clusters suggest that they are both formed in similar processes, i.e., by a gas phase mechanism. The spectrum also suggests that FAB leads to desorption of the intact glycerol molecules, with no significant amount of neutral degradation products formed (such as $[G-H_2O]$).

In the FAB spectrum of cholic acid in a glycerol matrix, no M^+ or MH^+ ion is observed. The ion of highest m/z due to this analyte is an $[M-H_2O]H^+$ ion at m/z 391. One could envisage two possible scenarios. In the first, the cholic acid is desorbed intact, and protonation results in complete fragmentation via water loss. In the second, fast atom bombardment induces dehydration, the molecule desorbs as $[M-H_2O]$, and is then protonated. K^+ IDS-by-FAB can be used to investigate these possibilities. When K^+ ions are injected into the selvedge region, only the MK^+ ion for cholic acid is observed, indicating that the desorption of the intact molecule occurs, and protonation leads to essentially complete fragmentation. This also points out the analytical utility of this method. The formation of the MK^+ ion confirms the molecular weight, and is useful when the analyte is an unknown.

In our laboratory, the FAB mass spectra of cardiac glycosides is under study. The FAB spectrum of a commercially available sample of thevetin, $C_{42}H_{64}O_{19}$, showed an MH^+ ion at m/z 873, and an intense ion 14 amu lower. Before attempting to interpret the mass spectrum, there must be a determination of whether the spectrum was for a pure compound. the K^+ IDS-by-FAB spectrum of thevetin in glycerol is shown in Figure 2. K^+ attachment to two compounds, separated in mass by 14 amu, shows that the original sample was a mixture and the lower mass compound was the major component.

These examples, demonstrate that injection of K^+ ions into the selvedge region of a FAB experiment is useful in providing insights into the nature of FAB ionization, and has applications in molecular weight confirmation and purity analysis. The spectra are cleaner, and less complex, than if KCl were introduced into the matrix. We present this as a method which can be extended to other ions in addition to K^+ , and demonstrates the basic approach to a new FAB-based method.

THE CHARGE STRIPPING OF ALKALINE EARTH SPECIES GENERATED BY SOLID FAB

K.A. Caldwell and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry,
University of Nebraska, Lincoln, NE 68588

INTRODUCTION

The study of trends within a group is of fundamental importance in chemistry. Series of diatomic molecules composed of elements from two different families provide a simple system for studying these trends.

Under solid FAB (matrixless) conditions interesting ions can be desorbed and studied by FAB MS/MS.¹ In addition to the species reported earlier, we have observed MX^+ and MY^+ ions ($M = \text{Mg, Ca, Sr, Ba}$), ($X = \text{F, Cl, Br, I}$), and ($Y = \text{O, OH, MO}$).

The CAD/CS spectra of MX^+ reveals a trend in the relative ion intensities of M^+ and X^+ . The translational energy loss of MX^+ accompanying charge stripping yields the second ionization energy of MX , which can be seen to vary periodically.

DISCUSSION

M^+ , MX^+ , and MY^+ are among the major ions produced by solid FAB of the alkaline earth halides. Figures 1 & 2 contain the CAD/CS spectra (air as collision gas) of the CaX^+ and MBr^+ series. CaX^+ and MBr^+ represent series of diatomic species in which one of the elements is a different member of a group. For example, in the CaX^+ series the Ca is bonded to different members of the halogen family.

The abundance of X^+ increases monotonically with decreasing ionization potential of X. (See Figure 1.) There is an analogous trend for the abundance of M^+ . (See Figure 2.) Also, the abundance of M^{++} increases as the electron affinity of the halogen to which it is associated in MX^+ increases.

The MX^{++} or MY^{++} formed by charge stripping is a prominent ion in the CAD/CS MIKES spectrum of MX^+ and MY^+ . By measuring the translational energy loss of these ions upon charge stripping, one can obtain the energy required to remove an e^- from MX^+ or MY^+ , the second ionization energy (IP2) of MX or MY . These values, along with the experimental second IP's of M are listed in Figures 3 & 4. The alkaline earth metals can be viewed as standards that validate the experimental procedure since their second IP's are well known.

For a given metal bonded to a different halogen, IP2 increases as the halogen becomes more electronegative. Conversely, for a given halogen bonded to a different metal, IP2 decreases as one proceeds down the alkaline earth metal group. The values for MOH^+ parallel the trend for MX^+ .

These trends can be understood by considering a molecular orbital approach. As the separate M^+ and X (or Y) are brought together from infinity, a bond is formed. Using CaX^+ as an example, the energy of the HOMO formed upon bonding with a halogen lower in that family is expected to be higher. The valence electrons of a lower member in the halogen family are higher in energy than a previous member. Also the orbital overlap can be expected to decrease as the halogen atomic number increases. The lowest IP2 would be expected for BaI and the greatest for MgF , as is observed.

The low IP2 for M_2O can be understood by a simple picture of the electronic structure:

The e^- on the uncharged metal resides in a nonbonding, slightly antibonding, σ orbital. This view has been presented in the discussion of the bonding in MX .² Indeed, the first ionization of, for example, $BaCl$ is analogous to the second ionization of Ba_2O^+ , each involving the removal of an e^- from a nonbonding orbital located on Ba. The energy required to remove an e^- is relatively low: 5.0 eV for $BaCl_2^+$ and ca. 9 eV for Ba_2O^+ .

The closed shell MX^+ species are isoelectronic with neutral alkali halides and have high ionization energies.

EXPERIMENTAL

Experiments were carried out on a Kratos MS50 TA (EBE) equipped with a Kratos FAB source operated at 8 KV and an Ion Tech FAB gun. Aqueous solutions of MX_2 were produced on the probe tip by adding $M(OH)_2$ to a drop of diluted HX . This solution was dried in vacuo.

The MS/MS spectra are CAD MIKES spectra obtained by scanning ESA2. Air was admitted to the second collision cell, until the main beam intensity was reduced by ca. 20%. The use of air or O_2 as the collision gas increases the abundance of the MX^{++} charge stripped product ion.

The data in Figures 3 & 4 were obtained by measuring the translational energy loss upon CS of the parent ion. The experiment is performed by focusing the parent on the detector with ESA2 slaved to ESA1. Using a MID built in this lab, ESA2 is unlinked from ESA1 and scanned in peak switch fashion. The voltage to ESA2 can be precisely divided, and variable width proportional energy scans were made over both the parent and charge stripped ions. For CS, the ESA voltage that transmits the parent ion is reduced by 1/2, because the product ion is 1/2 the energy to charge ratio-both being nominally 8 KV ions. The data are collected and signal averaged on a Nicolet 1170 ADC and transferred to a Data General Nova 4X computer for processing.³

The peaks are fit by Gaussians and the position of the center and the width of the Gaussian used to obtain the intercept of a line tangent to the curve with the abscissa. The tangents on the high energy side of the peaks yield a minimum or onset value for the energy required to remove an e^- from the parent ion.

ACKNOWLEDGMENTS

We are grateful to Enrico Davoli* for stimulating discussions about solid FAB. In addition, appreciation is extended to Darrell Giblin of the Midwest Center for Mass Spectrometry for pointing out that the intercept of the tangent line to the Gaussian peak could be used for consistent, unbiased treatment of the data, and for helpful discussions.

ON PREFORMED IONS AND ION-MOLECULE REACTIONS IN FAB
J. Shiea, J. Nestor and J. Sunner
Department of Chemistry, Montana State University

INTRODUCTION

The ionization processes in Fast Atom Bombardment are not well understood. Two major mechanisms have been considered - ion/molecule reactions and precursor ion formation.

When a FAB mass spectrum is very different from the ionic composition in the matrix prior to the impact of the fast atom, ion molecule reactions (IMR) must occur during the desorption event. Several observations support that IMR's are indeed important in FAB. The observed preference for analytes with higher gas-phase basicities (GB) is quite consistent and kinetic models based on IMR has been constructed that well reproduces the FAB spectra of selected systems¹.

When the DI spectrum reflects (changes in) the ionic composition of the liquid matrix prior to the impact of the fast atom, it is reasonable to assume that desorption of the solvated ions is an efficient process. Several experimental observations support such precursor ion formation. For example, it is often found that analyte signals increase substantially when acids are added to the matrix - "the acid effect". The object of the present work was to investigate the reasons for this "acid effect".

RESULTS

It has been found that the "acid-effect" has several different explanations: A) Acids frequently improve the solvation of analytes. Thus, Figure 1 illustrates the dramatically improved solvation of adenosine in glycerol as HCl is added.

B) Protonation of the analyte frequently inhibit the destruction of the analyte by radiation induced chemistry. This is illustrated in Figure 2, which shows the effect for diethanolamine in glycerol as a function of matrix viscosity (temperature). This effect is expected to be particularly important for larger molecules with many reactive sites.

C) Protonation of a relatively volatile (non-polar) analyte increases analyte signal by suppressing the selective evaporation of the analyte. An example is tetramethylethylenediamine.

D) Protonation of the analyte usually effects the desorption energetics, such that the extent of fragmentation decreases. The effect is very common but small.

E) Ionization of an analyte effects its surface activity. Thus, when two analytes are present, the suppression of one by the other may be overcome, leading to increased analyte signals.

F) We have not found strong evidence for efficient precursor ion formation for the systems that we have studied with the exception of very high viscosity matrices. This is illustrated in Figure 3, which shows that analyte to matrix ion ratios for DEA glycerol solutions increases strongly above 10,000 cP.

MITIGATION OF BEAM-INDUCED DAMAGE IN DESORPTION IONIZATION MASS SPECTROMETRY:

Johnny D. Reynolds and Kelsey D. Cook, Department of Chemistry,
University of Tennessee, Knoxville, TN 37996-1600.

Optimally, desorption ionization generates molecular or quasi-molecule ions as well as structurally significant fragments. Beam-induced reactions can, however, alter the structure of the analyte, resulting in the appearance of ions not directly related to the undamaged analyte. For example, FAB beam-induced reduction frequently results in the addition of one or more electron(s) and/or hydrogen atom(s). As a result, ions at $[M+1]$ and $[M+2]$ can have intensities greater than would be expected based upon isotopic abundances. Primary beam flux (1-2) and energy (3-4), and matrix composition (5-6), all have been shown to affect the appearance of desorption spectra. This study assesses the relative importance of these factors in controlling damage, and considers how the parameters interact with each other.

To assess the extent of beam damage, FAB spectra were obtained for a series of organic dyes in glycerol under standard conditions (8 kV Xe primary atom, emission current (i_e) = 1 mA). In all such spectra (e.g., methylene blue in Figure 1), the abundance of ions at $M+1$ and $M+2$ clearly exceeds expected isotopic contributions. Electrohydrodynamic (EH) MS confirmed that the samples were not contaminated with reduced species, since the predicted isotopic ratios were reproduced to within experimental error ($\pm 5\%$) (EH spectra are free of beam-induced reduction artifacts).

In order to assess the dependence of beam damage on the primary atom flux (i_p), it was necessary to establish the relationship between the measurable emission current (i_e) and i_p . Because secondary ion yields are known to be linearly dependent upon i_p , the observed linear dependence of Cs^+ intensity on i_p at various beam energies confirmed that i_e is a reasonable measure of i_p .

The most notable change in the dye spectra with increasing flux was an increase in absolute signal. This more than offset the rise in noise (RSD of signal) so that better signal/noise (S/N) could be obtained at high flux. More importantly, the signal/background (S/B) and signal/matrix (S/M) ratios decreased with increasing flux, so that better limits of detection (LOD) should be obtained at low flux.

Two measures of beam damage were considered: the extent of reduction ($X = \{\text{measured intensity-isotopic contribution}\}/\text{isotopic contribution}\}$) and extent of fragmentation ($F = E_{\text{fragment ions}}/E_{\text{molecular ions}}\}$). Both were smallest at low emission current (e.g., data for methylene blue in Figure 2). Reduction damage was more sensitive to changes in i_p than was fragmentation.

In contrast with the flux data, noise increased faster than signal as primary atom energy increased, so that better S/N was obtained at lower energies. Better S/B, S/M and LOD were also obtained at lower energies. Beam damage, however, was least at higher energies, despite the higher background (e.g., data for methylene blue in Figure 3). Plots like Figure 4 demonstrate that flux and energy interact. However, S/B and X were more sensitive to changes in emission current than energy, suggesting that i_p is more important in controlling damage and sensitivity.

Another factor that affects beam-induced reactions is choice of matrix. Thioglycerol (T) and m-nitrobenzyl alcohol (M) are better radical scavengers than glycerol (G). The effectiveness of these matrices in controlling damage is $M > T > G$ (e.g., data for methylene blue in Figure 5). Comparing the data for methylene blue in the three matrices, the importance of the parameters in controlling damage is matrix $>$ flux $>$ energy.

Finally, the nonlinearity of a plot of $\ln ([M+H]^+/M^+)$ vs E^+ for the dyes suggests that simple thermodynamic (Nernst) behavior is not the only factor involved in determining the relative extent of dye reduction (Figure 6). There must be some degree of kinetic control of the reactions involved.

EFFECT OF SORBITOL CRITICAL BEHAVIOR ON FAB TOTAL ION CURRENT

Brian D. Bennett and Richard A. Day
Department of Chemistry
University of Cincinnati
Cincinnati, OH 45221

The temperature dependence of secondary ion intensity was studied for a sorbitol matrix. The FAB total ion current of the supercooled melt of sorbitol decreased dramatically with increasing temperature (fig. 1). This drop in total ion current begins at 55° C.

Figure 1. Total ion current (m/z 70-300) of sorbitol as a function of target temperature.

The rapid decrease in total ion current correlates with a phase change. The supercooled melt of sorbitol undergoes an endothermic change at 55° C when analyzed by differential scanning calorimetry (DSC).¹ Rheologically, this transition has been described as softening of the supercooled sorbitol melt with increasing temperature. The effect of this transition on FAB total ion current may be a function of the increased heat capacity of the softened sorbitol melt. The increase in internal degrees of freedom generally associated with increased heat capacity allows for transfer of the incident atom energy to modes which do not give rise to secondary ion formation and ejection. The supercooled melt of sorbitol is a glass forming system. Glass forming compounds are characterized by their reluctance to crystallize once they have been melted. Its choice as a FAB matrix lies in the fact that exposure to high vacuum and elevated temperatures does not lead to recrystallization and loss of fluidity.² The supercooled melt was formed by extensively heating a supersaturated sorbitol solution. Water was removed by further heating until a brown caramel was formed. Upon cooling to room temperature spontaneous crystallization does not occur and a solid is formed. This solid can be described essentially as sorbitol hydrate, however the actual water content is unknown. True sorbitol glass is formed by melting crystalline sorbitol until an opaque phase clears and then cooling to room temperature. The term supercooled melt used here refers to melted sorbitol which has been cooled to a temperature which lies between its glass transition temperature ($T_g = -80^\circ\text{C}$) and the melting temperature of pure crystalline sorbitol. The supercooled melt of sorbitol used in this study does not recrystallize under any of the experimental conditions.

In our hands saturated solutions of sorbitol invariably recrystallize under high vacuum in the ion source at 80° C. When a saturated sorbitol solution is used as the supporting matrix for an analyte, secondary ion emission for that analyte is lost upon crystallization. Ackerman et. al.³ have studied a variety of analytes by FAB using saturated sugar solutions. The secondary ion emission for each compound studied was very temperature dependent. Each had a distinct temperature at which secondary ion emission was maximized. This temperature is known as the BMT (best matrix temperature). The BMT ranged between 80 and 100° C for all compounds studied. When the temperature rose past this range secondary ion emission for analyte return to baseline values. This effect was ascribed to depletion of water. They propose that analyte partitions into water. As water ebulliates from the matrix analyte follows, thus presenting analyte on the surface to incident atoms. Therefore, when water is depleted this

mechanism for analyte transport would be gone. However, the loss of analyte ion emission could be due to crystallization of the sugar from the saturated solution.

Maintenance of matrix fluidity may be a key factor in sustained secondary ion emission in FAB. Fluids, as opposed to solids, can absorb incident atom energy in a way which prevents sample damage. Also, if transport of analyte is required, adequate mobility is necessary. Certainly crystallization of the supporting matrix would impede these mechanisms.

The secondary ion emission of leu-enkephalin and tetramethylammonium hydroxide in supercooled sorbitol melt was studied as a function of temperature. These samples were prepared by adding aqueous solutions to the sorbitol melt on the target which was maintained at 100° C. Excess water was removed with a heat gun. Once in the source compartment a conditioning temperature was used to remove water. The ramp was slow to avoid excessive sample loss due to splashing and held at 150° C for 2 minutes. No visible signs of water ebullition were evident. The temperature could be lowered or raised without any sign of crystallization. After conditioning the sample was run on a Finnigan-MAT TSQ-70 using the liquid cooled solids probe to apply heat to the copper FAB target. The Ion Tech saddle field gun was operated at a potential of 7 KeV and 1mA emission current with xenon gas. Various temperature ramps were used as well as selected isothermal settings.

The effect of temperature on leu-enkephalin secondary ion emission is very similar to that observed for various analytes in saturated sugar solutions. In general, total ion current for sugar ions decreases with increasing temperature and ions due to analyte go through a maximum at relatively high temperature. As seen for the supercooled sorbitol (neat), a sharp decrease in total ion current for sorbitol ions occurs at 55° C. The maximum yield of leu-enkephalin pseudo-molecular ions occurs at 100° C.

The behavior of TMAOH is much different. At 55° C a sharp increase in molecular ion yield is seen. This increase occurs when the temperature is increased or decreased past the ion current-temperature maximum. Interestingly, the supercooled melt at 55° C is essentially solid. There probably is not a discreet decrease in viscosity decrease since supercooled sorbitol melts follow Vogel-Tammann-Fulcher behavior (viscosity vs. temperature is logarithmic with no discontinuities). Therefore the overall mobility of TMAOH in supercooled sorbitol does not change significantly i.e. transport does not play a role in this increase. This increase must be associated with the phase change. The TMA⁺ ion emission does not increase as temperature is raised to 150° C where fluidity has been increased dramatically. Thermal decomposition could not be significant since the maximum occurs again as the sample is cooled to ambient.

The secondary ion emission of TMAOH as a function of temperature indicates that mobility of TMAOH in supercooled sorbitol is not an important factor in its desorption. Also, Ligon⁴ has shown that mobility cannot account for transport of analyte to the surface of glycerol within the time frame of the FAB experiment. Further, the flux of the beam is not high enough to mix the sample, at least on the molecular scale. If a substance is to be sputtered at all it must be in or near the surface system prior to the FAB experiment. For hydrophobic compounds a surface excess is most likely obtained before the FAB experiment.

It should be noted that supercooled sorbitol is considered to be a fluid. Melted sorbitol must be supercooled below its glass transition temperature before it acquires thermodynamic properties of a solid (crystal). Even as a glass, sorbitol retains the structural characteristics of a fluid (i.e. the liquid structure is frozen in.). It has been noted that incident atoms or ions at high flux decompose solids. Supercooled sorbitol at room temperature is solid, but on the molecular scale it behaves much more like a fluid. This may be why the incident atoms energy can be transferred to internal degrees of freedom which give rise to ion formation rather than decomposition.

EFFECTS OF SAMPLE PROBE SURFACE TEMPERATURE ON THE DETECTION OF PEPTIDES BY FAB/MS

I.A. Papayannopoulos and K. Biemann
Department of Chemistry, M.I.T., Cambridge, MA 02139

A thermoelectrically cooled sample probe, which was developed in our laboratory and allows reliable reproduction of desired probe surface temperatures (1), was used to investigate its effects on the detection of peptides by FAB/MS. Renin substrate, angiotensin I, and analogs thereof suppress the ionization of ACTH (1-10) when the latter is mixed with one or more of the former peptides in a 1:1 (or 2:1) ratio and the FAB mass spectra are recorded at the probe surface temperatures at which a mass spectrometer ion source usually operates. Upon cooling the probe surface, the total ion current decreases but the ionization suppression is removed (Figure 1). Suppression of the ionization of components in peptide mixtures from enzyme digests of proteins may often be removed in this manner, allowing for more complete detection of the various components of such mixtures (Figure 2). Because such suppression effects are not always removed by cooling the probe surface (Figure 3), FAB mass spectra should be recorded at probe surface temperatures in the range 4°C-10°C in addition to those recorded at higher temperatures in order to achieve more complete detection of all components of peptide mixtures.

- (1) Martin, S.A., Hill, J.A., and Biemann, K., *Proceedings of the 36th ASMS Conference on Mass Spectrometry and Allied Topics*, 795-796.

Figure 1. The protonated peptide molecule region of an equimolar mixture of angiotensin I and ACTH (1-10). The protonated angiotensin I molecule ($m/z=1296.7$) totally suppresses the ionization of ACTH (1-10) at higher temperature (A). As the probe surface temperature is lowered, the protonated ACTH (1-10) molecule ($m/z=1299.6$) begins to appear (B), until its intensity becomes greater than that of angiotensin I (C). Reduction of cooling begins to reverse the process (D) until, at the initial probe surface temperature, the ionization of the protonated ACTH (1-10) molecule is suppressed by angiotensin I (E). The sample was dissolved in a 1:1 mixture of glycerol and thioglycerol.

Figure 2. Partial FAB mass spectra (in glycerol) of an HPLC fraction from a chymotryptic digest of calf thymus glutaredoxin. By lowering the probe surface temperature (B) the signal-to-noise ratio decreases and two ions *ca.* $m/z=600$ disappear; however, the protonated peptide molecule at $m/z=674.3$, which is not present in the FAB mass spectrum acquired at higher temperature (A), is detected.

Figure 3. The protonated peptide molecule region of two peptides from a tryptic digest of glucagon. Both are easily detected at higher probe surface temperature (A), in contrast to a lower temperature, at which the ionization of the protonated peptide molecule at $m/z=1352.7$ is almost totally suppressed by the protonated peptide molecule at $m/z=1357.7$.

The Use of Non-Ionic Surfactants as Internal Mass Standards
for Exact Mass Measurements in FAB Mass Spectrometry

Marshall M. Siegel*, Rushung Tsao, Steven Oppenheimer, T. T. Chang

American Cyanamid Company, Medical Research Division,
Lederle Laboratories, Pearl River, NY 10965

Techniques reported for exact mass measurements in FAB mass spectrometry have included the successive insertion of a reference and a sample and the use of a rotatable or wobble probe with split targets for sample and reference. Because the sample and reference materials are analyzed separately the mass measurement accuracy is not optimal. More accurate mass measurements are obtained when the reference material is used as an internal mass standard when mixed together with the sample. Exact mass measurements in FAB mass spectrometry utilizing PEG's (polyethylene glycols) [1,2] and PPG's (polypropylene glycols) [3] as standards have been demonstrated for manual peak matching and for computerized exact mass measurements. The PEG's and PPG's produce reference peaks 44 and 58 daltons apart, respectively.

In our hands, the PEG's are useful up to ~700 daltons in either MB ("magic bullet", dithiotreitol/dithioerythritol 4/1) or MNBA (meta-nitrobenzyl alcohol) matrices for producing $[M+H]^+$ and/or $[M+Metal]^+$ ions, at resolutions >6,000. Above ~700 daltons, the ion abundances of the PEG's are low. To remedy this situation, PPG's were proposed as high mass standards [3]. PPG's work best with MNBA as a matrix but tend to suppress the sample intensity. Also, the reference peaks are further apart than the PEG's by 14 daltons, increasing the likelihood for errors in the exact mass measurements.

The low mass oligomeric mixtures of PEG's up to ~700 daltons serve as excellent internal calibration standards. When these mixtures are reacted with alkyl phenols (with masses from ~200 - 350 daltons), mono-substituted PEG surfactants are produced which are useful as internal mass standards up to ~1400 daltons. The structures of these surfactants are illustrated and their useful ranges are listed in Table. (These non-ionic surfactants are available from GAF Corp., Wayne, NJ.) These surfactants are most sensitive with MB as the matrix and most useful adulterated with KCl to produce $[M+K]^+$ ions. When neat or mixed with MB, no $[M+H]^+$ ions are produced. The relative sensitivities of the metal-adduct surfactant molecular ions (for the most abundant metal isotopes) are: $[M+Rb]/[M+K]/[M+Na]/[M+Cs]/[M+Ag]/[M+NH_4]/[M+Li] = 12.0/10.0/6.7/6.0/1.3/1.1/1.0$.

When oligomeric fractions of the alkylphenoxy PEG derivatives were isolated by HPLC, the mass range of the internal standards was extended to ~2,000 daltons. (HPLC conditions: Zorbax CN column, Heptane/50% Isopropanol-50% 2-Methoxy Ethanol 80%/20% -> 20%/80%, 2.0 ml/min.) Figure 1 illustrates the FAB mass spectrum of an isolated HPLC cut and the original surfactant mixture as $[M+K]^+$ ions. The cuts of higher mass oligomers tend to have two oligomeric components. For computerized peak matching two reference peaks are necessary. Therefore, sets of lower mass cuts have to be mixed while the high mass fractions can be directly used. The advantages of the isolated surfactants versus the surfactant mixtures for exact mass measurements are: 1- Less background interference from other surfactant components, 2- The sample signal can be optimized by minimizing the amount of surfactant necessary for the reference signal. Typically, sample sensitivity enhancements of 2 to 10 times are observed in the isolated surfactant because excess surfactant in the surfactant mixture suppresses the sample signal, and, 3- By reducing the amount of surfactant needed for the measurement, the likelihood of source contamination is reduced. Examples of computerized peak matching using isolated surfactant fractions for the 1,300 to 2,000 dalton mass range at 10,000 resolution are listed in Table II and one example is illustrated in Figure 2.

LIQUID CHROMATOGRAPHY/HIGH PRESSURE FAST-ATOM BOMBARDMENT MASS SPECTROMETRY: CHEMICAL IONIZATION OF SPUTTERED SPECIES

TONI J. THOMPSON, SAUL W. FINK AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, HOUSTON, TEXAS 77204-5641

INTRODUCTION: Fast-atom bombardment (FAB) and high-pressure fast-atom bombardment (HPFAB) are soft ionization techniques that can produce spectra with abundant molecular ions but little structural information. Liquid chromatography/high-pressure fast-atom bombardment (LC/HPFAB) uses the recently developed liquid chromatography/fast-atom bombardment (LC/FAB) technique under HPFAB conditions. The HPFAB technique has been shown to enhance the abundance of molecular ions compared to that observed in conventional FAB ionization by collisionally stabilizing the molecular ions and ionizing the sputtered neutral species.¹

EXPERIMENTAL: A hybrid tandem mass spectrometer (VG 70-SEQ) with an EBQQ geometry (5 keV Xe atoms) was used for these studies. A continuous flow FAB probe was built for use in the LC/FAB and LC/HPFAB studies. The liquid was introduced into the mass spectrometer at a flow rate of approximately 6 $\mu\text{L}/\text{min}$ through a 75 μm i.d. fused silica capillary column contained within this probe. The FAB source was modified in three ways for this study. The first modification was to reduce the ion volume of the source block to increase the ion extraction efficiency. The second modification was the use of a movable slit to change the size of the ion exit aperture. The small aperture allows us to conduct HPFAB studies while a large aperture was used for FAB studies. The third modification was the addition of an ionizing filament to the source block. Polyethylene glycol (PEG) was used to analyze the effects of high pressures, matrices, buffers, and reduced ionization chamber size over a wide mass range. The PEG was made of equimolar concentrations of average molecular weights of 200, 300 and 600 in solution. The matrices were varied between 10% and 30% glycerol and 5% and 20% ethylene glycol to obtain the best spectra and the greatest pressure stability in the mass spectrometer. Methane and isobutane were used in the LC/HPFAB studies. During the buffer studies, 0.1M ammonium acetate was added to the mobile phase.

RESULTS: The effect of reducing the ion chamber size on ion abundance was investigated. Pressures in the source housing were more stable (i.e. less ion gauge fluctuation) using the reduced ion volume source block or closed source. The spectrum of positive ion abundances using the reduced ion volume source shows the same molecular ions but at less abundances than with the open source block. The reduction in abundances is approximately 1 order of magnitude.

Fast-atom bombardment mass spectrometry uses a larger ion exit aperture than HPFAB. This larger aperture creates a lower pressure within the ionization chamber. In HPFAB, the sample is enclosed in a high-pressure region. The reagent gas, added to the ionization chamber, can react with the sputtered molecules via ion/molecule reactions to enhance the ion abundances.

In LC/HPFAB, the solvent can serve as the reagent gas. We have investigated the use of an LC mobile phase as a reagent gas in LC/HPFAB. Research has shown HPFAB enhances the molecular ion abundances of neat polar compounds of MW 500u by three orders of magnitude compared to FAB.¹ The abundances of molecular ions of carbonyl-containing organic compounds has been shown to increase with the use of water as a CI reagent gas.² Figure 1 is the spectrum of PEG in 20% ethylene glycol/80% water using LC/FAB. Figure 2 shows the spectrum of the same solution using LC/HPFAB in which the mobile phase functions as the reagent gas. Figure 2 shows an increase in ion abundances of greater than two orders of magnitude compared to Fig. 1. These increased abundances are a result of ion/molecule reactions including proton-transfer occurring in the source.

Figure 3 shows the spectrum of PEG in 20% ethylene glycol/80% water with approximately 0.1 M ammonium acetate. Both the protonated molecule and the ammonium adduct ion ($[\text{M} + \text{NH}_4]^+$) can be observed. However, the ammonium adduct ion is in lesser abundance than the protonated molecule. This is in direct contrast to the abundances observed in thermospray mass spectrometry for PEG with approximately 0.1 M ammonium acetate added to the mobile phase.

CONCLUSIONS: LC/HPFAB has been shown to increase the abundances of protonated PEG over LC/FAB. This increase is due to ion/molecule reactions occurring within the source. Since the mobile phase in LC analyses usually contain water, the ability to use water as a buffer/reagent gas in LC/HPFAB is ideal. Water as a CI reagent gas increases the abundance of protonated molecules by 100-200 fold. Preliminary results show ammonium acetate, added to the mobile phase, produces ammonium adduct ions but in lower abundance than protonated molecules.

ACKNOWLEDGEMENTS: The National Aeronautics and Space Administration/Johnson Space Center provided financial support for this research.

PEPTIDE DIMERIZATION REACTIONS IN THERMOSPRAY AND FAB IONIZATION

SAUL W. FINK, DOUGLAS F. DYCKES AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, HOUSTON, TEXAS 77204-5641

INTRODUCTION: Thermospray and fast-atom bombardment (FAB) are "soft" ionization techniques that have been used to characterize peptide and protein samples.^{1,2} Tandem mass spectrometry (MS/MS) has been used to obtain additional structural information for biological samples. We have used thermospray, FAB, and FAB MS/MS to study the formation of dimers in peptide samples containing one or more glutamic acid residues.

EXPERIMENTAL:

THERMOSPRAY LC/MS: A quadrupole mass spectrometer (HP Model 5988A) and a gradient HPLC system (SSI Model 230) were interfaced with two Vestec ThermosprayTM ion sources. Compared to the old ion source, the new version (model 721) has a smaller desolvation chamber, an auxiliary tip heater, and a needle-tip repeller. Two vaporizer probes used were the standard probe with a tip i.d. of approximately 150 μ and the restricted probe which has a stainless steel capillary tip with an i.d. of 100 μ . Glutamic acid was prepared at a concentration of 1×10^{-4} M in 0.1M ammonium acetate. The peptide samples were introduced by direct injection in a mobile phase of 0.1M ammonium acetate.

FAST-ATOM BOMBARDMENT MS/MS: A hybrid, tandem mass spectrometer with an EBQQ geometry (VG Analytical, 70-SEQ) was fitted with a saddle-field FAB gun (8 keV Xe atoms). The samples were dissolved in 0.5M HCl and placed in the matrix, m-nitrobenzyl alcohol, on the FAB probe tip. Collision-induced dissociation (CID) spectra were obtained with argon as the collision gas and a collision cell pressure maintained at 1×10^{-6} mbar. The collision energies ranged from 20 to 30 eV.

RESULTS: Glutamic acid (GLU) was chosen as a model compound to study the formation dimers in peptides. Glutamic acid was seen to lose water, A in Scheme I, in the thermospray ion source. The protonated pyrroglutamic acid $[M-H_2O+H]^+$, C in Scheme I, is less abundant in the mass spectra than $[M-H_2O-H]^+$, E in Scheme I. This follows solution phase acidities in which the negative ion pyrroglutamic acid ($pK_a=10$) is more stable than the positive ion ($pK_a=0$). The proton-bound dimer of the positive ion pyrroglutamic acid, $[2M-2H_2O+H]^+$, and the negative ion, $[2M-2H_2O-H]^-$, D and F in Scheme I, were observed using thermospray. In FAB, the GLU residue does not form pyrroglutamic acid. The CID spectrum of the proton-bound dimer, m/z 295, fragments to yield the protonated monomer.

Scheme I: A postulated mechanism for dimer formation from glutamic acid in thermospray and FAB ionization.

1. Barber, M.; Bordoli, R. S.; Sedgwick, R. D. and Tyler, A. N. *J. Chem. Soc., Chem. Commun.*, 1981, 325-327.
2. Stachowink, K.; Wilder, C.; Vestal, M. L. and Dyckes, D. F. *J. Am. Chem. Soc.*, 1988, 110, 1758-1765.

We have studied peptides containing one or more glutamic acid residues to study the formation of dimer ions. VAL-GLY-ASP-GLU (VGDE) is a peptide that incorporates a C-terminal GLU. Another peptide, PHE-LEU-GLU-GLU-ILE (FLEEI), has two adjacent internal GLU residues.

The thermospray negative ion mass spectrum (Fig. 1) of VGDE produced using the new source and restricted probe displays ions at m/z 417, $[M-H]^-$, a proton-bound dimer at m/z 835 and a sodium-bound dimer at m/z 857. The FAB positive ion mass spectrum (Fig. 2) of VGDE displays the protonated molecular ion at m/z 419 and the proton-bound dimer at m/z 837. The structure of the dimer was confirmed using CID of m/z 837 which fragmented to yield the protonated monomer at m/z 419.

Figure 1: The thermospray negative ion mass spectrum of VGDE (new source/restricted probe).

Figure 2: The FAB positive ion mass spectrum of VGDE.

The thermospray negative ion mass spectrum of FLEEI produced using the new source and restricted probe (Fig. 3) displays the molecular ion and a proton-bound dimer at m/z 1297. The spectrum also shows a sodium and potassium-bound dimer at m/z 1319, and m/z 1335, respectively. The FAB positive ion mass spectrum (Fig. 4) shows the protonated molecular ion at m/z 650 and a proton-bound dimer at m/z 1299 which was confirmed by CID of m/z 1299, which fragmented to give the protonated monomer.

Figure 3: The thermospray negative ion mass spectrum of FLEEI (new source/restricted probe).

Figure 4: The FAB positive ion mass spectrum of FLEEI

CONCLUSIONS: Different dimer ions are produced in thermospray and FAB for glutamic acid. Thermospray produces a proton-bound dimer from pyroglutamic acid, $(M-H_2O)$. The positive ion proton-bound dimer produced using FAB is $[2M+H]^+$. The peptides studied produced an abundance of the molecular ion with less relative abundance of the dimers.

ACKNOWLEDGEMENTS: We wish to thank Dr. Marvin L. Vestal for his many invaluable discussions. We thank the National Institute of General Medical Sciences Health for providing financial support.

EFFECT OF PEPTIDE HYDROPHOBICITY ON MOLECULAR ION YIELDS IN NITROCELLULOSE ADSORPTION, PLASMA DESORPTION MASS SPECTROMETRY

Rong Wang, Ling Chen, Robert J. Cotter
The Johns Hopkins University, Baltimore, MD 21205

INTRODUCTION

Plasma desorption mass spectrometry (PDMS) has been widely used in the analysis of polypeptides and proteins [1]. Direct analysis by PDMS combined with enzymatic digestion provides molecular weight information for each peptide fragment with high accuracy. This is called PD protein mapping. In these studies, nitrocellulose membrane-protein adsorption is the most commonly used sample preparation. However, we have noted that different peptides or proteins have quite different intensities, especially in PD protein mapping while some of the expected peptide fragments are not be observed in spectra. Some peptides or contaminants appear to quench (or suppress) others, either in positive or in negative PDMS. Nielsen and Roepstorff have observed that suppression effects were only related to the potential net charge but not to the average hydrophobicity of the individual peptide [2]. On the other hand, our previous study on tryptic digest of recombinant human growth hormone has shown that the hydrophobicity of peptide fragments does appear to play a significant role in suppression [3]. Thus we were interested in the role of nitrocellulose membrane in these phenomena and what causes the different behavior of peptides.

In this poster, we considered the interactions between peptide and nitrocellulose, and peptide with peptide. Four sets of peptides with a fixed number of amino acids but different hydrophobicity indexes (H.I.) were chosen as subjects to demonstrate the effect of peptide hydrophobicity. Mixtures of peptides from the same set were also studied to characterize the suppression effect in protein mapping analysis using nitrocellulose as matrix.

EXPERIMENTAL

All data were obtained on a Bio-ion (Uppsala, Sweden) Bin 10K plasma desorption mass spectrometer. The acceleration voltage was 18 KV for positive spectra and -16 KV for negative spectra. All peptides were purchased from Sigma Chemical Co. 1 nmole/ul peptide solution was prepared in 0.1% TFA aqueous solution. 5 nmoles were applied as sample size. Spectra of samples treated with (procedure I and II) or without rinsing (procedure I only) were both recorded for comparison.

(I). Equilibrium adsorption Once 5 ul of peptide solution was added onto the nitrocellulose surface, the sample foil was covered with a microscope cover-glass for 3 min. During this period of time, equilibrium of the peptide between solvent and nitrocellulose surface was established. The glass was then removed as well as most of the extra solution.

(II). Rinsing After procedure I, the sample foil was rinsed with 1 ml 0.1% TFA (aqueous) to remove Na, K contaminants and the weakly adsorbed peptides.

RESULTS AND DISCUSSIONS

-In the comparison of spectral quality of individual peptides, the more hydrophobic peptides appear to give higher molecular ion yield and better signal to noise ratio (Fig.1).

-Rinsing preferentially removes smaller peptides. There is no discrimination against more hydrophilic peptides.

Figure 1

Figure 2

-In our study of pure peptides, molecular ion intensities show no significant correlation with the charge state of peptides, either at pH 7 (Fig 2) or pH 1.9 (data not shown).

-In our study of suppression effects among peptides of the same size (same number of amino acid), all factors including hydrophathy, charge state, and solubility seem to have different degrees of effects. The most hydrophobic peptides tend to suppress others. However, when mixing only the three less hydrophobic peptides, the more positively charged peptide dominates the positive-ion spectra. In the process of mixing 0.1% TFA aqueous solutions of large peptides (more than 40 amino acids), the hydrophobic peptides precipitated in the presence of hydrophilic peptides which results in the mass spectrum of mostly hydrophilic components.

-The average hydrophobicity index (H.I.) of peptide or protein was calculated based on Bull and Breese's measurement of free energy to transfer each individual amino acid from aqueous solution to the air/water interface. It can be used to represent whether the peptide (or protein) is hydrophilic (positive value) or hydrophobic (negative value). H.I. can be successfully used to explain the behaviour of peptide or protein in fast atom bombardment mass spectrometry (FAB-MS), where peptide molecules are distributed between bulk liquid phase and its surface. Although average H.I. has significant correlation with molecular ion intensity in our study, it may not be a reliable parameter to examine the interaction between peptide and the nitrocellulose surface since no liquid phase is present in PDMS. Some discrepancy in our study of molecular ion intensity vs hydrophobicity index can be explained by also considering proportion of hydrophobic amino acid residues in the peptide. Perhaps a new parameter should be used to explain the behaviour of peptides on a nitrocellulose surface.

SINGLY-CHARGED IONS, MULTIPLY-CHARGED IONS, NEUTRALS AND MASS LIMITS IN PLASMA DESORPTION MASS SPECTROMETRY

R.J. Cotter and R. Wang
The Johns Hopkins University, Baltimore, MD 21205

The plasma desorption mass spectra of large peptides are generally characterized by an abundance of multiply-charged as well as singly-charged molecular ion species. It has been noted by us and by others that the intensities of multiply-charged molecular ions, as well as the average charge, generally increases with molecular size (Figure 1). In part this may be accounted for by the increase in number of basic sites resulting in multiple protonation. On the other hand, it may simply be that the charge density of these massive ions is sufficiently low that they appear "nearly neutral" in the desorption process. Finally, the fact that the charges may be widely separated in the molecule may result in ions which are stable in the gas phase to decomposition resulting from charge repulsion.

Thus, in this study we attempt to characterize the charge distribution of desorbed ions over a range of molecular weights by considering the effects of both ion transmission and ion detection on the initial distribution of ions desorbed in the source. Corrections to the "observed" (Figure 1) distribution produced some interesting results, with implications on the ultimate mass range of plasma desorption techniques.

Mass spectra were obtained on a BIO-ION (Uppsala, Sweden) model BIN-10K time-of-flight mass spectrometer with a 1 μ Ci Cf-252 ion source.

If an ion with initial kinetic energy U_0 traverses the drift region (D) in a time: $t = D(m/2neV)^{1/2}$, then the maximum radial drift (L) in that time (which may cause it to miss the detector) will be: $L = (2U_0/m)^{1/2}t$ or $L = (U_0/neV)^{1/2}$. Thus transmission is improved by higher accelerating voltages (V) and higher charge states (n), but is independent of mass (m). Detection efficiency is dependent upon ion velocity: $v = (2neV/m)^{1/2}$, and therefore upon mass, as well as charge state and accelerating voltage. Thus, in Figure 2 we determined the ion intensities of the +1, +2, +3 and -1 molecular ions of insulin as a function of

accelerating voltage (5KV to 22KV) and plotted as a function of ion velocity.

Because the ion signal from the fast-moving +3 ion did not increase between 18 and 22KV, we were able to determine the velocity at which all ions are detected. Linear extrapolation of all other ions to that velocity then provides a correction for the observed distribution of multiply charged ions as shown in Figure 3. Plotted as a function of charge/mass, it is possible to obtain an estimate of the neutral species. In addition, it appears that a large number of singly-charged ions are desorbed (but not detected) and that the average charge state falls around 1.3/10KDa.

The singly charged ions from large peptides are observed below "threshold," but are the prominent ions observed in UV-assisted laser desorption (1). It is suggested, from these experiments, that analog recording of a large group of ions of the same mass impinging on the detector at the same time would improve detection below "threshold" over detection of single ions by time-to-digital conversion.

FACTORS AFFECTING EH SOURCE FLOW AND EMISSION STABILITY: RELEVANCE TO MASS SPECTROMETRY

John F. Mahoney^a, Julius Perel^a, Terry D. Lee^b and Kassu Legesse^b
^aPhrasor Scientific Inc., 1536 Highland Ave., Duarte, CA 91010
^bCity of Hope, 1450 E. Duarte Rd., Duarte, CA 91010

Electrohydrodynamic (EH) ionization is currently being pursued as an alternative method for producing gas phase, high mass biomolecular ions. Additionally, EH ionization may have other applications for LCMS and polymer characterization¹. Historically, EH emission and capillary flow stability were adequate when using high viscosity, low vapor pressure solutions e.g., glycerol. For the most part, mass analysis of peptides and proteins require solvents having low viscosity and high vapor pressures. Unless proper precautions are taken, atomization of aqueous solvents in vacuum can be counterproductive for the acquisition of stable, repetitive mass spectra. EH ion source instabilities arise from two sources: flow instabilities influenced by the geometry and material of the capillary inlet system and secondly, emission instabilities inherent in the electrostatic atomization process influenced by the solvent chemistry. The present research has addressed these instability problems resulting in improved performance for EH emission of aqueous solvents in vacuum.

Flow modeling based on the idea that Hagan-Poiseuille flow rates should exceed the rates of solvent loss by evaporation from the capillary led to the following stability criterion for a two component mixture:

$$r^2/\ell > K\eta(p_1M_1^{\frac{1}{2}} + p_2M_2^{\frac{1}{2}})/\rho T^{\frac{1}{2}}\Delta P \quad (1)$$

where r and ℓ are the radius and length of the flow capillary respectively, K has the value 6.98×10^{-4} , M_1 and M_2 are the molecular weights of the solvent components with partial vapor pressures p_1 and p_2 , η and ρ are the solution viscosity and density, T is the absolute temperature and ΔP is the pressure difference across the capillary. The quantities in Eq. 1 are expressed in cgs units with the exception of the pressure terms expressed in units of torr. To eliminate flow instabilities induced by geometry, capillary inlet dimensions must be chosen so that the quantity r^2/ℓ is larger than the right-hand side of Eq. 1. Other flow instabilities are attributed to the existence of microbubbles which form at regenerative nucleation sites on the surface of capillary flow passages. Growth and expansion of microbubbles lead to discontinuous flow resulting in aperiodic current emission. This type of instability can be prevented by using non-metallic, nucleation-free surfaces (fused silica) and flow passages uninterrupted by couplings or tube-to-tube transitions of unequal diameters.

The effects of solvent chemistry on emission stability were empirically studied with the experimental arrangement shown in Fig. 1. After passing a focused EH ion/droplet beam through an unpressurized desolvation cell, the transmitted beam current vs. time profile was mapped using an x-y recorder connected to an electrometer displaying the Faraday cup signal. Variations in the amplitude of the current-time trace are a direct measure of EH emission stability. Emission instabilities are compared in Fig. 2 for several molar concentrations in 60:40 (by volume) water-methanol mixtures. Repeated experiments reveal that solutions near 1.5M ammonium acetate show good emission stability. Similarly, experiments varying the solvent composition keeping a fixed molarity (1.5M ammonium acetate) were conducted.

An EH source, using a solvent composition characterized by good stability performance, was installed on a JEOL HX100 HF mass spectrometer. Fig. 3 shows ten consecutive scans (43 s/scan) characterizing the typical scan-to-scan repeatability measured using a 1.5M 60:40 water-methanol mixture. The stability displayed by this series of scans is essential for continuing mass spectrometric investigations with dissolved biological samples.

DISTINGUISHING ISOMERIC AND ISOBARIC IONS BY THERMOSPRAY MS PRECEDED BY ELECTROCHEMICAL ELECTROLYSIS

T.A. Getek, W.A. Korfmacher, and J.P. Freeman
National Center for Toxicological Research
Jefferson, AR 72079 USA

Introduction: Thermospray mass spectrometry (TSMS) has proven to be an excellent interface for high-performance liquid chromatography (HPLC). One of the drawbacks, however, of TSMS is that in the majority of cases only the protonated molecule, $[M+H]^+$, is observed with very little fragmentation. In order to increase fragmentation for purposes of structural elucidation, "repeller" voltages were employed, as well as extending the temperature range of the thermospray (TS) effect (Plasmaspray™). Tandem TSMS is an expensive alternative for augmenting fragmentation for identification purposes. Because TSMS utilizes polar solvents with a volatile salt at an usual concentration of 0.1 M, interfacing an electrochemical cell on-line prior to TSMS is easily accommodated.

For electrochemically active compounds, the products of electrolysis may be sufficiently distinct so as to allow for discrimination of isomeric and isobaric (same nominal mass) compounds as observed via TSMS. This combination of electrochemistry (EC) with TSMS has been given the name "solution electrochemistry mass spectrometry" (SECYMS).

Experimental: A Delsi R-1010-C quadrupole with Nermag-Delsi TS source and Vestec TS controller were used. A coulometric ESA guard cell, 5020, was placed in series between the TS quadrupole and HPLC pump. SECYMS conditions for direct injections of aminophenols (AMP) were 90/10 H₂O/MeOH at 0.1 M ammonium acetate (AA) at a flow rate of 1.0 ml/min. HPLC/TSMS of AMP used a mobile phase of 90/10 0.1 M AA at pH 4.8/0.1 M AA in MeOH at a flow rate of 1.0 mL/min on a reversed-phase ODS-II column. Acetamidophenols (ACP) and guanine were continuously pumped into the TS source at $ca. 1 \times 10^{-4}$ M ACP and guanine in 90/10 H₂O/MeOH at 0.1 M AA at a flow rate of 1.2 mL/min. In order to solvate guanine, the AA was adjusted to pH 4.5.

Results: For AMP, TSMS detected only a $[M+H]^+$ ion at m/z 110 for each isomer; however, upon oxidation of each isomer a distinctive ion was observed as seen in Fig. 1: m/z 108 for *p*-AMP; m/z 217 for *m*-AMP; m/z 213 for *o*-AMP. In this way, the isomer of AMP was determined by direct injections.

The HPLC/TSMS of AMP generated three chromatographic peaks with the base peak at m/z 110. By using a combination of HPLC/EC/TSMS at a potential of +0.2 V (Fig. 2), a distinction between the isomers of AMP was possible *without* injecting the isomers of AMP separately to determine their retention times. At +0.2 V, only *p*-AMP and *o*-AMP were oxidized as shown by the hydrodynamic voltammograms in Fig. 3. The distinguishing ions, as seen in Fig. 2, were: m/z 108 for *p*-AMP (I); m/z 110 for *m*-AMP (II) (no change); m/z 124 and 213 for *o*-AMP (III). Because concentrations of AMP were low in the HPLC/EC/TSMS analysis, dimerization was not as evident for *o*-AMP compared to the direct injection analysis.

For ACP and guanine, the $[M+H]^+$ ion at m/z 152 was the base peak. A $[M+NH_4]^+$ ion and $[M_2H]^+$ ion was also detected for ACP by TSMS. Upon oxidation as shown in Fig. 4, distinctive mass spectral peaks were observed for each isomeric and isobaric compound: m/z 108 and 150 for *p*-ACP; m/z 152 and m/z 168 for *m*-ACP (very little change); m/z 167 for *o*-ACP; m/z 166 and 113 for guanine.

Conclusions: The method of SECYMS enables the mass spectrometrists to determine on-line the isomers of AMP and ACP, as well as isobaric compounds. The ease of use and the inexpensive cost of the electrochemical cell makes SECYMS a viable technique for determining structural isomers of electroactive compounds by TSMS.

CO₂ AS A MODERATING GAS IN ELECTRON CAPTURE
CHEMICAL IONIZATION

M.E. Molleken and A.G. Harrison
Department of Chemistry
University of Toronto
Toronto, Canada M5S 1A1

The use of CO₂ as a moderating gas in electron capture chemical ionization has been explored. All chemical ionization studies were carried out using a ZAB-2FQ mass spectrometer operating with a source temperature of 250°C.

The negative ion mass spectrum of CO₂ at high pressures shows signals for O⁻ and CO₃⁻; in addition, near-thermal energy electrons are present. The CO₃⁻ ion is essentially unreactive since CO₃ has an electron affinity of 3.3 eV [1] and CO₃⁻ has a proton affinity of approximately 324 kcal mol⁻¹ (measured by reaction bracketing using the FA-SIFT at the University of Colorado). The reactions of O⁻ have been documented [2].

With compounds of reasonable electron affinity, such as nitroarenes, polyfluoroaromatics and 1,2-diketones, negative ion mass spectra are obtained using CO₂ moderating gas which are very similar to the spectra obtained using CH₄ moderating gas; presumably in these cases the spectra are produced primarily by electron capture. However, compounds of low electron affinity show a reduced sensitivity and, in most cases, show spectra more closely resembling those produced by O⁻ CI. In addition, in many cases, these spectra are made more complex by the presence of substantial artifact peaks. Thus, aliphatic ketones show substantial [M+14]⁻ and [M+12]⁻ ion signals. These products are not enhanced by addition of O₂ to the reagent gas and do not arise by ion/molecule reactions of CO₃⁻ with M or by reactions of [M-H]⁻ or [M-2H]⁻ with CO₂; rather they appear to be the result of unidentified surface reactions in the ion source. The spectra also are rather non-reproducible from day to day. The use of CH₃CD₂COCDC₂CH₃ showed that, for this compound at least, the [M+14]⁻ ion corresponded to [CH₃CH₂COCOCCH₃]⁻ while the [M+12]⁻ ion corresponded to [CH₂=CHCOCOCCH₃]⁻. With acetophenones, in addition to an [M+14]⁻ artifact peak, an [M+28]⁻ artifact peak is observed as the result of a surface reaction. Experiments with C₆H₅COCDC₃ showed that the CD₃ group was lost in forming this product, which we believe corresponds to the molecular anion of phthalic anhydride.

USE OF CO₂ AS A BUFFER GAS IN HIGH PRESSURE ELECTRON CAPTURE MASS SPECTROMETRY. THE ELIMINATION OF UNUSUAL NEGATIVE IONS.

L.J. Sears and E.P. Grimsrud

Department of Chemistry, Montana State University, Bozeman, MT 59717

High Pressure Electron Capture Mass Spectrometry (HPECMS) involves the capture of thermalized electrons by an analyte, MX. This process of electron capture (EC), conducted at 0.1 to 1.0 Torr, may occur through dissociative (1a) or resonance (1b) capture of the thermal electron. Thermalized electrons are generally produced by the interaction of a high energy electron beam with the buffer gas.

It has been demonstrated that exceptionally high chemical specificities and sensitivities are often obtainable with EC reactions¹. This is the direct result of the nature of the reaction, shown in expressions 1a and 1b, which can have a rate coefficient 2 orders of magnitude larger than those of ion-molecule reactions.

Since the EC reaction can often proceed with very fast rates, certain chemical events (the results of which may not be observed in the more general field of Chemical Ionization Mass Spectrometry) may occur leading to the production of unusual or unexpected negative ions. Process X (1c) provides a generalized route by which unusual negative ions may be produced in HPECMS. Figure 1 shows four of these routes which we have found to be kinetically favorable, with respect to reactions 1a and 1b, for the production of negative ions under HPECMS conditions².

Reactive products generated by the interaction of the electron beam with methane are often involved in the formation of unexpected negative ions. As seen in Figure 1, which has been described in greater detail elsewhere², the various products of irradiated methane may be associated with any one, or all four of the Routes toward generation of unusual negative ions. A logical step toward the control or elimination of these unusual ions in HPECMS spectra is to simply alter the buffer gas used for thermalization of the electrons.

We have tried several gases and have found that CO₂ consistently provides EC spectra which are free of negative ions that arise from secondary processes. Additionally, the use of CO₂ as a buffer gas provides equivalent or lower levels of detection for most analytes as compared to sensitivities when using CH₄ as the buffer gas. Although other buffer gases did provide spectra which were represented only by ions from the primary EC reaction, they lacked the desirable feature of sensitivity for which HPECMS is so often used.

Figures 2, 3, and 4 show a comparison of EC spectra from CH₄ and CO₂ buffer gases of various compounds which are representative of unusual negative ion formation by Routes A, B, and C from Figure 1. In all spectra, the buffer gas pressure is 0.5 Torr, the source temperature is 150°C, the electron energy is 150eV, and the emission current is 0.2mA. Figure 2 provides examples of spectra of fluoranil, chloranil, and Pentac. In CH₄, these neutrals are altered at the walls of the ion source via a Route D process prior to electron capture. In Figure 3, tetracyanoethylene and tetracyanoquinodimethane are altered by reactions with hydrocarbon free radicals generated in the CH₄ plasma. In both Figures 2 and 3, the use of CO₂ as the buffer gas provides EC spectra which are simplified and reflective of the molecular structure. Figure 4 provides the only case in which CO₂ did not provide simplified spectra which were free of negative ions originating from secondary processes. The trifluoroacetic anhydride (TFA) derivatives of the aminoanthracene (AA) and aminophenanthrene (AP) provide examples of compounds which undergo positive ion molecule reactions and neutralization (Route B) prior to EC. In Figure 4 we see that the major negative ions in the spectra of 3-AP-TFA isomer are the result of prior positive ion-molecule reactions, irregardless of which buffer gas is used. For those compounds which follow a Route B process, it may not be possible to eliminate the occurrence of unusual negative ions. To do so would require the elimination of positive ion-molecule reactions which may not be fundamentally possible.

There is evidence available which suggest that CO_2 may be an exceptional buffer gas with respect to electron energy thermalization^{3,4,5} and collisional stabilization⁶ of the initially formed negative ion. Additionally, our experience with CO_2 has shown that it consistently provides EC spectra which are free of the effects of secondary processes.

SENSITIVITY STUDY OF PERFLUOROCARBONS AND PERFLUOROCARBONS CONTAINING
NON-FLUOROCARBON GROUPS

S. K. Huang, K. Despot and T. W. Bierl
Adamantech inc., 1501 Blueball Ave., Linwood, PA 19061-0895

The detection of residual impurities such as perfluorocarbons (PFCs) containing one or two hydrogens, perfluorinated ketones, alcohols or ethers in PFCs by the negative ion chemical ionization mass spectrometry (NICIMS) has been a problem. The problem is associated with the relatively low electronegativity of these compounds with respect to PFCs which show strong response in the NICI condition. In an attempt to improve the signal strength of these impurities, the relative response of various model fluorocarbons with respect to the spiked internal standard, perfluoro-cis-decalin, in different NICI reagent gases was studied by an HP-5988 GC/MS system. As shown in Table 1, CH_4 is in general the best NICI reagent gas for the sensitive detection of perfluorinated alkanes, alkenes and aromatics. However CO_2 and NH_3 are good NICI reagent gases in detecting hydrogen- and oxygen-containing PFCs. Table 2 shows the relative sensitivity of the same model fluorocarbons with respect to the *E*-cis-decalin. The sensitivity ratio shown in this table has been normalized to the same number of molecules entering the ion source of the mass spectrometer by dividing the signal strength of each compound by its number of moles prepared for the solution. The sensitivity of the spiked *E*-cis-decalin was taken arbitrarily as one in this case. Some rough trends can be extracted from Table 2: 1) a highly cyclic PFC gives more sensitive response than a single cyclic PFC, 2) cyclic or aromatic PFCs seem also more sensitive than the open chain PFCs, 3) a branched PFC appears to be more sensitive than the straight chain PFC, and 4) PFCs containing heteroatoms are much less sensitive than PFCs in NICI.

Because of the effective wall reactions, PFCs undergo altered reactions (1) in NICI. As a result, a response factor variation as a function of sample amount is observed. As shown in Figure 1, the response ratios of the perfluorinated 1-methyl adamantane, 2,5-dimethyl [3,3,1] bicyclononane and 1,3-dimethyl-5-propyl cyclohexane to the internal standard, *E*-cis-decalin change with the injection volume from the same mixture. This phenomenon was also found to depend on the NICI reagent gas employed, which leads to a different linear dynamic range for each reagent gas as shown in Table 3. It was found that the employment of CF_4 yielded the largest linear range in the calibration curve. On the other hand, NH_3 gave the most sensitive response to the analyte's concentration.

Comparison of Gas Phase and Liquid Phase Ionization: Chemical Ionization at Atmospheric Pressure vs. Field Assisted Ion Evaporation

T. R. Covey, B.I. Sushan, and B. A. Thomson
Sciex, Inc. 55 Glen Cameron Road, Thornhill, Ontario Canada L3T 1P2
J.D. Henion
Equine Drug Testing Cornell Univ. Ithaca, N.Y. 14850

The mechanism by which ions can be emitted from a liquid solvent into the gas phase has been termed Ion Evaporation (IE). Experimental evidence combined with a theoretical model suggested that as a charged droplet evaporates in air, a critical point is reached at which it is kinetically and energetically possible for ions at the surface of the liquid to "evaporate" into the air (1). Interest about this process has raised further questions about the details of the ionization mechanisms involved (2) and how it compares to other methods of liquid introduction. This presentation shows both positive and negative ion spectra with Ion Evaporation and APCI from a series of compounds ranging from low mass neutral compounds to high mass highly charged molecules which lend credence to the Ion Evaporation theory. The compounds shown are lovastatin (neutral in solution), a monosulfonated azo dye (singly charged), a disulfonated azo dye (doubly charged in solution), adenosine triphosphate (triply charged in solution), and β -lactoglobulin (21 charges). A comparison is made with Atmospheric Pressure Chemical Ionization (APCI) to highlight the fundamental differences in these two ionization techniques.

This work was done on a Sciex API III triple quadrupole mass spectrometer equipped with the standard *Atmospheric Pressure Ionization* source. The *Ion Spray* probe was used to generate Ion Evaporation spectra and the *Heated Nebulizer* probe with a corona discharge was used to generate APCI spectra.

Spectra were obtained by flow injection analysis in 50/50 methanol/H₂O 0.1 mM NH₄OAc, pH = 4.5. Flow rates were 40 μ L/min for the Ion Evaporation Spectra and 1 mL/min for the APCI spectra.

Conclusions drawn from the 20 spectra shown can be summarized as follows:

1. Field Assisted Ion Evaporation is a *pure desorption technique* having no gas phase or thermal component.

2. Compounds neutral in solution can produce ions by Ion Evaporation via association in solution with a charged molecule such as acetate or NH₄. Reagent ion monitoring experiments indicate that the neutral molecule and the charged adduct associate in solution and are then desorbed to the gas phase (3). The desorption process is so mild that these complexes do not fragment but remain intact during transfer to the gas phase. No fragmentation has yet been observed with this technique.

3. For a compound having a spectrum containing several multiply charged molecular ions, the charge state is quantized, i.e. a charged state is never skipped. This has important implications for the determination of the molecular weights of unknowns from multiply charged ions.

FIELD IONIZATION AT LOW VOLTAGE
Michael J. Coggiola and Charles A. Spindt
SRI International, Menlo Park, CA 94025

Historically, field ionization has required high voltages to achieve a field strength of 10^7 - 10^8 v/cm needed to induce electron tunneling from a molecule into the source. Ionization thresholds in excess of several kilovolts, and typical operating potentials of 7-15 kV are characteristic of the wire and foil-type sources used. The volcano-style field ionization source developed at SRI in the late 1970's produced field ionization above 800-900 volts, and usable mass spectra at voltages between 1.5 and 2.5 kV. FI at these voltages was possible because the physical dimension of the volcano opening was on the order of 15-25 μm , and the volcano-to-counter electrode spacing was typically 25 μm . Thus, high local field strengths could be developed with modest applied potentials.

More recently, we have developed a new microvolcano field ionizer that bears only a passing resemblance to the original volcano ionizer. Prototype devices have been microfabricated from a single silicon wafer, and consist of a 10×10 array of volcano structures, each surrounded on the top surface by a metallic counter electrode. The volcano rim diameter has been made as small as 0.75 μm , and as large as 2 μm . There are several major advantages of this design over the conventional volcano field ionizer, including: the integral counter electrode that ensures precise alignment; single unit construction requiring no assembly; and improved mechanical strength and ruggedness associated with the monolithic structure.

Because of its very much smaller dimensions, the microvolcano would be expected to exhibit a significantly lower threshold for ionization than the conventional volcano source. Figure 1 shows the measured voltage-current curves for a prototype microvolcano array. The curves were obtained by counting the total ion signal as a function of the applied voltage between the microvolcano rim and the counter electrode. The drive voltage in these experiments was half-wave rectified 60-Hz ac, and the ion extraction/acceleration potential was 1.5 kV. Note that no mass analysis was performed, however, other experiments (see below) confirmed that the ion signal was due primarily to parent molecular ions. The results obtained with 0.2 Torr of toluene vapor supplied to the back of the microvolcano array are shown by the solid symbols. The measured onset of field ionization is ≈ 48 volts ac. Similar results are obtained using a dc drive voltage. The apparent saturation of the current above 70 volts is an artifact of the limited dynamic range of the detection system. After operation for several hours, the ionization threshold voltage was found to decrease, with the lowest measured value being ≈ 30 volts. It is presumed that some type of activation process is responsible for the observed reduction in threshold voltage. The open symbols in Figure 1 show the measured signal level when the toluene vapor was pumped from the source. The ion signal is due to a combination of residual toluene within the inlet line, and background organic vapors within the vacuum test chamber.

Mass spectra were also obtained using microvolcano field ionizer arrays interfaced with a simple quadrupole mass filter. Spectra were obtained from a variety of simple hydrocarbon species, including toluene, benzene, n-propylbenzene, n-butylbenzene, acetone, and butane. In each case, the microvolcano source produced mass spectra that were very characteristic of field ionization, with $> 98\%$ of the observed signal attributable to M^+ ions. Spectra showed no appreciable change with applied voltage, other than the expected intensity variation.

By using a dual microchannel plate detector equipped with a phosphor screen, it was possible to image a portion of the ion signal produced by a microvolcano array. This magnified ion image clearly showed the discrete ionization sites associated with individual microvolcanos. A typical image consisted of 10-15 overlapping, circular spots aligned on an evenly spaced grid. Each spot showed a radially symmetric intensity pattern that was most intense in the center. Near threshold, individual image spots showed significant temporal intensity variations. At voltages well above threshold (2x), the patterns became very stable, eventually merging into a uniform intensity distribution on the microchannel plate detector.

The microvolcano field ionization source described here has a number of unique, and potentially useful features. Although the prototype device consisted of 100 microvolcanos, standard photolithographic techniques could be used to produce larger arrays of 100 x 100 microvolcanos, thus potentially providing a 100-fold increase in ion current. Moreover, multiple arrays could be fabricated in close proximity to each other to provide an even larger active area.

As a result of achieving field ionization at such low voltages, it is possible to increase the operating pressure of the microvolcano source without producing an electrical breakdown between the rim and counter electrode. The excellent mechanical strength of the silicon substrate will allow a pressure differential between the front and back sides of the device in excess of 200 Torr. Given the dimensions and potentials involved, it should be possible to observe field ionization at atmospheric pressure.

This work was supported by CommTech International.

Figure 1. Measured voltage-current curves for a 10 x 10 microvolcano array. The volcano drive voltage was half-wave rectified 60-Hz ac, with the sample vapors indicated on the Figure. The effective onset of field ionization above the noise level is 48 volts ac. The apparent saturation above 70 volts is due to the limited dynamic range of the detector.

LD/FTMS. A Study of Variables Affecting Performance.

David A. Weil, Joseph E. Campana, Robert R. Weller

Asgeir Bjarnason, Science Institute, University of Iceland,
Dunhaga 3, IS-107, Reykjavik, Iceland.

Laser desorption mass spectrometry (LDMS) has been applied successfully to a number of important classes of compounds that are generally problematic for mass spectral analysis. This report describes a study whose purpose is to enhance the performance of LDMS and expand the set of compound classes that can be routinely analyzed by using laser desorption.

Performance criteria used in evaluating the performance of the LD/FTMS technique were resolving power (RP), high-mass detection, sensitivity, and detection limit. The production of abundant molecular or molecular-like ions is desirable to determine the molecular weight of the sample and to apply MS/MS experiments for structural information.

Because the compounds of greatest interest in the biosciences are isolated only in minute quantities, we have devised sample handling and manipulation procedures for reducing the detection limits in LD/FTMS. The microdeposition of the sample on the mass spectrometer probe target enables picomole detection limits to be achieved from biomolecules with a single laser shot and at high resolution.

The positive-ion LDMS mass spectrum of alpha-melanocyte stimulating hormone (MSH), which was obtained on 100 pmole of sample and with a single laser shot, is shown in Figure 1. This mass spectrum shows a resolving power of 7,200 (FWHM) and a S/N of greater than 10. Medium resolution positive- and negative-ion LDMS mass spectra were obtained with a single laser shot on 500 pmole of MSH (Figure 2). Peptide sequence information was obtained directly from the mass spectrum. The positive-ion spectrum (Figure 2A) shows the A and B series while the negative-ion spectrum (Figure 2B) shows the C and Z series of fragment ions. Other fragment ions resulted from internal and side-chain fragmentation. The absolute detection limit for LDMS when used with the microdeposition technique was estimated by studying RbCl. Sixteen attomoles of Rb was detected as $^{85}\text{Rb}^+$ at a S/N of 6/1, which corresponds to a limit of detection of five attomoles at a S/N of 2/1.

Metal-containing compounds are often problematic for mass spectral analysis because many are thermally unstable, air-sensitive or both. As a part of our study of this class of compounds, we have successfully analyzed by LD/FTMS a platinum complex. The positive-ion laser desorption mass spectrum (Figure 3) shows peaks corresponding to cationized molecules $[\text{M}+\text{Na}]^+$ (m/z 908) and $[\text{M}+\text{K}]^+$ (m/z 924), and fragment ions that correspond to the loss of a triphenylphosphine ligand. Fast atom bombardment (FAB) was unsuccessfully applied to the analysis of this compound. The LD/FTMS technique thus appears to hold promise for great progress in the field of mass spectral analysis of organometallics.

MULTIPHOTON IONIZATION OF RHODAMINE 6G: STUDY OF FRAGMENTATION AS FUNCTION OF PHOTON ENERGY AND INTENSITY

A. Holle, R. Frey, H. Kaminski, G. Weiss, J. Franzen, and D. Koch;
Bruker-Franzen Analytik GmbH, Kattenturmer Heerstr. 122,
D-2800 Bremen, FRG

Multiphoton ionization followed by time-of-flight mass analysis, is a powerful method to obtain structural and molecular weight information of large neutral molecules. In many cases the fragmentation can be reduced to an extent, that only molecular ions are produced. Increasing the laser power increases the fragmentation, while different wavelengths select different fragmentation channels, i.e. give additional structural information.

Neutral molecules are vaporized by pulsed infrared CO₂-Laser radiation. The desorbed intact molecules penetrate a pulsed supersonic jet, which cools them and carries them into the multiphoton-ionization region. Thus this multistep desorption/ionization method allows in particular the examination of labile, nonvolatile substances. The measurements have been performed with a Bruker TOF 1. A more detailed description of the apparatus can be found in ref.1-3.

fig. 1

The results for Rhodamine 6G (fig. 1) show how different photon energies (wavelength) at constant intensities influence the multiphoton ionization mass spectra. Mass 443 corresponds to Rhodamine 6G without Cl and is desorbed as a neutral molecule. Different ionization laser wavelength drastically change the whole mass spectrum, especially in the mass range little below the molecular ion (i.e. Rhodamine 6G - Cl). Below 261 nm (= 4.75 eV) fragments of Benzene rings can be produced. Varying the laser power at constant laser wavelength (260 nm), leads to more small fragments and less signal on the molecular ion, but does not change the fragment ratio in the higher mass range (fig.2). The results show the necessity and the possibilities of desorbing in two separate steps, which can be optimized independantly.

DESORPTION AND DISSOCIATION OF SMALL BIOMOLECULAR IONS BY UV-LASER IRRADIATION

Franz J. Mayer, Werner Ens, Yishi Mao, Xuejun Tang and Kenneth G. Standing
Physics Dept. University of Manitoba, Winnipeg, Canada R3T 2N2

LASER DESORPTION:

Laser induced desorption of small organic molecules has been investigated in a linear time-of-flight spectrometer (Manitoba TOF I [1]). In contrast to previous work employing transient recorders for current measurement [2], we have used single ion detection. This enables measurements at lower laser irradiance (power density 10^3 to 10^6 W/cm²). An excimer laser (Lumonics Hyperex 460 HR) generated 10 ns pulses at 400 Hz and 308 nm. The laser light was focused by a single lens onto the target and spectra of compounds with different linear absorbance were recorded. (Examples are shown in Fig. 1, 2, 4, 5.) As expected, lower threshold irradiances were observed than in the work of Hillenkamp et. al. [2].

Fig. 1

Fig. 3

Fig. 4

Fig. 2

Fig. 1 shows a laser desorption spectrum of GGE at a power density of 4×10^4 W/cm²; the first molecular ions were detected at a power density of 10^3 W/cm². In contrast to SIMS spectra and laser desorption spectra at high irradiance ($>10^7$ W/cm²) [2] neither sodium ions, silver ions from the substrate, nor cationized molecular ions were detected at these low power densities. Also the molecular ion yield is only weakly dependent on the power density as shown in Fig. 4, suggesting a single photon desorption mechanism.

Fig. 3 shows a laser induced matrix assisted desorption of Acetyl-Alanine. Here the frequency doubled output of an excimer laser pumped dye laser (Lumonics Hyperdye-300) was used. Pure Acetyl-Alanine does not show up in a laser desorption spectrum at 266 nm, but when combined with Nicotinic Acid in a mass ratio of 1/20, M^+ and $(M+2H)^+$ ions of Acetyl-Alanine appear. Further experiments on matrix assisted desorption of larger organic molecules are in progress.

Fig. 5 and Fig. 6 compare laser desorption vs. SIMS of the same sample of DNP-Proline.

Fig.5

Fig. 6

LASER DISSOCIATION:

We are investigating photo-dissociation as a tool for obtaining sequence information on biomolecules. For that purpose the laser was focused onto the accelerated secondary ion beam of dinitrophenyl-derivatised peptides produced by a 20 keV Cs^+ ion beam in a reflecting time-of-flight spectrometer (Manitoba TOF II) [3]. Alternate-pulse data-acquisition of events with and without laser dissociation, and subtraction of the separately stored spectra, enables separation of different decay pathways.

Preliminary results show that photon bombardment can produce considerable additional fragmentation. Most of the normal metastable decay pathways are suppressed and the decomposition may follow only one of a few decay channels.

Fig. 7. shows the daughter ion mass spectra of a dinitrophenyl octapeptide, where only the ions around mass 86 u are enhanced by the laser interaction, as seen by comparison with the corresponding SIMS spectrum (Fig.8). In this case no new sequence information is produced. Further photodissociation experiments with different laser parameters are currently in progress.

The advances of Multiphoton Ionization mass spectrometry compared to other methods has been described in literature [1]. The unique features of this method together with a reflectron-time-of-flight instrument include high mass range, ionization leading to radical cations, selective and very efficient ionization by resonant MUPI, the possibility to change the fragmentation from soft to hard by merely adjusting the ionizing photon density and simultaneous collection of all ions. Due to the intrinsic mechanism of the multiphoton activation of a molecule the ionization efficiency is largely dependent on the wavelength used.

A desirable feature for the instrument would be a simple EI-source with sufficient sensitivity to monitor the all neutral molecules produced in the desorption process [2]. Electron impact ionization complements the selective resonant MUPI, in the sense that all compounds are ionized, ionization efficiencies do not vary greatly from one compound to the next. For this reason a good ion source should give the possibility of producing MUPI- as well as EI-mass spectra nearly simultaneous.

Therefore we have investigated the possibilities of producing short electron pulses by shining UV-light from a frequency doubled dye laser to a metal surface. The ion source is shown schematically in figure 1. The modification of the MUPI ion source required for EI-ionization consists merely of a 0.25 mm Ta wire or a small stripe of Cu held in place between the repeller and the first extraction lens of the ion source at an electric potential intermediate to that of the two mentioned plates. The wire crosses both the molecular beam and the laser beam normally used for MUPI, and is perpendicular to both these beams. If photons in the wavelength region between 290 nm and 240 nm hit the wire or the stripe, a swarm of electrons instantaneously leave the surface according to the photo-electric effect. Using a 15 μ J pulse (10^{10} W/cm²) yield in the formation of $1 \cdot 10^7$ electrons from the Ta wire and $2 \cdot 10^8$ from the Cu stripe. These electrons are accelerated to the repeller and ionize incoming sample molecules in the supersonic jet. Molecules closer to the wire at the time of the electron pulse are ionized with less energetic electrons than those nearer to the repeller. However, the point of incidence not only defines the electron energy, but also the initial electric potential of the ion formed in the accelerating field. By adjusting the voltage on the ion reflector to selectively reflect ions of limited kinetic energy (and therefore initial electric potential), narrow peaks can be obtained at the detector. By realigning the laser beam (without focussing) to just miss the Ta wire,

Fig. 1 Experimental setup of the combined multiphoton - electron ionization source. a) UV-laserbeam for MUPI, b) UV beam for EI, c) Ta-wire or Cu stripe.

all ions in the spectra disappeared completely, thereby eliminating the possibility of a contributing photoionization process.

Such experiments were already published by Honig et al. [3]. But in these cases electron beams in the microsecond timescale could only be obtained because the thermionic electron emission dominates when photon energies are involved that lie below the work function of the metal. In our case similar results can be obtained if photons with an energy below 292 nm strike the Ta wire (lower than the work function of Ta (4.25eV) or the Cu stripe (work function Cu (4.84eV)). In this cases the strong signals for the metal ions are observed.

Figure 2 and 3 displays some results from investigations with this EI-source. The mass spectrum in figure 2 shows the accumulation of 100 spectra of propene in He gas, introduced via the pulsed valve. The spectrum is nearly identical to literature EI spectra.

Figure 3 shows the accumulation of 100 EI spectra of caffeine, introduced into the pulsed molecular beam of He via IR-laser desorption from the probe tip indicated in figure 1. The spectrum shows good correlation with literature spectra and displays a molecular ion with enhanced intensity. This very desirable feature - also observed with other compounds - is probably due to the low temperature of the molecules in the supersonic beam rather than the slightly lower electron energies involved in the ionization process.

Multiphoton Ionization Mass Spectrometry :
Steroids and Nucleotides

J. Lindner, J. Grotemeyer*, E.W. Schlag

Institut für Physikalische Chemie, TU München,
Lichtenbergstr. 4 D-8046 Garching, FRG.

In this work we present the investigation of Steroids and Nucleotides using Infra-Red (IR) laser desorption of neutral molecules followed by resonantly enhanced Multiphoton Ionization (MUPI).

The soft and hard MUPI-MS of the following steroids are reported: 16-Epi-estriol, 17-Epi-estriol, 16,17-Epi-estriol, Estriol-16,17-diacetate and Estriol-3-methyl-ester.

For the first time we report MUPI-MS of nucleotides. The molecular ion was detected for DMT-thymidine triester (MW = 788,2) as well as for Bz-DMT-deoxyadenosine triester (MW = 901); Bz = Benzoyl, DMT = Dimethoxytrityl.

The mass spectrometer used is a BRUKER TOF1 and has been described in detail elsewhere [1]. The features of Multiphoton Ionization Mass Spectrometry include separation of desorption and ionization in time and space, selective and very efficient ionization by resonant multiphoton ionization, the possibility to change the fragmentation from soft to hard by merely adjusting the ionizing photon density and simultaneous collection of all ions [2].

Figure 1 shows the soft MUPI-MS of 16,17-Epi-estriol, the ionizing wavelength being 270.0 nm. The hard MUPI-MS of steroids show intensive breakdown pattern, due to the decomposition of the macrocycle. The EI- mass spectra of steroids reveal (M-18)⁺-peaks, which can be assigned as a dehydration reaction [3]. In contrast, no (M-18)⁺ was observed in the MUPI-MS of the investigated steroids.

The second, even more interesting group of organic compounds analyzed with MUPI-MS are the nucleotides. To improve the desorption process, the samples are encased in a polyethylene tablet mixed with finely divided gold powder. This minimizes the fragmentation during the desorption process. The ionization wavelength was 240.0 nm.

Figure 2 shows the partial hard MUPI-MS of Bz-DMT-deoxyadenosine triester (MW= 901,0). Beside the molecular ion an interesting peak at mass 598 Da occurs, which can be assigned as the counter ion of the DMT-ion, (M-303)⁺. In the MUPI-MS of DMT-thymidine triester (MW= 788,2) the molecular ion is clearly observable, whereas further mass peaks can be found in the lower mass region at m/z= 334, 320, 303 and 240. The dominant peak is mass 303 Da, corresponding to the DMT- ion, which is very stable.

The results of the hard MUPI-MS of the steroids demonstrate, that the absorption of three UV-photons leads to the generation of small fragment ions. In order to get larger fragment ions, the third photon has to be lower in energy. We will carry out two color experiments, to test the validity of this thesis.

The nucleotide MUPI-MS indicate, that the matrix assisted laser desorption is a good tool to desorb fragile involatile compounds.

RESONANCE ENHANCED MULTIPHOTON IONIZATION DETECTION OF THE THERMAL
DECOMPOSITION PRODUCTS INDUCED BY LASER DESORPTION OF OLIGOPEPTIDES

Liang Li and David M. Lubman, Department of Chemistry
The University of Michigan, Ann Arbor, MI 48109

In this work, laser desorption is used to volatilize labile peptides into the gas phase as neutral species. The molecules are then entrained into a supersonic jet expansion, transported into a time-of-flight mass spectrometer (TOFMS) and ionized using resonance enhanced multiphoton ionization (REMPI). It is shown that the products detected by REMPI in the TOFMS depend upon the conditions of the desorption process. If a thin layer of material ($\sim 1 \mu\text{m}$) or the material dissolved in a glycerol matrix is used in the desorption process then molecular ions of peptides can be detected by REMPI. When the laser power is raised then fragmentation characteristic of REMPI is observed. However, if a thick layer of material ($> 10 \mu\text{m}$) is used for desorption, a strong M-18 ion peak is observed in the TOFMS. As the laser power is increased, then fragmentation characteristic of the M-18 ion is observed rather than fragments characteristic of REMPI. It is demonstrated that the resulting thermal decomposition product from the laser desorption process in these thick samples is a 2,5-diketopiperazine which is formed by cyclization of the amino acid moieties in position 1 and 2 from the peptide with elimination of water. In addition, it is shown that 2,5-diketopiperazines can be formed in the laser induced thermal decomposition process for peptides and their derivatives whose N-terminal group is not blocked. This is demonstrated for species ranging from di- to pentapeptides as shown in Table I.

As an example, Figure 1(a and c) shows the R2PI/MPI induced mass spectra of the two isomeric dipeptides Tyr-Leu and Leu-Tyr desorbed from thin layer samples by pulsed infrared radiation ($10.6 \mu\text{m}$). These spectra were taken at an ionization laser power of $\sim 5 \times 10^6 \text{ W/cm}^2$ which induced some fragmentation which is useful for structural studies. The molecular ion (m/z 294) is observed as a strong peak in each case and the fragmentation observed is distinctly different for the two isomers, the laser power is decreased, the molecular ion only observed without fragmentation.

Figure 1(b and d) shows the R2PI/MPI induced mass spectra of the same two peptides desorbed from thick samples on the probe surface. The mass spectra obtained are almost identical for the isomeric dipeptides. The molecular ion is visible only as a very minor peak while the $[\text{M}-18]^+$ ion (m/z 276) forms the base peak in the mass spectrum. The ratio between the signal intensities of the M^+ and $[\text{M}-18]^+$ peaks can be varied by changing the position of the infrared beam on the surface. It is assumed that the decomposition is thermally induced as the thick sample absorbs the radiation.

The laser-induced R2PI/MPI mass spectrum of a synthetic sample of cyclo-(Leu-Tyr) is shown in Fig. 2. This spectrum is similar to that observed in Fig. 1(b and d) minus the molecular ion peak. The peak at m/z 86 in Fig. 1(d) is an MPI-induced fragment which originates from the intact molecule. Thus, we conclude that the species formed from thermal decomposition during the laser desorption process is indeed the cyclic dipeptide or 2,5-diketopiperazine.

Figure 1. R2PI/MPI mass spectra of (a) Tyr-Leu and (c) Leu-Tyr obtained using a thin film of sample formed on the desorption surface. R2PI/MPI mass spectra of the thermally decomposed species induced during the desorption of (b) Tyr-Leu and (d) Leu-Tyr. Ionization was produced using $\lambda = 266$ nm at a power density of 5×10^6 W/cm². The desorption laser power density was $\sim 5 \times 10^6$ W/cm².

Figure 2. R2PI/MPI mass spectrum of cyclo-(Leu-Tyr)

FRAGMENTATION OF CATIONIZED BIOMOLECULES IN LASER DESORPTION USING A CO₂ LASER

W. B. Emary, B. Spengler and R. J. Cotter
The Johns Hopkins University, Baltimore, MD 21205

Soft ionization techniques like Laser Desorption (LD), Fast Atom Bombardment (FAB) or Plasma Desorption (PD) have the valuable capability to create parent molecular ions of large organic molecules without significant fragmentation. Nevertheless, fragmentation is an important prerequisite for obtaining structural information about the analyte.

Compared to PD and FAB, LD can be more widely varied between soft and hard ionization. Laser fluence as well as wavelength are important factors controlling energy deposition and thus fragmentation. In addition, the process of cation attachment can strongly influence fragmentation in infrared laser desorption (IR-LD).

In this study the fragmentation behavior of organic molecules cationized by different alkali ions is described for IR-LD. K⁺-attachment leads to soft ionization for a wide variety of different compounds. However, Li⁺-attachment in general leads to an even higher amount of fragmentation and thus structural information. Increased fragmentation has been reported before in collision induced dissociation experiments of lithium attached molecules [1].

Studies on tryptophan support the assumption of gas phase attachment of neutral molecules by alkali ions in IR-LD, and show differences, as well as parallels to UV-LD.

IR-laser desorption mass spectra were obtained using a CVC-2000 time-of-flight mass spectrometer (Wiley-McLaren type), equipped with a pulsed CO₂ laser (10.6 μ m, $t=40$ ns) [2]. The delay between the laser pulse and the drawout pulse is variable (10-80 μ s), allowing the investigation of time dependant processes.

The mechanism of ion and neutral desorption, alkali attachment and fragmentation has been studied on tryptophan. Directly desorbed ions are detected at short delays. Because they have higher initial kinetic energies than desorbed neutrals [4-6] they will have escaped the acceleration region at longer delay times and thus can be distinguished from ions formed in the gas phase from desorbed neutrals. The generation of the desorbed ions is assumed to take place in the condensed phase or even in a high particle density region closely above the surface, where the collision probability is comparable to CI-conditions.

Figure 1
Tryptophan, short delay, no lithium added

Figure 2
Tryptophan, long delay, lithium added

The IR-LD mass spectrum of tryptophan at short delay times shown in Figure 1 is very similar to the UV-LD mass spectrum [7], where generation of ions is assumed to take place in the condensed phase. Only the alkali attached parent molecules are not observed for tryptophan in UV-LD. They are observed both at short and long delays in IR-LD and are assumed to be generated by gas phase attachment of desorbed neutral molecules. At long delay times only the potassium attached molecule and the K^+ -ion are observed for tryptophan. The desorbed ions ($M+H^+$, F^+) have already moved out of the acceleration region.

Addition of Lithium (Figure 2) leads to increased fragmentation. Besides alkali free fragment ions ($M=130, 159$), lithium attached ($M=137, 166$) and lithium-hydrogen exchanged fragments ($M=194$) are observed.

Figure 3
Stachyose, no lithium added

Figure 4
Stachyose, lithium added

Desorption of neutral fragments is not observed for tryptophan, indicated by the lack of potassium attached fragments. This is an important difference from UV-LD [6]. The data gives an explanation for the large amount of fragments, observed by UV positionization of UV-laser desorbed molecules [7], compared to UV-positionization of IR-laser desorbed molecules [8]. Another difference to UV-LD is that, in general, no alkali attached fragments are observed in UV-LD. This supports the idea, that alkali attachment is a gas phase process in IR-LD, whereas it is a condensed phase process in UV-LD [9].

Applications of admixing of lithium salts to substances of analytical interest show increases in structural information. Figure 3 shows the IR-LD mass spectrum of stachyose. IR-LD of stachyose after addition of half the molar amount of lithium bromide is shown in Figure 4. Fragmentations are characteristic two bond ring and glycosidic cleavages. Increase in fragmentation and thus structural information has been observed as well for peptides, like His-Ser-Gln-Gly-Thr-Phe and Leu-Trp-Met-Arg-Phe-Ala.

ISOTOPE ANALYSIS IN INVOLATILE SAMPLE BY LASER DESORPTION ELECTRON IMPACT (LD/EI)

Zhi-min Yuan, Catherine Fenselau, W.B. Martin and R.J. Cotter, University of Maryland
Baltimore County, John Hopkins University, Baltimore, MD 21228

Progress in desorption techniques has permitted the extension of mass spectrometry to analysis of involatile and thermally labile molecules such as glutathione conjugates. Most of these techniques produce even electron molecular ions, whose unimolecular fragmentation proceeds by closed shell processes and elimination of neutral molecules. Homologous cleavage of carbon-carbon bonds is not observed. The enzyme mechanism study reported here hinges on the analysis of deuterium labels on adjacent methylene groups in an involatile glutathione conjugate of cyclophosphamide. The bond between these methylene groups in unconjugated cyclophosphamide readily cleaved under electron impact. We have undertaken to combine laser desorption of neutral molecules and ionization by electron impact into an analytical technique that will accommodate the involatility of the sample and produce the carbon-carbon bond cleavage required for the isotope analysis.

Toward the objective of understanding the role of glutathione in the cross resistance which some patients develop to alkylating antitumor agents. We have demonstrated that the conjugation with melphalan, chlorambucil and, in the present work, cyclophosphamide is catalyzed by glutathione transferases. In aqueous solution nitrogen mustards exist in equilibrium as amines and cyclic aziridinium ions. It was of interest to determine which (or both) of these forms is the substrate for glutathione transferase(s). To do this we took advantage of the fact that the alpha and beta methylene groups lose their positional identities in the symmetric aziridinium intermediate. Consequently, deuterium labels at one position in cyclophosphamide can end up either methylene group in the conjugated product. As a class, glutathione conjugates are involatile and thermally labile, and they have not been successfully analyzed by electron impact, even derivatised. The monoglutathione conjugate derived from cyclophosphamide was no exception. However, the combined LD/EI technique was successfully applied to this analysis to bring neutral sample molecules into the gas phase, where ion radicals were produced by electron impact. Cleavage of the carbon-carbon bond alpha to the mustard nitrogen indicated that no scrambling had taken place in either the enzymatic reaction or chemical reaction, i.e. the chloride ion of cyclophosphamide is directly displaced by glutathione during the conjugation reaction.

Experimental

LD and LD/EI mass spectra were obtained on a modified CVC Products (Rochester, NY) Model 2000 time-of-flight mass spectrometer. A Tchisto (Needham, MA) model 215G pulsed carbon dioxide laser provides 40 nS pulses with energies up to 700 mJ at a wavelength of 10.6 micrometers. The laser beam is focussed by a 19 inch focal length

ZnSe lens, passes through a ZnSe window in the vacuum housing and enters the pulsed electron impact source. LD mass spectra were obtained by turning the electron filament current off and the time lag focus to zero. Samples were applied to the probe tip in solution of KCl. The time delay between the laser pulse and the mass spectrometer trigger pulse was adjusted to produce well resolved M+K molecular ions. For the LD/EI mass spectra, the laser spectra, the laser power was reduced just below the onset of K⁺ ion emission and formation of M+K ions. This insured that only neutral species were desorbed. The electron filament current was then turned on, and the time lag focus was adjusted to produce the best energy focussing. Glutathione conjugates of cyclophosphamide were purified by RP-HPLC.

The figure below presents the LD and LD/EI mass spectra of deuterium-labeled monogluthathione conjugate of cyclophosphamide. The fragmentation shown locates the deuterium labels in the original carbon.

AN EFFECTIVE METHOD FOR ASSISTING LASER DESORPTION OF NON-VOLATILE COMPOUNDS

Shankai Zhao, A. G. Sharkey, Jr., D. M. Hercules
Department of Chemistry, University of Pittsburgh, PA 15260

INTRODUCTION

Laser Desorption Mass Spectrometry has found increasing applications for organic compounds. Matrices for assisting laser desorption of non-volatile compounds have been successfully used by several researchers. A simple method introduced here is using common solvents (water, methanol, toluene,...) as liquid matrices to assist laser desorption of non-volatile compounds.

EXPERIMENTAL

The instrument used is a LAMMA-1000 Laser Microprobe Mass Spectrometer.

1 μ l of sample solution is placed onto a thin Formvar film [Poly(vinylformaldehyde)]. The film is pulled together into a ball that keeps the sample solution sealed under vacuum in the ion source region. The ball is then introduced into the ion source chamber by the aid of a double sided sticky tape attached to a metal substrate.

Another method is to use nitrocellulose membranes or soft, fine fibrous paper as sample substrate. It is easier to handle and gives more reproducible results.

RESULTS

Spectra of different kinds of compounds such as Vitamin B12, Chlorophyll a, Erythromycin, Stachyose, Bradykinin, Gramicidin S and Angiotensin have been obtained. The molecular ions or the pseudo molecular ions are greatly enhanced. Spectra shown in Fig. 1 and 2 demonstrate the ability of this method to keep common solvents under vacuum. The spectrum of toluene was taken after it was introduced into the ion source for 20 minutes. For comparison, a standard EI spectrum of Toluene is shown on the right top corner. the spectrum of glycerol with lithium carbonate is shown in Fig. 3, which cannot be obtained in the normal way by LAMMA-1000, and is similar to Cooks' (1) results. No cluster ions of glycerol appear in the spectrum. Spectra shown in Fig. 4, 5 and 6 are the results of different kinds of samples. The $(M+H)^+$ ions of Vitamin B12 shown in Fig. 4 demonstrate the "soft ionization" character of this method. It has not been observed by the use of nicotinic acid as matrix in the LAMMA-1000.

The method provides the possibility of the application of solution chemistry in LD-MS. An example of the charge-transfer derivatization is shown in Fig. 7 and 8.

According to the reaction:

Pauw (2) found that the FAB spectra match quite well with the solution chemistry by using N,N,N',N'-tetramethyl-1,4-benzenediamine (TMPD) as a donor and Benzoquinone (BQN) as an Acceptor. The spectrum of TMPD + BQN shows a prominent peak at M^+ (m/z 164), $\text{TMPD} + \text{NH}_4\text{Cl}$ at $(M+H)^+$ (m/z 165), and the neat TMPD at $(M-H)^+$ (m/z 163). Busch (3) found that the effect of using charge-transfer agents for derivatization will be more pronounced with the solid complex in the case of using glycerol as matrix.

Fig. 7 and 8 demonstrated that by using the method of keeping the sample solution in vacuum, the spectra of laser desorption match quite well the solution chemistry.

CONCLUSION

Using common solvents as liquid matrices has several advantages compare with other liquid matrices used in desorption techniques: Both polar and non-polar compounds are soluble; have very low viscosity; are chemically inert; no spectral background interference and have high dielectric constants.

The contributions of using common solvents as liquid matrices by this method for laser desorption are as follow:

- 1). Liquids are better adapted for promotion of ion formation.
- 2). The solution phase lowers the energy required to desorb ions by solvation and separation.
- 3). Desolvation in the gas-phase can carry away the excess internal energy of the molecular ions.
- 4). Explosive events happened during high power density laser radiation in the solution assisting desorption and clusters formation.

Moreover, it provides the possibility of application of solution chemistry in laser desorption mass spectrometry and the possibility of applying varieties of matrix used in other desorption techniques in LD-MS. Some of these applications are being investigated by the authors.

CHARACTERIZATION OF A GLOW DISCHARGE PLASMA AS A FUNCTION OF SAMPLING ORIFICE POTENTIAL

William S. Taylor, John G. Dulak, and Suhas N. Ketkar

Extrel Corporation, 240 Alpha Drive, Pittsburgh, Pa. 15238

INTRODUCTION

Glow discharges can provide stable ion sources for use with mass spectrometry. Much of the recent research regarding glow discharge mass spectrometry (GDMS) has focused on the development of glow discharge quadrupole mass spectrometry (GD-QMS) (1,2). In order to obtain optimum sensitivity in these devices, analyte ion signals must be maximized. It has been observed that placing a small positive bias on the sampling orifice plate (which is immersed in the plasma) results in a signal enhancement. For the purposes of optimizing instrument performance, the objective of this study is to characterize plasma parameters such as electron temperature, plasma potential, and charged particle densities as a function of the sampling orifice bias. This is carried out with the use of Langmuir probes. Details of the mathematical manipulations used here have been outlined elsewhere (3).

EXPERIMENTAL

Data were obtained with the use of an EXTREL EXT 1000 glow discharge mass spectrometer which is equipped with a sampling orifice plate to which a potential can be applied. The discharge was operated at 1 kV and 3 mA with an argon pressure of 700 mtorr. The cathode was 303 stainless steel. The Langmuir probe was a piece of tungsten wire 0.24 cm in length and 0.127 mm in diameter, which was positioned 4 mm from the cathode. The voltage on this probe was varied from -24 to +24 V during which time the collected current was measured. In this way, the I-V characteristic curves were generated from which all other plasma parameters were derived.

RESULTS AND DISCUSSION

A plot of plasma potential as a function of orifice bias is presented in Figure 1. This data illustrate that the plasma potential can be correlated directly to orifice bias for orifice voltages greater than 0V. When the bias on the sampling orifice is at or below 0V this relationship breaks down. In addition, the translational energy of the analyte ions with respect to the mass spectrometer is also directly related to the voltage placed on the sampling orifice.

The effect of sampling orifice bias on electron temperature is given in Figure 2. Here we observe that this parameter also correlates positively with the voltage

applied to the sampling orifice, but to a lesser extent than the plasma potential. The increase in electron temperature over the range of orifice potentials examined here is approximately 0.2 eV. In addition, our results indicate that there is no significant dependence of charged particle density on orifice bias.

CONCLUSION

The fact that plasma potential and ion energy both correlate with positive orifice bias indicates that ion energy is defined by the plasma potential, which is itself defined by the voltage placed on the sampling orifice. Furthermore, the weak dependence of electron temperature on orifice potential suggests that no significant increase in ionization is occurring in the plasma by either Penning ionization by Ar metastables or electron impact. This assertion would appear to be borne out by the relative insensitivity of the charged particle density to orifice bias. Therefore, we can conclude that mass spectrometric signal enhancements resulting from positive orifice voltages are due to improvements in ion transport to the mass spectrometer rather than being the result of increased ionization.

Phrasor Scientific, Duarte, CA 91010

Electrohydrodynamic (EH) emission is an unusually mild ionization method which rarely if ever results in fragmentation of the sample molecule. Ions are extracted directly from solution by a high electric field. In our previous work, we have characterized the output from an EH source and found, in addition to sample and solvent ions, solvent cluster ions with mass to charge ratios extending beyond the range of our mass spectrometer (11,500). As a consequence of this "droplet emission, most of the sample is trapped in large solvent clusters and is not observed. Thus, the required sample amounts for EH spectra of peptides are unacceptably high for most applications. This work describes a modification of our EH source intended to circumvent some of these problems.

The output from the EH nozzle (Figure 1) is focussed with a series of lens elements into a gas filled collision cell. Ions are extracted from the other end of the collision cell and focussed onto the first slit of our JEOL HX100HF double focussing mass spectrometer. Length of the collision cell was 2.5 cm. Argon was used as the collision gas in most instances although some experiments were done with isobutane. Sample solution is transported to the EH nozzle by a 30 cm X 25 um ID fused silica capillary from sample tubes at atmospheric pressure. All samples were dissolved in 1.5 M ammonium acetate in water : methanol (60:40) at a concentration of 1 ug/ul. Spectra were acquired using a JEOL DA5000 data system.

The effectiveness of the collision cell for desolvating sample ions residing in charged solvent droplets was first evaluated by measuring the total ion transmission through the cell with a Faraday cup. Initially, the transmitted current sharply decreases with small changes in pressure. The current then reaches an inflection followed by a region of gradual decrease with increasing pressure. The shape of the curve suggests that the beam incident on the collision cell consists of two distinct components. The sharp decrease was attributed to the scattering of small ions. The gradual decrease following the inflection was attributed to charge loss from more massive droplets which undergo partial or complete desolvation. The shape of the curve has been successfully modeled by empirically fitting values for the scattering cross sections for the molecular ions and the large solvent droplets.

Spectral data appear consistent with the scattering model. When spectra were taken of a pentapeptide with no collision gas (Figure 4), a spectrum was obtained similar to those obtained with previous source designs. The ion and droplet components are clearly evident. As gas is introduced into the cell, the ion component

of the spectrum quickly disappears and the apparent distribution of the droplets is shifted to higher m/z values. Further increases in the pressure nearly eliminate the droplet component from the spectrum. The ion spectrum reappears, but only if the potential of the collision cell is carefully matched to the electric sector voltage.

With the new source, some of the objectives have been achieved. It is now possible to obtain molecular ions for peptides less than 1000 MW on a routine basis using much less sample than was previously necessary. In some instances, sample concentrations as low as 0.1 $\mu\text{g}/\mu\text{l}$ are sufficient. With increasing molecular weight, molecular ion signals decrease dramatically, and little success has been achieved beyond mass 1000. For the larger structures, adducts of sample with components of the solvent indicate full desolvation has not been achieved. Interestingly enough, although the instrument slits have been set for a resolution of 500, ions at higher mass are fully resolved, an indication that ions extracted from the collision cell are well focussed and have a uniform energy.

One apparent problem is the inability of the collision cell to stop all of the droplets. This problem may be solved by operating the EH nozzle at a lower potential. It remains to be seen whether full desolvation of large sample ions can be achieved under conditions compatible with our mass spectrometer.

Physicists have extensively studied the interactions of positrons with matter since the initial prediction of positrons by Dirac and their discovery by Anderson in the early 1930's. These studies have taken several forms: measurements of scattering cross-sections, lifetime spectroscopy, and angular or energy analysis of the annihilation gamma radiation. The ways in which positrons interact with molecular gases have been elucidated and will be discussed elsewhere (1) in this meeting. Briefly, positrons can ionize molecules by impact at high energy, by positronium formation at energies up to 6.8 eV below the ionization energy of the molecule, and by non-resonant (pick-off) or resonant (attachment) annihilation at energies below 1 eV.

The goal of our research is to study all of the above processes in order to understand the energetics and physics involved by interacting positrons of a selected energy with target molecules and measuring the mass spectra of the ions with a time-of-flight mass spectrometer.

Our source of positrons is a new facility attached to the Oak Ridge Electron Linear Accelerator (ORELA) which is described in (2) and shown schematically in Figure 1.

Figure 1. Overhead view of the ORELA positron source. T is the electron target, M is the positron moderator, B are bending solenoids, MS is the time-of-flight mass spectrometer, and D is a NaI(Tl) gamma-ray detector.

The ORELA is an induction-type accelerator which produces nanosecond pulses of 150 MeV electrons at an average power of 10 to 50 kW. The positrons are produced by the forward-scattered gamma bremsstrahlung striking a set of tungsten plates mounted directly behind the ORELA tantalum target. The tungsten moderator and pulsed extraction tube produce pulses of 3000 eV

positrons having pulse widths of 10 to 20 nsec at a repetition rate of up to 800 Hz. The number of positrons produced is 3×10^7 per second at 10 kW of ORELA power. These high-energy positrons can be used directly for positron impact ionization (yielding the spectra below) or they can be moderated with a thin tungsten film to produce low-energy (<3 eV) positrons with an efficiency approaching 40%. The pulses of positrons are directed into the ion source of a time-of-flight mass spectrometer where the ions produced are accelerated, mass-analyzed, and detected by a channelplate detector. The analyte species is introduced as a gas at pressures of 1×10^{-6} to 1×10^{-5} Torr. Figure 2, below compares the spectra obtained for isobutane and benzene under conditions of (a) 70 eV electron impact, (b) 2700 eV electron impact, and (c) 3000 eV positron impact. The spectra are quite similar, confirming the expectation that positrons and electrons act similarly at these energies. Current work is focussed on extending the energy range of the positrons down to below 1 eV where positron attachment can occur. Initial spectra from these studies are tantalizingly different.

Figure 2. Mass spectra of isobutane and benzene under conditions of (a) 70 eV electron impact, (b) 2700 eV electron impact, and (c) 3000 eV positron impact.

**ELECTROSPRAY IONIZATION-MASS SPECTROMETRY
AND TANDEM MASS SPECTROMETRY**

Joseph A. Loo, Charles J. Barinaga, Charles G. Edmonds,
Harold R. Udseth, and Richard D. Smith
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory*
Richland, WA 99352

Electrospray ionization coupled with mass spectrometry (ESI-MS) has its roots 20 years ago with the pioneering experiments by Malcolm Dole(1) and has been recently rejuvenated by the work from the laboratory of John Fenn, who first published elegant results of electrospray ionization mass spectra of large molecules with molecular weights up to 40 kilodaltons and demonstrated the unusual propensity for multiple charging produced by this soft ionization technique(2). The ability to produce multiply charged molecular ions for biomolecules allows mass spectrometers to analyze compounds with molecular weights (MW) much in excess of the instrument's mass (m) limit, but within the mass-to-charge (m/z) range of most conventional mass spectrometers. In fact, proteins with molecular weights in excess of 130,000 daltons have been successfully analyzed by ESI-MS with a quadrupole mass spectrometer of limited m/z range (1700) in our laboratory.

The mechanism for desorption of multiply charged molecular ions from highly charged liquid droplets is presently unclear. However, an ion evaporation model in which Coulombic explosion of rapidly evaporating liquid droplets of high charge density results in smaller sized charged droplets and continues this sequence until solute field-assisted desorption occurs is generally accepted. For peptide and proteins, we had previously observed(3) a crude correlation between the maximum positive (multiply protonated) charge state observed in our electrospray ionization mass spectra with the total number of basic amino acid residues (i.e., arginine, lysine, and histidine) in the primary sequence and to some extent, the N-terminal amino group. For example, glucagon (MW 3483) possesses 2 arginines, 1 lysine, 1 histidine, and the N-terminal amino group; its ESI mass spectra shows the $(M + 5H)^{5+}$ as the highest multiply charged species. However, the correlation for hen egg white lysozyme, and protein with 18 basic amino acids, is poor; the $(M + 14H)^{14+}$ is the highest charge state molecular ion observed. Little information is known regarding the effect of tertiary structure (either solution phase or gas phase) on the multiple charging phenomenon of electrospray ionization.

We have compared the ESI mass spectra of large proteins with and without reduction of its disulfide bridges. By cleavage of cysteine-cysteine bonds and thereby affecting the tertiary structure of the protein, a dramatic increase in the number of positive charges is observed. An ESI mass spectrum of egg white lysozyme shows the $(M + 20H)^{20+}$ as the highest charged species with the addition of 1,4-dithiothreitol (DTT). Disulfide-cleavage reactions may allow the protein to relax into more extended conformations, allowing "buried" basic amino sites to be more fully protonated. Over 175 positive charges are resolved in the mass spectrum for the albumin dimer molecule with the addition of DTT, an increase of over 50 charges relative to the unreduced form.

Highly charged ions desorbed from the droplets are sampled through a nozzle-skimmer orifice to be detected by the quadrupole mass spectrometer. The typical applied nozzle voltage for positive ion analysis is +200V with the skimmer at ground potential. Solvent clustering with the analyte is substantially reduced by collisions within this region. Increasing collision energies also yields significant fragmentation of large peptide and proteins. Singly and multiply charged sequence ions can be detected. Collisionally activated dissociation of selected multiply charged molecular ions for large peptides with MW > 3000 Da can easily be performed with a triple quadrupole MS to obtain structural information, with singly and multiply charged b and y type sequence ions generally dominating the spectra.

We thank the U.S. Department of Energy, Office of Health and Environment Research, for support of this research under Contract DE-AC06-76RLO 1830.

Chalk River, Ontario, Canada, K0J 1J0

In previous work we have shown that time-of-flight mass spectrometry (TOFMS) with multichannel gated pulse counting detection is well suited for quantification of the fast pulse ion signals generated by pulsed tunable dye lasers tuned to atomic resonant transitions. The precision and dynamic range of isotope ratio measurement was limited by the count rate of the ions which in turn was limited by the pulse repetition rate of the pump laser. We report here the application of a high repetition rate (5 to 7 kHz) copper vapour laser (CVL) and associated dye lasers to the measurement of 234/238 and 235/238 ratios in natural uranium.

An Oxford Lasers 40 W CVL was used to pump two kit dye lasers that had been adapted for high flowrate. Littman type oscillator cells were used with optional prism beam expanders; the dye laser bandwidths were 0.1 cm⁻¹ with the expanders, and 1.2 cm⁻¹ without. The pulse energy varied between 10 and 100 μJ. The TOFMS featured a two-stage acceleration region with static electrode potentials, a 5 m drift tube, and a microchannel plate detector. A mass resolution of 1400 could be obtained with this TOFMS, but a resolution of 600 was typically used for uranium isotopes. The gated pulse counter was configured for six signals: 234, 235, 238 and three background signals. Background counts were subtracted from isotope counts after each counting period.

Well defined two colour resonance signals were observed for the 570 to 630 nm spectral region. For isotope ratio measurements, the prism beam expanders were removed and the scheme outlined below initially was used for resonance ionization.

Ion counts were accumulated at a rate 0.25 ²³⁸U ions/pulse until 1x10⁶ ²³⁸U counts were obtained (≈ 12 min) and the resultant isotope ratios are listed in Table 1, in which each ratio is an average of six consecutive measurements. The overall average 234/238 ratio is in exact agreement with the known value, and the precision is close to that expected (6% rsd) from Poisson statistics.

The results for 235/238 ratio showed that the observed uncertainty, 4%, was 8 times larger than that expected, 0.5%. This was attributed to steep dependencies of the isotope ratio on wavelength observed during the experiments (Figure 1), and to slight instabilities in the wavelength caused by mechanical vibrations and thermal drift. Steep dependence of the ratio on wavelength was observed over a narrow range, e.g. 0.02 nm, despite a laser bandwidth of 0.04 nm. Various excitation schemes were used, including one colour schemes and those with very small isotope shifts in the first step, but for none was the wavelength sensitivity low enough for precise 235/238 measurement. This problem was partly attributed to the unavoidable large isotope shifts, e.g. 0.4 cm⁻¹, in the second step. Possibly, the wavelength sensitivity could have been suppressed by use of sufficient dye laser pulse energy to oversaturate the transitions. Saturation of the second transition, in this case to a virtual state, was attempted by use of 50% of the CVL energy for ionization, but the wavelength sensitivity remained too high.

The 235/238 ratio was also dependent on orientation of the linearly polarized dye laser beams with respect to each other, for two-colour resonance excitation schemes. For example, a 12% enhancement of the 235/238 ratio was reproducibly observed for parallel vs perpendicular orientation, for the following scheme:

This result was consistent with the suppression of the ^{238}U photoexcitation rate predicted from polarization induced anisotropic distributions of the magnetic sublevels of the atomic states involved in the transitions.

DIODE LASER APPLICATION TO
RESONANCE IONIZATION MASS SPECTROMETRY

D. H. Smith, J. P. Young, and R. W. Shaw
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-8121

We have demonstrated the use of semiconductor diode lasers to stimulate the first step in a resonant ionization process for lanthanum. These lasers are attractive for several reasons: They are inexpensive (\$75 for the laser and about \$5000 for the stabilized power supplies and temperature controller); they can be scanned by manipulating the temperature (coarse) and current (fine); they are rugged and reliable. The principal questions to be answered in the experiment were whether or not such lasers had sufficient power to produce appreciable numbers of ions and, if so, whether they would be stable enough for laboratory use. The answer to both these questions is yes.

Diode lasers are available with several central wavelengths about which they can be scanned over a limited range. One of these wavelengths is 750 nm, and we tuned the laser in question to 753.9 nm to stimulate the electronic transition in lanthanum from the ground state to the metastable state at 13260 cm^{-1} . Ionization required resonant absorption of a second photon to a higher state and subsequent absorption of a third photon to the continuum; these two photons were provided by a copper-vapor laser pumped dye laser.

Good signals were obtained, as shown in the figure. The bottom trace was taken with the laser detuned from 753.9 nm; the upper trace was taken with the laser tuned to that wavelength. The large peak centered at about 584.9 nm was due to the action of the diode laser. We thus demonstrated the suitability of diode lasers to applications such as these; we are presently assembling two more diode lasers so we can use them for all resonant steps leading to ionization.

Using two of these lasers makes it possible to estimate the relative populations of various electronic energy levels in the atomic sample. This is of interest because resonance ionization can access only one level per laser; any atoms not in that state are lost to the experiment, reducing the efficiency of sample utilization. We estimated the ratio of the population of the ground state of lanthanum to that of the level at 1053 cm^{-1} . We obtained values (68 at 1350 deg. C and 38 at 1500 deg. C) that are higher than those predicted when one assumes a Boltzmann distribution. We ascribe this anomaly to optical pumping.

The optical spectra obtained with our apparatus had much higher resolution than we had anticipated. It was good enough to allow resolution of the hyperfine splitting of ^{139}La and to measure the constants associated with it. We believe this to be due to the selection of a velocity subset of the ions by the mass spectrometer's ion source, thus reducing the effects of Doppler broadening on the spectra.

It is possible to envision a mass spectrometer consisting entirely of a battery of lasers, a vacuum system, and a detector, with no conventional mass separating device. The low cost and high reliability of diode lasers make this a feasible concept. In the near term, it seems certain that application of these lasers to analytical problems will expand rapidly.

MEASUREMENT OF MAGNESIUM ISOTOPIIC RATIOS IN THE STUDY OF BI-DIRECTIONAL
CELLULAR MAGNESIUM FLUXES

Baltimore, MD. 21201

Magnesium ions play a significant role in regulation of key cellular physiological and biochemical processes. Most research on magnesium fluxes has been done using radioactive ²⁸Mg, a short-lived isotope available irregularly from one supplier in the country, and can yield only unidirectional fluxes. Our work used the stable isotope ²⁶Mg (99.5% enriched, Oak Ridge National Laboratory, Oak Ridge, TN.) as a tracer for the measurement of bi-directional fluxes in the giant muscle fibers of the acorn barnacle. Bi-directional fluxes are obtained with a single isotope using dilution of the tracer by the natural isotopic distribution of Mg. This particular cellular model was chosen because of the ease of obtaining samples and because previous data on Mg fluxes exist in it.

Muscle fibers taken from a single animal were attached to a teflon slide and immersed into a specially made lucite chamber containing a medium free of Na and Ca (to prevent spontaneous contraction) consisting of TRIS, 10mM K and 1 of 3 ²⁶Mg enriched concentrations: 5mM, 25mM, 60mM (pH=7.6). Aliquots of medium were removed at time points 0, 15, 30, and 60 minutes and were analyzed directly using thermal ionization mass spectrometry and the silica gel technique (1). Mg masses 24, 25, and 26 were sequentially scanned for 8 seconds each (1 scan of data). A mean and relative standard deviation was calculated at the end of 10 scans (1 block of data). A mean of at least 2 blocks was collected for each sample.

Natural abundance accuracy and precision are reported in Table 1. Ratios were corrected for fractionation using the method described by Miller, et.al.(2,3). This method relates observed fractional intensities of individual masses with the deviation from expected fractional intensities. A mean slope and intercept were calculated from natural abundance magnesium measurements:

$$y = -0.069x + 1.666$$

where x = mass

y = the deviation from expected fractional intensity

i.e., $y = \frac{\text{observed fractional intensity} - \text{expected fractional intensity}}{\text{expected fractional intensity}}$

Table 2 reports the results of experiments at the 3 concentrations of highly enriched Mg. Absolute amounts of ²⁶Mg and ²⁴Mg are calculated from the isotope ratios at each time point. The initial ²⁶Mg level in the medium decreases due to both flow into the cell and efflux of natural abundance Mg from the cell. The relative standard deviation (RSD) for the determinations are somewhat higher than is expected for TIMS on our Finnigan THQ quadrupole mass spectrometer. We presume this to be due to the silica gel and not the unprocessed sample since natural abundance magnesium standards showed similar RSD. Results of the muscle fiber flux determinations are reported elsewhere (4).

THE IMPORTANCE OF ABUNDANCE SENSITIVITY IN THE MEASUREMENT OF LARGE ISOTOPE RATIOS

J E Cantle, Z A Palancz, P M Read, P M Charalambous, VG Instruments, Winsford, Cheshire. UK

The maximum isotope ratio that can be measured by any mass spectrometer is ultimately limited by its abundance sensitivity. As the ions travel through the Spectrometer, their kinetic energy and direction can be changed as a result of collisions with residual gas molecules. This alters the position at which they arrive at the focal plane with respect to unscattered ions and is observed as an increase in the background level extending over several mass units from the peak centre and proportional to its intensity. Small peaks in the vicinity of a larger one can only be measured if they exceed this background level.

Abundance sensitivity depends upon the pressures inside the instrument. The pressure in the analyser section is critical because this forms the largest part of each ion's trajectory. The source pressure also influences abundance sensitivity when collisions in this region become important and gas diffuses into the analyser vacuum.

The abundance sensitivity of the ISOLAB instrument is minimised by use of ultra-high vacuum (UHV) techniques and is improved by the presence of electrostatic analysers (ESA) which filter out the scattered ions.

In the reverse geometry instrument, many unwanted ions are removed by the magnet and only those ions that collide after the ESA remain unfiltered. In the forward geometry instrument all of the ions are transmitted by the ESA and filtering of scattered ions is only carried out before the intermediate slit. The number of collisions after this will be fewer than in the single sector magnet instrument because the pressure will be held lower by the differential pumping regimes around both the source and the intermediate housing slits. Therefore the abundance sensitivity of the two sector ISOLAB 54 is expected to be inbetween the performance of the single sector and reverse geometry instruments at a level of 5×10^{-9} at (unit mass separation from U238).

The three sector ISOLAB 54 can be considered to be equivalent to an electrostatic analyser followed by a reverse geometry spectrometer with an effective source pressure of 1×10^{-9} mbar. The expectation that the abundance sensitivity of this enhanced configuration will be below 5×10^{-8} has been proven to be true.

For the ISOLAB 120, sophisticated UHV design enables source vacuum levels of 10^{-8} mbar to be maintained during measurements and an operating analyser pressure of below 10^{-9} mbar. The effect of the larger 96 cm radius electrostatic analyser and the larger 60 cm radius magnet has resulted in further enhancements because its dispersion length will increase the distance between peaks and reduce the background contributions from the tails of neighboring masses. It has been found that the abundance sensitivity of the two stage ISOLAB 120 is better than 1×10^{-7} and that of the three stage configuration is better than 5×10^{-9} , again demonstrating the advantages of the use of a large analyser. At low masses abundance sensitivity is further enhanced (see figure 1) due to the larger physical separation of adjacent masses.

THE EFFECT OF ULTRA-HIGH VACUUM ON
THERMAL IONIZATION PROCESSES

J.R. Tackett, R.E. Ellefson and C.J. Wiedenheft
EG&G Mound Applied Technologies*
Miamisburg, OH 45343-0987

We have observed an unusual delay in Pu and U ion production during a normal heating pattern when our triple-filament thermal-ionization source operates at a pressure less than 3×10^{-8} Torr. At lower pressures ($< 10^{-8}$ Torr) Pu⁺ ion current increases rapidly after the delay growing to 5 to 10 times the normal intensity as indicated in Fig. 1. Figures 1 and 2 show the general features of these phenomena for Pu⁺ and U⁺ ion production, respectively, for different ion source pressures. In Fig. 3, we show that normal Pu⁺ production can be produced by the introduction of a stable flow of O₂ from a dry air leak. Once the leak is turned off and the source pressure drops to about 10^{-8} Torr, the rapid increase in Pu⁺ ion current spontaneously occurs while the heating currents to the sample filament or the ionizing filament remain constant. This enhanced ionization of Pu is nearly independent (short term) of the sample filament current implying that the enhanced ionization phenomena for Pu occurs at the ionizing filament. The enhanced Pu ion current also decreases spontaneously as indicated in Fig. 3 at about 135 min. When the sample filament is turned off, the Pu⁺ signal drops rapidly but a residual 5 mV signal is seen from Pu deposited on the filament during the operation at 10^{-8} Torr source pressure. The equivalent residual signal for U is 0.7 mV. Residual Pu (2 ng) has been measured by alpha particle counting of an ionizing filament exhibiting the enhanced ionization. Additionally, at the lower pressures ($< 10^{-8}$ Torr) the Re ionization filament at 2080 °C exhibits a steady growth in Re⁺ ion output to a factor of two in one hour in the constant current mode of operation.

The data for this effect was obtained on a NBS-type 12"-90° sector mass spectrometer equipped with a 330 L/sec turbomolecular pump with a LN₂ trap for the source and a glass LN₂ cold finger directly above the ion source. The analyzer is ion pumped. When changing samples, the source is vented with dry N₂ (trapped with LN₂) to prevent accumulation of water vapor in the source. Additionally, the filament pins are vacuum baked as a final step in their cleanup process. This pumping system and the efforts to restrict water vapor from the source region reduced the source ion base pressure from 2×10^{-7} to 3×10^{-8} Torr after 8 months of the practice and the pressure during sample analysis was reduced to about 1×10^{-8} Torr. Pumpdown time was dramatically reduced reaching 5×10^{-8} Torr in 20 min of pumping after a sample change. As we approached these low pressures, we began to experience the delay effect and the finally the enhanced ionization phenomena. The improvement in vacuum basically reduce water vapor and other sources of oxygen; this fact was identified as the common cause of the loss of control of the ionization process. To restore normal operation, we first introduced an air leak by carefully loosening a bolt on the source flange to raise the pressure to about 10^{-7} Torr. This restored control but repeated use of this technique again accumulated water vapor and slowed pumpdown. The solution to this was the introduction of dry air through a variable leak valve to produce 8×10^{-8} Torr (1.6×10^{-8} Torr O₂ partial pressure) in the ion source. This produces normal operation.

* Work Performed under US-DOE Contract No. DE-AC04-88-DP43495.

There are two mechanisms involved in these phenomena. The first relates to the importance of oxygen in the thermal ionization process. Although Re probably does not form a stable oxide at the operating temperature, oxygen incident and partially adsorbed on the Re surface (in the form of H_2O , CO , O_2) together with the metal atoms incident appears necessary as a reagent for normal thermal ionization to occur. Many of the ionization enhancers reported in the literature (boric acid, silica gel) bring oxygen to the metal at the hot filament; in our case, the oxygen is presented as a reagent gas from the source region atmosphere. As the source pressure decreases, the delay time period lengthens but the product of the estimated oxygen partial pressure times the delay time gives a constant dose of oxygen equal to 5×10^{-7} Torr-min. The second mechanism of enhanced ionization in the absence of much oxygen could be the deposition of Pu on the bare Re ionizing filament surface to an extent that Pu collects in grain boundaries or as islands of Pu which surface ionize much like Re itself. The rapid growth could relate to the increased percent agglomeration as more Pu collects. The normal operating pressure of most commercial thermal ionization mass spectrometers is in the range of 5 to 20×10^{-8} Torr for which there is adequate oxygen for producing a stable ion beam.

Introduction

Gas chromatography/mass spectrometry (GC/MS) using a general purpose mass spectrometer is a viable alternative available to the biomedical community for the determination of trace metals in biological samples. GC/MS offers the advantages of shorter analysis time and less specialized instrumentation compared to other mass spectrometric techniques (TIMS, ICP/MS) which are exclusively dedicated to metals determination. GC/MS methods involve the formation of volatile and thermally stable metal chelates and have been studied by a number of investigators. A critical flaw preventing the widespread applicability of GC/MS methods has been the observation of carry-over, or memory, in the sequential analysis of samples with different isotope ratios. We have investigated the memory effect using lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), as a chelating agent for determining non-natural isotope ratios of Cr, Ni, Cu, Zn and Pb.

Experimental

Preparation of synthetic mixtures: A series of synthetic mixtures were prepared for each of the metals using standard solutions of the natural elements and solutions of the enriched isotopes (spikes) ^{50}Cr , ^{62}Ni , ^{65}Cu , ^{68}Zn and ^{204}Pb . Weighed amounts of these solutions were mixed to give four to five mixtures for each element with increasing amounts of the spike.

Preparation of metal chelates: The chelating agent Li(FDEDTC) was synthesized using bis(trifluoroethyl)amine, n-butyllithium and carbon disulphide. The metal chelates were prepared at a pH of 3 using an acetic acid-sodium acetate buffer. A 0.02 M solution of Li(FDEDTC) in distilled, deionised water was used to form the metal chelates which were then extracted into methylene chloride. For Cr, an oxidation step using $\text{KMnO}_4\text{-H}_2\text{SO}_4$ was included prior to chelate formation.

Gas Chromatography/Mass Spectrometry: A 10m DB-1 fused silica capillary column was used in a Finnigan-MAT 8230 GC/MS system. The isotope ratios were determined by recording the highest intensity ion containing the metal using selected ion monitoring in the voltage peak switching mode. The cluster of ion peaks used corresponded to the molecular ion for Ni, Cu and Zn and a fragment ion formed by the loss of one ligand for Cr and Pb. The mixtures were analysed in the sequence of increasing amount of the spike with three to four injections made for each sample.

Results and Discussion

The isotope ratios determined from the different synthetic mixtures of each element were used to calculate the concentration of the metal in the spike solution by the principle of reverse isotope dilution. The constancy in the isotope ratios obtained by replicate injections from each of the synthetic mixtures as well as the close agreement of the concentration values calculated from the synthetic mixtures was taken as evidence for the absence of any significant memory effect. The results obtained showed no measurable memory effect for Cr and a very slight memory effect for Ni. These results are illustrated in Figures 1 and 2 which show the measured ratios for the sequential analysis of natural and enriched isotope solutions of Cr and Ni, respectively. In these figures, the isotope ratios measured in the chelate correspond to the spike isotope (^{50}Cr , ^{62}Ni) and the highest abundant natural isotope (^{52}Cr , ^{58}Ni). Similar experiments for Cu, Zn and Pb showed significant memory effect. During the sequential analyses of different synthetic mixtures of Zn and Pb, there was a small memory effect as noted from the isotope ratio data obtained from the first injection. In the case of Cu, it was necessary

to reject the data of 2 to 4 injections before approaching a constant value for each synthetic mixture. The extent of memory effect will depend upon the differences in the isotope ratios of samples to be analysed sequentially. However, good experimental design for isotope dilution technique puts the isotope ratios in a relatively narrow range and GC/MS can still be used for these elements. As an example, the concentrations of Cu and Pb in the NIST urine reference material, SRM-2670, are shown in Table 1. As can be seen, good agreement was observed between the certified and measured concentration values. Zinc was not determined due to the non-availability of certified reference material.

Conclusion

GC/MS using Li(FD EDTC) as a chelating agent can be employed for the determination of isotope ratios and concentrations of Cr and Ni without any appreciable memory problem. For Zn and Pb, the method can be used by neglecting the data obtained from initial one or two injections, when analysing samples with different isotope ratios. Among the different elements studied, Cu showed a large memory effect. As demonstrated in the present work, it is possible to determine Cu concentrations by controlling the range of isotope ratios of different samples to be analysed by GC/MS. This can easily be achieved by performing optimum spiking during the isotope dilution step.

MEASUREMENT OF TRACES OF CHD_3 IN CD_4

O.A. Mamer, Biomedical MS Unit, McGill University,
1130 Pine Ave West, Montreal, Que., Canada, H3A 1A3

and

H. Koch, MSD Isotopes, Pointe Claire, Que., Canada, H9R 4P7

The determination of traces of CHD_3 in CD_4 by conventional mass spectrometry requires the measurement of very weak and very strong signals in the same analysis.

A simple approach to this problem is to measure the relative intensities at nominal mass 19 for the CD_4 sample with resolving power 5000. The $^{13}\text{CD}_3^+$ fragment ion in the spectrum of CD_4 has an abundance $A \times B$ that of the molecular ion of CD_4 , where A is the abundance of ^{13}C relative to ^{12}C (0.0111: natural abundance), and B is the usual relative intensity of the $^{12}\text{CD}_3^+$ fragment relative to the molecular ion $^{12}\text{CD}_4^{+}$ (0.862: measured in a separate analysis). The molecular ion $^{12}\text{CHD}_3^+$ (m/z 19.05013) and the $^{13}\text{CD}_3^+$ fragment (m/z 19.04566) are easily separated at 5000 resolution and will have intensities that are comparable and easily measured if the $^{12}\text{CHD}_3$ impurity is comparable with the ^{13}C content of the carbon in the methane. The contribution to $^{13}\text{CD}_3^+$ by H. loss from $^{13}\text{CHD}_3$ may be ignored in these calculations if the impurity is small.

The break-seal container is opened by manually breaking the fragile seal in a dry nitrogen atmosphere to exclude water as much as possible from the sample. The methane may be at sub-ambient pressure, and dry nitrogen will back-fill the tube as the seal is broken. A gas-tight syringe is used to remove approximately 50 μl of the methane-nitrogen mixture and is introduced to the EI ion source of a 2AB-HS via the septum inlet (50°C). The mass spectrometer is scanned over the nominal range m/z 18-20 and the intensity ratio for the molecular ion $^{12}\text{CHD}_3^+$ (m/z 19.05013) to the $^{13}\text{CD}_3^+$ fragment (m/z 19.04566) is measured. The figure shows an example of such a measurement in which the ratio has been measured to be 0.41. The CD_3H impurity relative to the CD_4 content then is equal to:

$$0.41 \times 0.0111 \times 0.862 = 0.00393 \text{ or } 0.39\% \text{ approximately.}$$

It is important to know with certainty the ^{13}C content of the carbon used to make the deuteriomethane. The method is simple and requires only a few minutes per determination.

EI INDUCED FRAGMENTATION OF 2-ARYLOXY-3-CYCLOHEXYL-6-(1,1-DIMETHYLETHYL)-3,4-DIHYDRO-2H-1,3,2-BENZOXAZA PHOSPHORINE-2-OXIDES

C. Naga Raju^a, Chhabil Dass^b and G. Sudhakar Reddy^c

^bDepartment of Neurology, University of Tennessee, Memphis, Tennessee 38163

^cShrader Analytical & Consulting Laboratories, Inc. 3814 Vinewood, Detroit, Michigan 48208

A series of 2-aryloxy-3-cyclohexyl-6-(1,1-dimethylethyl)-3,4-dihydro-2H-1,3,2-benzoxaza phosphorine 2-oxides(A) have been studied by EI mass spectrometry in an attempt to understand their fragmentation behavior. These are potential anticancer drugs¹ and were synthesized by reacting 2-cyclohexylaminoethyl-4-t-butylphenol(B) and arylphosphorodichloride in benzene at room temperature for 2-4 hours.²

(A)

(B)

1A, R=H; 2A, R=2-CH₃; 3A, R=3-CH₃; 4A, R=4-CH₃; 5A, R=3,4-(CH₃)₂;
6A, R=2,3-(CH₃)₂; 7A, R=2,5-(CH₃)₂; 8A, R=2-Cl; 9A= R=4-Cl

The accurate mass measurements of some selected ions from compounds 3A and B were performed on a VG 70-70E-HF mass spectrometer interfaced to a 11-250M+ data system at a resolution of 10,000 by peak matching to a closest PFK reference ion. The CAD spectra were recorded by B/E linked scan in the 1st FFR employing helium as the collision gas.

The molecular ions generated from this series of compounds are very stable often giving rise to the base peak in their spectra. Elimination of cyclohexyl, propyl and isobutylene moieties from the molecular ions represent major fragmentation modes. The aryloxy and arylphosphone fragments are also lost from the M⁺ as evidenced by the CAD spectral data.

Based on the B/E linked scan spectra recorded for compound 3A on ions m/z 413(M⁺) and m/z 370(M-C₃H₇)⁺, it appears that the propyl radical is lost from the cyclohexyl ring and not from the t-butyl group. A mechanism involving an initial ring opening followed by a hydrogen transfer and subsequent C-C bond fission is proposed as in Scheme 1. The CAD spectrum of ion m/z 370 from compound 3A exhibited an ion at m/z 340 corresponding to a loss of C₃H₄ confirming its ionic structure (Scheme 1).

In an attempt to make a comparative study the mass spectrum of the starting material, 2-cyclohexyl-aminoethyl-4-*t*-butyl phenol(B) was also studied. The base peak in the spectrum of this compound is due to the M^+ ion at m/z 261 which again loses a propyl radical to give an intense fragment ion at m/z 218. This represents a major fragmentation pathway. Expulsion of methyl, C_4H_9 , pentyl and cyclohexyl fragments from the M^+ afford ions at m/z 246, 205, 190 and 178, respectively. All these fragmentations and the resulting ionic structures were confirmed by CAD spectral data and accurate mass measurements. A similar mechanism shown in Scheme 1 appears to be operative in the elimination of propyl radical in compound(B). Furthermore, the ring opening of cyclohexyl moiety prior to fragmentation also supports the loss of C_3H_{11} fragment from the molecular ion of compound B.

In conclusion, all the fragmentation processes observed support the assigned molecular structures for these compounds.

During our investigations on the synthesis of organophosphorus esters bearing anticholinesterase activity, we have prepared a series of 2,10-dichloro-6-aryloxy-dibenzo[d,g][1,3,6,2]dioxathiaphosphocin-6-oxides (1-6).¹ The electron ionization mass spectra of these compounds have been examined since they contain a novel eight membered dibenzo dioxathiaphosphocin ring system.

3.	2-CH ₃	3-CH ₃
4.	2-CH ₃	6-CH ₃
5.	H	2-Cl
6.	3-CH ₃	4-Cl

The low resolution mass spectra were recorded on a JMS-300 mass spectrometer using direct inlet probe at 70 eV. The high resolution mass measurements of some selected ions from Compound 3 were performed on a VG 70-70E-HF mass spectrometer at a resolution of 10,000 by peak matching to a closest PFK reference ion. The CAD spectra were taken in the 1st FFR using helium as the collision gas.

The mass spectra of this series of compounds exhibited stable M⁺ ions. The molecular ion further expels an aryloxy ion to give a (M-OR)⁺ ion which forms the base peak in their spectra. The (M-OR)⁺ ion decomposes into various ions by other competing reaction pathways.

Based on the accurate mass measurements and metastable transitions recorded for Compound 3, the major fragmentation reactions are interpreted as shown in Scheme 1.

The molecular ion gives rise to an ion at m/z 330 with the elimination of C₈H₇O (aryloxy) moiety. The (M-C₈H₇O)⁺ ion further loses PO₂ radical to form an ion at m/z 268. It can also expel PO₃ to yield a weak

Scheme 1

ion at $m/z\ 252$. Expulsion of C_8H_3ClS moiety from the $(M-C_8H_9O)^+$ results in an ion at $m/z\ 189$. Similarly, a loss of C_8H_3ClOS from this ion forms an ion at $m/z\ 173$. All these fragmentation reactions are supported by CAD spectral data. The proposed ionic structures are in good agreement with the accurate mass measurements.

In the course of our investigations on novel heterocyclic systems we have synthesized a series of 1,4-dithiane dioxide, 1,4-dithiane tetroxide and 1,4-thiomorpholine dioxide derivatives in good yields.¹ The mass spectral studies on these systems are undertaken to understand their fragmentation behavior in the gas phase.

The 70 eV low resolution mass spectra were recorded on a JMS-300 mass spectrometer using a direct inlet system. The high resolution spectra of some selected compounds were recorded on a Kratos MS-50. The accuracy of masses for several ions measured was within ± 3 ppm.

The following representative compounds from each series were examined under EI conditions. The M⁺ ion in all of these compounds is less

1, R=H

2, R=Cl

3, R=H

4, R=NO₂

5, R=H

6, R=CH₃

7, R=NO₂

significant and undergoes further decomposition depending upon the structure of the molecule. For example, an expulsion of SO₂ molecule from the M⁺ of dithiane tetroxides(3,4) is seen as one of the competing processes while it is absent in dioxides(1,2). Similarly, the elimination of SO₂H radical from the molecular ion is predominant in dioxides while it is less significant or absent in tetroxides. It is interesting to note that both SO₂ and SO₂H moieties are lost from the M⁺ of thiomorpholine dioxides(5-7). Furthermore, the loss of methoxy radical from the M⁺ of 5-7 represents another competing reaction. The base peak in these compounds is due to the styrene radical cation. A similar trend is seen in the mass

**Presented at the 37th ASMS Conference on Mass Spectrometry and Allied Topics
May 21-26, 1989, Miami Beach, FL**

spectra of dithiane tetroxide where the styrene ion appeared as the base peak. On the contrary, the formation of the styrene ion at m/z 104 is less significant in the case of dithiane dioxides. The base peak in these compounds is due to a substituted thiophenyl ion which results from the M^+ by SO_2H loss.

The proposed ionic structures and fragmentation reactions are supported by high resolution data.

PHENYL AND PYRIDYL GROUP MIGRATION ON ELECTRON IONIZATION OF ENAMIDES DERIVED FROM 1,3-BENZOTHAZINES AND ISOQUINOLINES:

D. B. MacLean, J. Wang, L. Fodor and R. W. Smith.

McMaster Regional Centre for Mass Spectrometry, Department of Chemistry, McMaster University, 1280 Main St. W., Hamilton, Ontario, L8S 4M1, Canada.

Enamides derived from 3,4-dihydro-1-methylisoquinolines and 3,4-dihydro-1-methyl- β -carboline have been used extensively in the synthesis of alkaloids and related heterocyclic systems. The utility of these enamides rests upon their ability to cyclize either photochemically or thermally as shown below for the isoquinoline system.

Enamides of the type shown in figure 1 were examined by EIMS to see if a similar process might occur in the mass spectrometer ion source and also to examine the mass spectral behavior of this group of compounds. Full scan electron impact mass spectra (EIMS), mass analysed ion kinetic energy scans (MIKES) and collisional activation spectra (MIKES, He collision gas, parent ion transmission = 50%) were recorded on a VG ZAB-E mass spectrometer (VG Analytical, Wythenshawe, UK) using a direct insertion probe. Typical experimental conditions were: source temperature, 200°C; electron energy 70eV; resolution, 1000 for low resolution and MIKES, and 5000 for elemental composition determinations.

Figure 1

Compounds 1-5, and 8 exhibited intense ions corresponding to loss of CO from the M⁺ and [M-H]⁺ ions. The EIMS of compounds 3 and 6 are shown in figure 2. The loss of CO implies that aryl (and vinyl) group migration must occur. The [M-CO]⁺ ion then fragments further by loss of H, CH₃, OCH₃, Y, CH₂Y, and CH₂NY. Table 1 summarises the MIKES data and elemental composition determinations for compound 3. In contrast, 6 and 7 showed no loss of CO but simple cleavage reactions were observed.

Examination of the literature of related systems was not helpful. Simple amides^{1,2a} do not lose CO from the M⁺ ion. The cyclic enamides, α - and γ -pyridones^{2b}, and the fused α -pyridones³, 2(1H)-quinolinone and 1(2H)-isoquinolinone, all exhibit ions corresponding to loss of CO from the M⁺ ion. However, compounds in which the 1(2H)-isoquinolinone system or its naphthyridine analogue are incorporated into more complex ring systems show no tendency to lose CO in their EIMS as is the case for compounds A^{4a} and B^{4b} shown above.

The EIMS of compounds 1-3 (X = S) are similar. Loss of the neutrals shown in table 1 are common to all three compounds. The molecular ion loses CO with migration of the phenyl group to

nitrogen yielding an ion at m/z 299 which, by loss of phenyl in the case of compound 3, affords the m/z 222 ion. The latter is also formed directly from the molecular ion by loss of the aryl group. The ion at m/z 222 loses CH_2N to yield m/z 194 which is also formed from m/z 299 by loss of $\text{C}_7\text{H}_7\text{N}$. The ion at m/z 179 is formed from m/z 194 by loss of CH_3 . The process leading to m/z 208 is more complex. It may indicate that the $[\text{M}-\text{CO}]^+$ ion has a different structure than that discussed previously. This second ion may form by migration of phenyl to carbon rather than nitrogen. The expulsion of C_7H_7 would yield the ion at m/z 208. In compounds 4 and 5 the same processes are observed, however, the intensities of the ions are low (<5%).

Figure 2

Cyclization of these compounds was not observed under EIMS conditions, CO elimination followed by aryl group migration to either the nitrogen or the exocyclic methylene was observed.

Investigation of the Hindered Amine Light Stabilizer Mechanism using Isotopic Labeling

NG K., Piatek B., Klemchuck P.,* Gande M.,* Corporate Analytical Research and Additives* Research Departments. CIBA-GEIGY Corporation, Saw Mill River Road, Ardsley, N.Y. 10502

2,2,6,6-tetramethyl piperidiny compounds are very effective light stabilizers for polymers. Literature reports that nitroxyl and polymer bound hydroxyl amine ethers are the intermediates. N-alkoxy-tetramethylpiperidines react with peroxy radicals to generate nitroxyls and dialkyl peroxides as shown in Scheme 1. This mechanism is generally accepted as the "HALS CYCLE" mechanism. An alternate OXIDATIVE mechanism is being proposed. Reaction of the N-O-R ether with an alkyl peroxy radical results in the cleavage of the R group to form a ketone and the nitroxyl as shown in Scheme 2. In this study the R group of the light stabilizer is cyclohexane. By the use of a variety of isotopic labeling experiments and gas chromatography/ mass spectrometry analysis as shown in Figures A, B, and C, the generally accepted "HALS CYCLE" mechanism has been disproven and the alternate OXIDATIVE mechanism is supported

Cleavage beta to a radical site to give an olefinic product is a favorable fragmentation of ions in the gas phase. Near threshold, such cleavages can form ion-neutral complexes followed by readdition at the other end of the double bond. We here extend this concept by proposing the reaction $\underline{3} \rightleftharpoons \underline{2}$ (Scheme I). The distonic species $\underline{5}$ has previously been studied.

Metastable spectra and associated translational energy releases starting from $\underline{1}$ and $\underline{5}$ are given in Table 1.

Table 1. Metastable Spectra and Translational Energy Releases ($T_{0.5}$) from $C_3H_8O^+$ Isomers.

		$-H^+$		$-H_2O$
$CH_3CH_2CH_2OH^+$ ($\underline{1}$)	10	(46.2 meV)	100	(19.5 meV)
$\cdot CH_2CH_2OH^+CH_3$ ($\underline{5}$)	100	(116 meV)	98	(21.0 meV)

The loss of water requires isomerization to a species containing only one C-O bond, placing the oxygen in a position to be lost in water. The two losses of water have similar energy releases, consistent with decomposition from the same reacting configuration.

Studies of labeled ions (Table 2) demonstrated that hydrogen is lost predominantly from the methyl group of $\underline{5}$. About 2/3 of the water lost contained the hydrogen initially on the oxygen of $\underline{5}$, as did nearly all of the water lost from $\underline{1}$. Only a small portion of the methyl hydrogens of $\underline{5}$ were lost in water, and the hydrogens of the C_2H_4 moiety were lost in water about equally.

Comparison of CAD spectra of the products of H^+ loss from metastable 1 and 5 to reference CAD spectra of $C_3H_7O^+$ ions demonstrates that the product of both transitions is the same, and that the product is protonated propanal. This seems good evidence that both ions lose H from structure 1, justifying the proposals in Scheme I. However, the translational energy releases are quite different for the two H losses (Table 1), demonstrating that the two reactions differ in some way.

THE OXIRANE ISOMERS $\cdot\text{CH}_2\text{OCH}_2\cdot$, $\cdot\text{CH}_2\text{CH}_2\text{O}\cdot$, AND HCOCH_3
AND THEIR IONIZED COUNTERPARTS

C. Wesdemiotis, B. Leyh, A. Fura, and F. W. McLafferty

Baker Laboratory, Chemistry Department, Cornell University,
Ithaca, NY 14853-1301, U.S.A.

C-C and C-O bond rupture in oxirane leads to $\cdot\text{CH}_2\text{OCH}_2\cdot$ and $\cdot\text{CH}_2\text{CH}_2\text{O}\cdot$, respectively. These biradicals and methoxycarbene, HCOCH_3 , have been proposed as intermediates in the thermal and photochemical reactions of acetaldehyde and oxirane, but they have never been experimentally detected. We prepared these neutrals in the gas phase via neutralization from the corresponding radical cations and studied their structures and reactivities by collisionally activated dissociation (CAD), reionization into cations and anions, and further CAD analysis (MS/MS/MS) of the neutralized-reionized parent ions.

The precursor radical cations $\cdot\text{CH}_2\text{OCH}_2^+$, $\cdot\text{CH}_2\text{CH}_2\text{O}^+$, HCOCH_3^+ , and oxirane $^+$ were prepared by electron ionization of 1,3-dioxolane, ethylene carbonate, methyl glyoxylate, and oxirane, respectively. Their structures were confirmed by CAD and neutralization-anionization (NR^-) experiments. $\cdot\text{CH}_2\text{OCH}_2^+$ and HCOCH_3^+ yield upon NR^- stable molecular anions which show dominant, structurally diagnostic $\text{CH}_2=\text{CHO}^-$ (m/z 43) and OCH_3^- (m/z 31) fragments, respectively (Figure 1). Collisional excitation of oxirane $^+$ in the field-free region preceding that of CAD does not change its CAD spectrum, indicating that ionized oxirane does not ring-open readily to $\cdot\text{CH}_2\text{OCH}_2^+$, as predicted by MO theory.

Figure 1. NR^- , benzene (30% Transmittance), spectra of
(A) $\cdot\text{CH}_2\text{CH}_2\text{O}^+$ and (B) HCOCH_3^+ .

All four $\text{C}_2\text{H}_4\text{O}^+$ precursor ions lead upon neutralization-cationization (NR^+) to recovered $\text{C}_2\text{H}_4\text{O}^+$ molecular cations showing that a substantial proportion of the neutrals are formed below their fragmentation thresholds. CAD of the mass-selected recovered molecular ions (MS/MS/MS) combined with NR^- data reveals that both the biradicals and methoxycarbene as well represent bound structures with finite barriers towards isomerization and fragmentation.

Upon CAD all $\text{C}_2\text{H}_4\text{O}$ neutrals studied yield mainly CH_3^+ + $\cdot\text{CHO}$ (e.g., Figure 2). Neutralization-CAD-cationization (NCR^+) of $\cdot\text{CH}_2\text{OCH}_2^+$ leads to recovered $\text{C}_2\text{H}_4\text{O}^+$ molecular ions shown by MS/MS/MS to be composed of 22% $\cdot\text{CH}_2\text{OCH}_2^+$, 76% oxirane $^+$, and 2% CH_3CHO^+ ; thus, undissociated $\cdot\text{CH}_2\text{OCH}_2\cdot$ has partly isomerized to oxirane and a trace of acetaldehyde. The 1,3-H rearrangement $\cdot\text{CH}_2\text{OCH}_2\cdot \rightarrow \text{HCOCH}_3$ is not observed. Similarly, NCR^+ of

$^+\text{CH}_2\text{CH}_2\text{O}^+$ produces reionized $\text{C}_2\text{H}_4\text{O}^+$ parent cations consisting of 56% $^+\text{CH}_2\text{CH}_2\text{O}^+$ and 44% CH_3CHO^+ , which indicates partial $^+\text{CH}_2\text{CH}_2\text{O}^+$ isomerization to CH_3CHO ; no detectable amount of oxirane or vinyl alcohol is found.

Figure 2. (A) $^+\text{NR}^+$, Xe(70% T)/ O_2 (70% T) and (B) $^+\text{NCR}^+$, Xe(70% T)/He(30% T)/ O_2 (70% T), spectra of oxirane $^+$.

$^+\text{NR}^+$ of oxirane $^+$ under multiple collision conditions yields recovered $\text{C}_2\text{H}_4\text{O}^+$ ions whose CAD spectrum is identical to that of the original oxirane $^+$ precursors and characteristically different from the CAD spectra of $^+\text{CH}_2\text{OCH}_2^+$ and CH_3CHO^+ . This is consistent with high isomerization barriers not only for the oxirane ion (vide supra), but also for the oxirane molecule. Our experimental results are summarized in the potential energy diagram of Figure 3.

Figure 3. Potential energy diagram of the neutral $\text{C}_2\text{H}_4\text{O}$ isomers.

TRIMETHYLSILYL GROUP MIGRATIONS IN THE MASS SPECTRA OF
DERIVATIZED CHOLESTEROL OXIDATION PRODUCTS

Meg Annan, Bruce A. Wasilchuk, P.W. Lequesne, Paul Vouros
Northeastern University, Boston MA 02115

The high susceptibility of cholesterol to undergo oxidation in the presence of air and/or light results in the formation of a variety of oxides, many of which have been suspected of causing the cell death and lesion development associated with atherosclerosis. As a part of a study aimed at the characterization and quantification of cholesterol oxides, the fragmentation behavior of the trimethylsilyl (TMS) derivatives of these compounds was examined.

Of interest was the presence of an ion, $[M-71]^+$, which is thought to be analogous to the $[M-56]^+$ ion commonly seen in the spectra of TMS derivatives of 16- and 17-ketosteroids. The ion, $[M-56]^+$, which was initially thought to be due to D-ring cleavage, was later reported by Brooks¹ to be a result of TMS group migration followed by A-ring cleavage at the C_1-C_{10} and C_3-C_4 bonds. We report here related evidence of TMS migrations towards electron rich centers in the electron impact mass spectra of cholesterol oxides.

Deuteriated cholesterol oxide analogues, d_9 -TMS derivatives and TMS derivatized d_3 -(2,2,4)-oxides, as well as linked scanning in the B/E mode were employed in order to demonstrate the occurrence of and further understand the nature of these TMS migrations. The oxides examined were 5 β ,6 β -cholesterol epoxide, 5 α ,6 α -cholesterol epoxide, 6-ketocholestanol, 7-ketocholesterol, 25-hydroxycholesterol, and 3 β ,5 α ,6 β -cholestantriol. All of the spectra were obtained using a VG-70-250SE double focussing mass spectrometer.

A table of ions resulting from TMS migration followed by A-ring cleavage at the C_1-C_{10} and C_4-C_5 bonds is shown below. While several of the compounds, 5 β ,6 β -cholesterol epoxide, 6-ketocholestanol, 7-ketocholesterol, and 25-hydroxycholesterol, also exhibited the analogous migration/cleavage process leading to the $[M-56]^+$ ion, fragmentation leading to the $[M-71]^+$ ion is more prevalent. Included in this table is an ion, $[M-56-113]^+$, possibly arising from a concerted loss of the side chain and A-ring cleavage initiated by TMS migration.

TABLE 1

OXIDE	TMS- d_0	d_9 -TMS	TMS-2,2,4- d_3	NEUTRAL LOSS
α -epoxide	403	412	403	-71,-71,-74
β -epoxide	403	412	403	-71,-71,-74
6-keto	403	412	*	-71,-71
	305	314	*	-56-113,-56-113
7-keto	403	412	401	-69,-69,-71
triol	403	412	403	-90-71,-90-71, -90-74
25-hydroxy	403	-	404	-71,-74

In the EI mass spectrum of the β -epoxide (Figure 1), the $[M-71]^+$ ion is indicated as well as the ions observed in the spectra of the d_9 -TMS-epoxide and the TMS derivatized d_3 -(2,2,4)-epoxide. Similar results confirming TMS migrations were obtained for the other oxides as well. The table and the spectrum show that there is some degree of variation, among the different compounds, in the number of hydrogens transferred to the B-ring during TMS migration and A-ring cleavage. The presence of an $[M-70]^+$ ion as well as an $[M-71]^+$ ion is, in fact, common. A proposed mechanism for the generation of the more frequently observed $[M-71]^+$ ion is shown in Scheme 1. In general, however, the generation of ions such as those listed in the table involves the transfer of a trimethylsilyl group to an accessible electron rich center followed by radical induced cleavage of the A-ring. Of interest is the occurrence of an $[M-71]^+$ ion in the spectra of 25-hydroxycholesterol, which is another possible example of long range TMS migration.

These data, as well as the results of linked scans are quite consistent with TMS migrations. Furthermore, they demonstrate that this process is general in the sense that it takes place in a wide variety of compounds having an electron rich center within proximity of the TMS group. The effect of structure on the mass and intensity of ions resulting from TMS migrations is, as yet, unknown.

SUBSTITUENT EFFECTS IN THE MASS SPECTRA OF SUBSTITUTED DIPHENYL 1-PHENYLAMINO-1-PHENYLMETHANEPHOSPHONATES M. Rahi,¹ K. Jayasimhulu,² S.J. Smith,¹ and H. Zimmer¹ ¹Department of Chemistry, ²Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati Ohio 45221, 245267-0056

Alpha-Heterosubstituted phosphonate carbanions are very useful in organic synthesis (1). Zimmer et al. (2) have found that chemical shifts of ³¹P, ¹³C, and ¹H NMR of diphenyl 1-phenylamino-1-phenylmethane phosphonates, I, and their anions are influenced in a Hammett fashion by the

I

substituents R₁ and R₂. Based on these results, we became interested in investigating whether substituent effects also could be observed in the mass spectra of these compounds. Therefore, we investigated the influence of the substituents R₁ and R₂ on the abundance of certain ions in their mass spectra. A series of compounds substituted in the meta and para positions on the aniline moiety and/or the benzyl moiety were prepared, Table I, by the method outlined by Zimmer and Seemuth (1), and their mass spectra were recorded.

The molecules undergo fragmentation under electron impact corresponding to the scheme in which the major peaks of the spectra are illustrated.

The electron impact fragmentation data indicates significant changes in the fragmentation patterns in terms of relative intensities of various peaks with respect to different substituents in the phenyl groups.

In general, the molecular ions are low to medium in abundance. The fragment ion $m/z = [M-234]^+$, the most abundant in most cases, appears to have a good correlation with Hammett σ values. The intensity of this ion is enhanced by electron-releasing groups, while electron withdrawing groups tend to decrease its intensity. Plots of $\log Z$, where Z is the relative percent abundance of the ion, versus $\sigma_{m,p}$ and $\log Z$ versus σ^0 , results in linear fits in both cases. This linear relationship can be described by the equation.

$$F_m = 1.22 - 0.31 \Sigma \sigma_{m,p}$$

$$F_m = 1.23 - 0.35 \Sigma \sigma^0$$

REARRANGEMENTS OF FLUORINE-CONTAINING CATIONS

Thomas A. Shaler and Thomas Hellman Morton
Department of Chemistry, University of California
Riverside, California 92521

The rearrangements of 3- and 4-carbon mono-fluorinated cations have been experimentally probed. The technique which has been employed involves generating the ions as a component in an ion molecule complex. The ion-molecule complex in this case is an intermediate in the unimolecular decomposition of an ionized fluoroalkyl phenyl ether. Ionized primary alkyl phenyl ethers have previously been shown to yield phenol molecular ion and an alkene through the intermediacy of an ion-molecule complex¹. Placement of a fluorine substituent on the alkyl group will yield, upon ionization and carbon-oxygen bond heterolysis, a complex in which the fluoroalkyl cation is predicted to be unstable with respect to rearrangement. Subsequent proton transfer to the more basic phenoxy moiety will occur to give PhOH^+ and a neutral fluoroalkene. The structure of the neutral fluoroalkene thus formed reveals information regarding the pathways by which the fluoroalkyl cation has rearranged in the ion-molecule complex.

In our experiments, we collect and analyze the neutral products from the 70eV electron impact on primary fluoroalkyl phenyl ethers at 1×10^{-4} Torr. For this we use the EBFlow apparatus². Electron impact on phenyl ether **1** may initially form the ion-molecule complex **2**. The ion in this complex is a primary carbocation, destabilized by the electron withdrawing effect of fluorine, and is expected to rapidly rearrange. *Ab initio* molecular orbital calculations on the $\text{C}_3\text{H}_6\text{F}^+$ system have indicated that a number of rearrangement pathways should be facile³.

The neutral fluoroalkenes formed from **1** are shown in Scheme 1. The mixture of neutrals which was collected was analyzed by 282 MHz ¹⁹F NMR. Integration of the NMR signals yielded the relative amounts of the products which enabled us to estimate the branching ratios shown. The results indicated that about 70% of the products arise from a single 1,2 hydride shift, and about 30% come from a double 1,2 shift. Small amounts (<2%) of products arising from more than two 1,2 hydride shifts are also observed.

In a second set of experiments, we have examined the question of whether there is competition between a 1,2 methyl migration and a 1,2 fluoride migration, as predicted by *ab initio* calculations. In these experiments phenyl ether **3** was used as the precursor to the ion of interest. A summary of the neutral product analysis for the EBFlow experiment on this compound are shown in Table 1. The experiment was also performed on the hexadeuterio-analogue of **3** in which both methyl groups are perdeuterated. These results show that products arising from both methyl and fluoride shifts are formed. Alternative pathways, such as elimination of HF followed by re-addition of HF which would form the same products as a fluoride shift, can be ruled out from the deuterium labeled experiment.

Table I Isomer distribution from 70 eV EBFlow radiolyses of **3** (d_0) and (d_6) based on integration of ^{19}F NMR signals (corrected for differences in T_1 relaxation times).

Methyl shift	Rel. amount		Fluoride shift	Rel. amount	
	X=H	X=D		X=H	X=D

BENZOPHENONE IMINE FORMATION FROM BENZOPHENONE OXIME

Yee-Chung Ma and Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE. 19716

A GC/EIMS study was made of both unsubstituted and substituted benzophenone oximes (YArC(=N-OH)Ar) by varying the GC injection port, transfer line and ms source temperatures to confirm the origin of the unusual $[\text{M-O}]^+$ ion found by several groups in EIMS studies of benzophenone oxime⁽¹⁻³⁾.

EXPERIMENTAL

Experiments were performed with the Hewlett Packard 5890 GC-5970 MSD system. An HP-1 (Methyl silicone) capillary column was used for the separation. Benzophenone oximes were prepared by adding excess hydroxylamine hydrochloride to the corresponding benzophenones (in ethanol) at room temperature. After the reactions were completed, the solutions were injected into the GC injection port at different injection port temperatures or at different transfer line and source temperatures. The resulting GC traces and the mass spectra were investigated.

RESULTS AND DISCUSSIONS

(1) The formation of benzophenone imines (YArC(=NH)Ar) from neutral benzophenone oximes was found in the GC injection port at about 200-300 °C. However, no benzophenones were found under these conditions, in contrast to earlier work on the formation of benzophenone imines from the oximes⁽⁴⁾. The formation of the imines is strongly temperature dependent within an injection port temperature range of 100 °C (Fig.1,2). Thus thermal decomposition and ionization of the neutral products may explain the previously observed variations in the relative peak intensities in the mass spectrum of the oxime.

(2) Experiments were also done by changing the transfer line/source temperatures at a constant injection port temperature. Mass spectra of the "oximes" under high and low transfer line/source temperatures than were compared, and any imine formation should be observed from the characteristic ions of the imine in the mass spectra of the "oximes".

Formation of the unsubstituted benzophenone imine from the oxime is not obvious due to both the short contact time and overlapping ions in the spectra. Formation of substituted benzophenone imines was clearly indicated by an increase in the intensity of the ion at m/z 180, an ion that is characteristic of all imines. Figure 3 shows the mass spectrum of para-chloro benzophenone imine and the mass spectra of the "oxime" at two different transfer line temperatures. The difference spectrum between the spectra of the para-chloro benzophenone oxime at high and low transfer line temperatures compares well with the spectrum of the imine.

CONCLUSIONS

From our studies, it is evident that neutral benzophenone oximes can decompose thermally to imines in the hot injection port or ion source prior to ionization. The formation of $[M-O]^+$ ion in the mass spectra of the oximes and the variations in the relative intensities of some fragment ions are primarily due to imine formation.

DEUTERIUM ISOTOPE EFFECT IN SOLID PROBE MS ANALYSIS.

Jia-shen Wang
Clairol Inc., Stamford, CT 06922

OBJECTIVE

To enhance the analytical capability of the GC/MS system for structure elucidation by solid probe MS.

INTRODUCTION

It is a well known fact that an active hydrogen (e.g., -OH, -NH₂, or -NRH) in a compound can be replaced with deuterium in the presence of deuterium oxide. Indeed this is a common technique for making assignments in NMR. The advantage of using this technique in MS analysis is less obvious since a pure D-labeled species is difficult to maintain through the entire experimental process. A deuterium in an active site will exchange with the hydrogen in the surrounding area. The mass spectrum of a D and H mixture may not provide useful information. We have found, however, that the H- and D-species may show differences in thermal desorption processes. This paper presents a utilization of this technique to study HC Blue No. 1 (1) and its analogue (2) which is N₄,N₄-(2-Hydroxyethyl)-2-nitro-(p-phenylene-diamine).

EXPERIMENTAL

In this study, all analyses were carried out using a Finnigan 4000 mass spectrometer equipped with a solid probe. The ballistic mode was selected for heating samples. D-labeled compounds were prepared by dissolving a small portion of the sample in a few drops of D₂O (Aldrich, Milwaukee, WS 53233). Compounds 1 and 2 were provided by Mr. J. Anderson (Clairol Inc.).

RESULTS AND DISCUSSION:

N-hydroxyethyl is a functional group commonly found in dyes or intermediates. The major characteristic ions found in the mass spectra of this class of compounds are the molecular ion and the M-31 ion. The M-31 ion is usually the base peak. The mass spectra shown in Figure 1 are HC Blue No. 1 and its deuterated species. These spectra clearly suggest that the M-31 ion is formed by a simple cleavage of the hydroxyethyl group. The spectra also indicate that there are three active hydrogens in this compound. This D-labeled sample is actually a mixture of various D- and H-species. These species, however, show slight variations during the

Figure 1.

sample heating process. Figure 2 shows the RIC of this deuterated sample and the single ion chromatograms of the various molecular ions.

Figure 3 is the mass spectra of compound 2 and its deuterated species. Again the spectrum of the D-labeled was obtained from a D- and H-mixture. The D-labeled species in the various locations of the RIC are shown in Figure 4. Based on these spectra we are able to derive the formation of the base peak and to assign the number of active hydrogens in this compound.

Figure 2.

Figure 4.

CONCLUSION

The results have demonstrated that solid probe MS, which is generally considered to be a low resolving power method can provide significant separation for D,H-mixtures. As a result, the combined utilization of solid probe MS and D-labeling techniques can greatly enhance the analytical capability of a MS system for making structure assignments.

THE ELECTRON IONIZATION MASS SPECTRA OF NOVEL 2,3,4,5-BIS-O-(1-METHYLETHYLIDENE)-B-D-FRUCTOPYRANOSE DERIVATIVES AND RELATED SUGAR SULFAMATES. G.W. Caldwell, B.E. Maryanoff and J.A. Masucci; Dept. of Chemical Research, Janssen Research Foundation, Spring House, PA 19477-0776

The electron ionization (EI) mass spectral fragmentation of bis-Q-(1-methylethylidene) fructopyranose derivatives (Chart 1) and related sugar sulfamates (Chart 2) have been investigated by accurate mass measurements, isotopic labeling and metastable scans. The mass spectra of the 2,3:4,5-bis-Q-(1-methylethylidene) fructopyranose derivatives were not very dependent upon the nature of substitution - the mechanisms of the common fragmentation patterns are given in Scheme 1 and 2¹⁻⁹. Several pieces of evidence corroborate the proposed fragmentation pathway outlined in Scheme 1. Considering our example with X = OSO₂NH₂, both the elemental composition of the proposed fragments and the deuterium incorporation agreed with the fragmentation paths. The elemental composition of fragment A was found to correspond to C₁₁H₁₈O₈NS (found 324.075₉₁; -0.5 mmu), that of fragment B to C₆H₁₂O₇NS (found 266.033₄₀; +0.05 mmu), and that of fragment D to C₆H₈O₅NS (found 206.013₄₂; -1.1 mmu). The deuterium incorporation observed in the EI mass spectrum of 1-d₁₂ is consistent with Scheme 1. The deuterium incorporation for 1-d₁₂ at m/z 333 (324+9) and 269 (266+3) and the lack of deuterium incorporation at m/z 206 was observed. The loss of acetone (58 amu), from fragment A, and acetic acid (60 amu), from fragment B, were confirmed by neutral mass loss metastable link scans. There are eight prominent peaks in the lower mass range for compounds 1-10, common to all 2,3:4,5-bis-Q-(1-methylethylidene) fructopyranose derivatives: m/z 229, 171, 127, 113, 85, 69, 59, and 43 (Scheme 2). The loss of CH₂X (X = OSO₂NH₂), from compounds 1-10 produced a relatively abundant peak (3-78%) at [M-CH₂X]⁺ (m/z 229; fragment H) - the loss of acetone from fragment H gave [M-CH₂X-58]⁺ (m/z 171; fragment I). The ion abundance of fragment I ranges from 9-100% and thus is easily recognized in most EI spectra. A peak at [M-CH₂X-58-28]⁺ (m/z 143; fragment J) was observed in all EI mass spectra (except 2) at a low ion abundance (1-3%). These fragmentation pathways are outlined in Scheme 2. The elemental composition of fragment H was found to correspond to C₁₁H₁₇O₅ (found 229.107₄₅; +0.1 mmu), that of fragment I to C₉H₁₁O₄ (found 171.064₉₆; +0.8 mmu), and that of fragment J to C₇H₁₁O₃ (found 143.069₄₂; +1.4 mmu). The 1-d₁₂ and 6-d₁₂ analogues exhibited m/z 241 (229+12), 117 (171+6) and m/z 149 (143+6). The loss of acetone from fragment H was confirmed by neutral mass loss metastable link scans. The fragmentation pathway leading to fragment J could not be confirmed by metastable link scans. The EI spectral data for bis-Q-(1-methylethylidene) derivatives of several isomeric sugar sulfamates (Chart 2; 11-13) were investigated. While many of the fragments were similar to 1-10, there were structurally significant ions which could be used to distinguish these structures. Compound 11 contained a unique fragment at m/z 100 (C₅H₉O₂; 100.052₂₇; +0.2 mmu). The most pronounced peak in 12 was the m/z 143 ion (C₇H₁₁O₃, 143.071₅₆; -0.7 mmu), Compound 13 contained two unique ions at m/z 248 (C₈H₁₀O₆NS, 248.022₁₇; +0.7 mmu) and 238 (C₇H₁₂O₆NS, 238.037₉₂; +0.6 mmu).

Experimental

Electron ionization (EI) mass spectra were obtained using either a VG 70-250E mass spectrometer or an HP 5970 gas chromatograph/mass selective detector (GC/MSD) mass spectrometer.

THE INVESTIGATION OF [M-35]⁺ IONS IN 2-ALKYL-4,6-DINITROPHENOLS
J. S. Riley and G. D. Marbury, NSI Technology Services Corp.,
Research Triangle Park, NC.

An unusual fragment ion, the loss of 35 mass units, was observed in several 2-alkyl-4,6-dinitrophenols. This ion fragmentation process was characterized to establish if the [M-35]⁺ fragment could be useful for the identification of these compounds in environmental samples, as well as to study the *ortho* effect (1-3) chemistry believed to be involved in this reaction. Selected compounds were studied by electron impact with a VG-70-250SEQ tandem hybrid mass spectrometer (EBQQ geometry); low resolution unimolecular and CAD MS/MS and high resolution (25,000 10% valley) spectra were recorded. In addition, one compound was studied by photoelectron-photoion coincidence (PEPICO) time-of-flight mass spectrometry (4,5) to determine some of the energetics of the reaction.

An analysis of the low resolution data revealed that the [M-35]⁺ ion could be correlated with the formation of [M-18]⁺ ions. Also, the alkyl group has to be larger than methyl for the [M-35]⁺ fragment to be observed. High resolution measurements of these fragments yielded that the [M-18]⁺ ion corresponds to H₂O loss, and the [M-35]⁺ ion represents further loss of OH. The MS/MS results, shown in Figure 1 for 2-(1-methylpropyl)-4,6-dinitrophenol, indicate the [M-18]⁺ ion is formed directly from the molecular ion, and CAD enhances [M-35]⁺ formation. A breakdown diagram for 2-ethyl-4,6-dinitrophenol obtained by PEPICO is shown in Figure 2.

A mechanism for the formation of [M-35]⁺ ions is shown in Figure 3. The initial water loss can occur via hydrogen rearrangement going through a cyclic six-membered transition state, and the actual water loss may be driven by anchimeric assistance (6). The subsequent OH radical loss is an example of the *ortho* effect; an alkyl hydrogen atom rearranges to a nitro oxygen. Since the [M-35]⁺ ion is enhanced under CAD conditions and is dominant in the MS/MS spectrum of the [M-18]⁺ ion, these two neutral losses are stepwise. The PEPICO results indicate that [M-18]⁺ and [M-35]⁺ ion formations occur at parent ion internal energies of 1.55 and 2 eV respectively. Therefore, the potential barrier for the second step in the [M-35]⁺ formation is considerably smaller than the barrier for [M-18]⁺ formation and this would result in the [M-18]⁺ to [M-35]⁺ reaction to be fast relative to the [M]⁺ to [M-18]⁺ reaction. This suggests that the *ortho* effect is a strong driving force for secondary fragmentation of the [M-18]⁺ ion.

THE GAS-PHASE REACTION OF THE CYCLOPROPANE RADICAL CATION AND CYCLOPROPANE: FORMATION OF THE HEXAMETHYLENE DISTONIC ION

C.D. Warner, Department of Chemistry, Hastings College, Hastings, NE 68901; R.N. Hayes and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588.

The principle aim of this study is to investigate whether a gas-phase adduct is formed in a reaction between the cyclopropane radical cation and cyclopropane, and if so, characterize the adduct. This reaction is of particular interest because several studies have shown that the cyclopropane radical cation may react as a distonic radical cation (i.e., charge-radical site separate radical cation).^{1,2}

In order to obtain structural and kinetic information concerning the reaction adduct we employed two complimentary tools.^{3,4} First, tandem mass spectrometry combined with collisional activation (CAD) was used to determine the structure of an adduct formed in a chemical ionization (CI) source. Secondly, FTMS was used to determine possible changes in an adduct structure over time.

When cyclopropane is ionized in a chemical ionization source an adduct, $C_6H_{12}^{+•}$, is formed that fragments upon CAD to give the following structurally significant ions (see Figure 1); viz, m/z 83 $[M - H]^{+•}$, m/z 69 $[M - CH_3]^{+•}$, m/z 56 $[M - C_2H_4]^{+•}$, m/z 55 $[M - C_2H_5]^{+•}$, and m/z 42 $[M - C_3H_6]^{+•}$.

Gas-phase bimolecular adducts may exist as loosely-bound complexes. Complexes of this nature are not expected to undergo rearrangements, and upon collisional activation they should return to starting materials. The adduct ions formed in the reaction between $C_3H_6^{+•}$ and C_3H_6 undergo, upon CAD, multiple dissociation processes. Clearly, a major proportion of the adduct ions formed in this reaction possess a significant degree of covalency. Moreover, the metastable dissociations of the adduct closely resemble the CAD dissociations and also do not include any significant reversion to starting materials.

Figure 2

To investigate further the nature of the bonding in these adduct ions, several CAD spectra were obtained as a function of internal energy. This was accomplished by raising the pressure in the ion source of a third body, CS_2 , from zero to 40 times that of cyclopropane thereby changing the degree of collisional stabilization. Thus, the internal energy of the adduct may be decremented in a controlled manner. A histogram (Figure 2) showing the relative abundances of several key ions in the CAD spectra as a function of internal energy shows little change in going from the most to the least stabilized adduct. Therefore, the adduct must possess a stable structure.

The kinetics of adduct formation were investigated by varying the delay time between ionization and detection using an FTMS spectrometer. The relative abundance of the ion of m/z 42 ($C_3H_6^{+ \cdot}$) decreased while the relative abundances of ions of m/z 55, 56 and 69 all increased steadily from 300 msec to 3.25 sec (Figure 3). Clearly, the reaction has first order rate kinetics with respect to the cyclopropane radical cation.

Figure 3

On the basis of earlier gas-phase and solution chemistry, we propose that a linear adduct is formed between $C_3H_6^{+ \cdot}$ and C_3H_6 (Scheme 1).

Scheme 1

A strength of the CAD MS/MS technique is that an adduct structure may be determined by a comparison of the CAD mass spectra of appropriate model compounds with the CAD spectrum of the adduct. Of four model compounds studied only the 1-hexene radical cation closely resembles that of the adduct. This is perhaps not surprising as a facile 1,5-hydrogen shift of the initially formed 1-hexene radical cation would yield a distonic structure identical to that of the adduct. Conversely, a 1,5-hydrogen shift of the adduct would give rise to the 1-hexene radical cation.

The CAD spectra of two cyclic models, cyclohexane and methyl cyclopentane, are quite different from the adduct. Specifically, cyclohexane dissociates to give more abundant ions of m/z 83 [$M - H$] $^{+ \cdot}$ and 56 [$M - C_2H_4$] $^{+ \cdot}$, and the ion of m/z 69 [$M - CH_3$] $^{+ \cdot}$ is much diminished. The CAD spectrum of methylcyclopentane is dominated by the ion of m/z 69, whereas the losses of C_2H_4 and C_2H_5 are attenuated.

The losses of C_2H_4 and C_2H_5 from the 3-hexene radical cation are more abundant whilst the loss of CH_3 is less significant than that of the adduct.

In conclusion, the cyclopropane radical cation reacts with cyclopropane to give rise to a linear adduct whose structure most closely resembles that of the 1-hexene radical cation. Moreover, the CAD spectra of several possible precursors of $C_6H_{12}^{+ \cdot}$ are distinguishable while being similar as an isomeric group. The adduct has covalent bonding and is formed by a reaction that proceeds with first order kinetics.

MASS SPECTROSCOPIC STUDY OF SOME PERFLUOROCARBONS AND PERFLUOROCARBONS
CONTAINING NON-FLUOROATOMS OR GROUPS

S. K. Huang and A. Tuinman
Adamantech inc., 1501 Blueball Ave., Linwood PA 19061

It has been reported that the fragmentation pattern of perfluorocarbons (PFCs) under the negative ion chemical ionization (NICI) condition was little influenced by the change of the reagent gases, the pressure of the reagent gas, and the ion source temperature, etc. The most abundant molecular radical anion of PFCs was usually obtained in a typical NICI condition. The fragmentation pattern of PFCs containing heteroatoms or groups in a typical NICI condition however was found to be very different from of PFCs. Fragmentation patterns of some PFCs containing heteroatoms or groups, ionized by different ionization modes, were studied by an HP 5988 GC/MS system. A compilation of ions and their relative abundance by the ionization of perfluoroadamantane and its derivatives containing non-fluorocarbon groups under different ionization conditions is shown in Table 1. For the comparison purpose, some of the simpler fluorocarbons such as 1H-perfluoroheptane, perfluoro-1-t-butanol, perfluoro-2-butyl THF and perfluorinated isobutyl-1-bromobutyl ether were also studied.

As shown in the table, under typical NICI conditions, PFCs containing chlorine(s), methyl ester and hydrogen have a tendency to lose Cl, CO₂CH₃, and HF respectively. Although the molecular ion is still the major ion in NICI for perfluoroadamantanes containing one or two chlorines, the ion corresponding to an HF loss becomes the major ion (100) with respect to the molecular ion (91) for 2-H-Perfluoro-1,3-dimethyl adamantane. An ion corresponding to the loss of CO₂CH₃ is the major ion observed for methyl perfluoroadamantane in which very little or no molecular ion was detected. No molecular ion was observed in the NICI condition for 1H-F-heptane and F-t-butanol. Instead, ions corresponding to a loss of HF and H, respectively are the most abundant. Therefore it seems that non-cyclic or structurally unstable fluorocarbons containing non-electronegative atoms or groups can easily eliminate these heteroatoms or groups in NICI.

In the methane chemical ionization (CH₄/CI) condition, the abstraction of an F from PFCs by the reagent gaseous ions results in the formation of (M-F)⁺ which accounts for the most abundant ion for most of the fluorocarbons studied in this work. (M-Cl)⁺ and (M-Br)⁺ were the major ions observed for 1,3-dichloro-F-adamantane and F-isobutyl-1-bromobutyl ether, respectively. (M+H)⁺ was an abundant ion observed for F-t-butanol and methyl-F-adamantane. MS/MS spectral studies of several ions of these compounds by a VG-ZAB BEQQ hybrid mass spectrometer suggests that the protonation of F-t-butanol and F-2-butyl THF in the CH₄/CI condition was occurred on the fluorine atom not on the oxygen atom.

A common stable ion observed in EI for F-adamantane and its derivatives listed in Table 1 is C₈F₉X⁺ where X is F or Cl or CF₃. A higher percentage of M⁺ and (M-OCH₃)⁺ was found for methyl-F-adamantane. It appear that the CO₂CH₃ group is more competitive with fluorines on the -adamantane cage for the electron ionization than are other heteroatoms or groups. Therefore the CO₂CH₃ group appears to be a good "heat sink" or an energy moderator for F-adamantane through its stable resonance structures of F-Ad-C≡O⁺.

TPA61: A Study of the Fragmentation Pathway of a Series of Frog Alkaloids of the Pumiliotoxin Class.
Pu Quan-long, L.K. Pannell, H.M. Fales and R.T. Mason, NIDDK and NHLBI, National Institutes of Health, Bethesda, MD 20892.

AIM: Skin secretions from amphibians contain a wide range of biologically active substances, including lipophilic alkaloids. One of the largest group is the compounds referred to as the Pumiliotoxins. The structure of Pumiliotoxin B (PTX-B) which has a molecular weight of 323 is shown below:

As in the case of PTX-B, the structure of the major alkaloids have been solved by chromatographic purification followed by a combination of mass spectrometry, NMR and crystal structure methods. In these cases a large amount of extract is required. However, many new potent extracts are being isolated in which the activity is thought to be from the minor components or there is too little of the extract for isolation. Therefore a thorough understanding of the fragmentation pathways of the alkaloids will be useful in identifying these unknowns. While a comparison of the spectra of several related alkaloids provides a lot of information, the source of the fragmentation ions has previously been based on speculation.

METHOD: A Finnigan Ion-Trap Mass Spectrometer equipped with a "DC box" and a "Tickle" frequency generator allows the isolation and fragmentation of a single ion from a compound under GC/MS conditions. Following the MS/MS dc/tickle procedure, the daughter ion spectrum for all the ions in the EI spectrum of a compound may be obtained. After several compounds have been run, similarities in their fragmentation pathways can be seen like the group of ions at 150, 176, 193, 194 in the maps below:

However the saturated analog of PTX-A at mass 311 shows a different pattern as much of the fragmentation in the above compounds was directed by the unsaturation. Using these fragmentation diagrams, an assignment of the structure to the EI ions is possible.

CONCLUSION: With a good understanding of the shape of the fragment ions and of the fragmentation pathway, structures can often be assigned to unknown compounds solely on the basis of the mass spectra generated as they elute from the gas chromatograph, without need of larger amounts of pure compound.

CLEAVAGE MECHANISMS OF CHROMIUM- β -DIKETONATES
BY ELECTRON IONIZATION

B. Wencławiak, Universität Münster, Physikalisches Institut,
Wilhelm Klemm Str. 10, D-4400 Münster, FRG.

Electron ionization mass spectra (70 eV EI/MS) of tris chromium- β -diketonates of undecanedione (Hud), 2,2,6,6-tetramethyl-3,5-heptanedione (Hthd), and 2,2,7-trimethyl-3,5-octanedione (Htod) show characteristic fragmentation pathways. A loss of one ligand from each of the three isomeric chromium complexes yields the most abundant ion at m/z 418 [$\text{Cr}(\text{L})_2^+$].

As suggested by MacDonald and Shannon [1] an open chain structure of a ligand in the beta-diketonate is possible. A loss of 42 daltons from $\text{Cr}(\text{ud})_3$ and $\text{Cr}(\text{tod})_3$ (m/z 601 based on Cr52 isotope) and their respective $\text{Cr}(\text{L})_2^+$ can be explained by a McLafferty rearrangement due to sufficiently long ω -substituents (n-butyl and s-butyl) [2].

$\text{Cr}(\text{thd})_3$ (only t-butyl as ω -substituent) shows losses of 15 dalton and up to 3 subsequent losses of 42 daltons. The corresponding ions have very low intensities. EI-MS-MS spectra of the parent ion yield ions of these fragments with much higher abundancies (fig. 1).

The loss of methyl can be rationalized by the formation of a tertiary radical. The subsequent mass losses of 42 dalton could be explained by a radical mechanism with a three membered ring as intermediate before loss of propene occurs (fig. 2). Another possible explanation has been suggested elsewhere [3] and assumes a cyclopropane as intermediate.

Acknowledgements: Supported by a grant from Deutsche Forschungsgemeinschaft (FRG). The experiments were performed at the University of Colorado at Boulder and at the University of Toledo, Ohio.

FUNDAMENTAL STUDIES OF CHEMICAL IONIZATION
OF PORPHYRINS AND METALLOPORPHYRINS

Brian D. Beato and Richard A. Yost, Department of Chemistry, University of Florida, Gainesville, FL 32611

Under both ammonia and hydrogen chemical ionization conditions, porphyrins and metalloporphyrins yield pyrrolic ions useful in structure elucidation. These pyrrolic ions result from reduction and cleavage of the meso-bridge bonds. There has been some debate as to whether this reduction occurs in the gas phase, or if it is surface-induced. Data presented here support the theory that the pyrrolic ions arise from surface-induced decomposition. These experiments also indicate that the surface of the ion volume may have a significant impact upon both positive and negative chemical ionization mass spectra of non-volatile compounds. Ions which appear as fragment ions in the CI mass spectra of such compounds may actually be surface-induced decomposition product ions.

A porphyrin standard (2,3,7,8,12,13,17,18, -octaethyl-21H,23H-porphine) known as OEP, and its cobalt(II) derivative were studied under positive and negative H_2CI and NH_3CI conditions. All of the experiments were performed on a Finnigan MAT TSQ 45 triple quadrupole mass spectrometer, with removable CI ion volumes. The source was pressurized with 0.9 torr H_2 for the H_2CI experiments, and 0.4 torr NH_3 for the NH_3CI experiments. The porphyrin and metalloporphyrin samples were dissolved in methylene chloride and deposited on the rhenium filament of a direct exposure probe (DEP). The DEP was then inserted into the ion source and heated from ambient to 1350C at 600C/min. Collision energies and argon pressures were 25 eV and 1.0 mtorr for positive ions and 30 eV and 1.5 mtorr for negative ions.

When porphyrins or metalloporphyrins are introduced via a DEP into a high pressure ammonia or hydrogen chemical ionization source, two peaks typically arise. The first peak occurs as the compound vaporizes off the probe filament (about 250-350C). Some of the sample condenses on the ion volume, which can only be heated to 190C. As the DEP is heated to a maximum temperature of 1350C, the second peak appears, beginning around 900C. This second peak results from condensed porphyrins on the ion volume surfaces reducing and decomposing to form pyrroles, which vaporize as the ion volume temperature increases, and are ionized.

The positive NH_3CI and H_2CI mass spectra of both OEP and Co(II)OEP are characterized by these two peaks. The first peak consists of molecular (in the H_2CI case only) and protonated molecular ions and some monopyrrolic ions resulting from reduction and cleavage of the meso-bridge bonds. The second peak in both cases consists of much higher abundances of the monopyrrolic ions, but no molecular or protonated molecular ions. This second peak also includes ions which do not appear in the first peak. Daughter ion mass spectra indicate that these are reduced monopyrrolic ions resulting from surface-induced reduction. These results do not rule out the possibility of some reduction and fragmentation occurring in the gas phase, but they indicate that surface-induced decomposition is an important mechanism by which the monopyrrolic ions arise. In fact, such surface-induced decomposition is useful in structure elucidation because it greatly enhances pyrrolic ion formation.

When the porphyrin or metalloporphyrin solution is deposited directly on the inner surface of the CI ion volume, and a clean DEP filament is inserted into the H_2 plasma and heated, only one peak is observed. This peak appears at high DEP temperatures, and yields mass spectra very similar to those from the high temperature peak in conventional DEP experiments. An example of this is shown for OEP in Fig. 1.

Both H_2CI/MS and NH_3CI/MS analyses of free-base (metal-free) porphyrins often yield corresponding iron metalloporphyrin ions, even when care is taken to avoid contact of the porphyrin sample with metal during sample preparation. In order to determine whether this metalloporphyrin results from impurities in the solution or from the stainless steel ion volume, H_2CI/MS data were obtained from identical samples. Positive ion mass spectra yielded very little if any iron porphyrin ions, but these metalloporphyrin ions can be seen clearly in the negative ion mass spectra. When the stainless steel ion volume was electroplated with copper, and the $-H_2CI/MS$ experiment repeated, a remarkable decrease in the abundance of the iron metalloporphyrin was observed. This

indicates that pick up of iron most probably occurs on the surface of the ion volume. It is noteworthy that m/z 588, the iron metalloporphyrin ion, is only detected at lower DEP temperatures (around 300C), indicating that products of porphyrin/surface interactions are observed at both low and high DEP temperatures. It is also interesting that copper plating does not seem to result in metalation of OEP by copper to the extent that stainless steel results in pick up of iron by OEP.

Upon $-H_2CI$, $Co(II)OEP$ yields two distinct peaks as the DEP is heated. The first appears at about 300C, and consists entirely of the negative molecular ion, m/z 591. This negative ion is very stable and difficult to fragment via collisionally activated dissociation (CAD). The second peak arising in $-H_2CI$ mass spectra of $Co(II)OEP$ appears when the DEP reaches 900C, and consists of hydrogenated cobalt OEP adducts resulting from surface-induced reduction. The $[Co(II)OEP+6H]^+$ ion (m/z 597) was selected for a daughter ion MS/MS experiment. It fragmented much more efficiently upon CAD than did the m/z 591 ion, yielding m/z 568 and m/z 449 daughter ions.

In conclusion, it was shown that under $+H_2CI$ and $+NH_3CI$ conditions, porphyrins and metalloporphyrins decompose to a significant extent on the ion volume surface, yielding pyrrolic ions. In addition, metal-free porphyrins tend to metalate upon interaction with stainless steel ion volumes; this can lead to misinterpretation of the $-H_2CI$ and $-NH_3CI$ mass spectra of such porphyrins. It was also demonstrated that negative molecular ions of hydrogenated porphyrins fragment more easily upon CAD than do M^+ ions of the corresponding non-reduced metalloporphyrins. While this work does not rule out the possibility of reduction and decomposition of porphyrins and metalloporphyrins in the gas phase, it demonstrates the importance of the surface-induced decomposition mechanism. This work leads to interesting implications concerning mass spectra of other types of non-volatile compounds which may undergo surface-induced decomposition reactions within the ion source. Perhaps the nature of the ion volume surface is a variable such as choice of the CI reagent gas, pressure, and source temperature, which can be utilized to optimize certain mass spectra.

Studies of the Ion/Molecule Reaction of Esterification
by Ion Trap Mass Spectrometry

Joseph Shu-Cheng Chang and Richard A. Yost
Chemistry Department, University of Florida
Gainesville, FL 32611

The quadrupole ion trap mass spectrometer (QITMS) has the ability to perform MS^n and to permit ion residence times as long as a few seconds inside the trap. These capabilities make the QITMS especially useful for the study of ion/molecule reactions such as the investigation of reaction mechanisms and the elucidation of ion structures via mass-selective storage and MS/MS daughter scans in a single analyzer^{1,2}.

The ion/molecule reactions of esterification and transesterification of alcohols (e.g. ethanol, s-butanol and ethanol- d_6) and benzoic acid, benzoyl chloride, methyl benzoate and ethyl benzoate, with water or deuterium oxide as reagent gas, and the elucidation of the daughter spectra of alkyl benzoate have been demonstrated by MS^4 using a Finnigan MAT IIMS operated with both RF and DC voltages applied to the ring electrode of the ion trap analyzer.

Protonated water ions m/z 19 (H_3O^+) are isolated and allowed to react with ethanol neutrals to form protonated ethanol via proton transfer. The protonated ethanol ion m/z 47 ($C_2H_5OH+H^+$) is then isolated and reacted with benzoic acid. The resulting benzoic acid adduct ion m/z 169 ($C_6H_5COOH+C_2H_5OH+H^+$) then undergoes an elimination reaction (loss of H_2O) to form protonated ethyl benzoate m/z 151 ($C_6H_5COOC_2H_5+H^+$). When the protonated ethanol ion, m/z 47, is reacted with benzoyl chloride, there is a lower yield of protonated ethyl benzoate. This effect is probably due to competition between the elimination reaction (loss of HCl), and the dissociation of the adduct ion to form $C_6H_5CO^+$ ion (m/z 105). The transesterification of methyl benzoate with ethanol was performed by two methods: isolation of protonated ethanol m/z 47, which is then reacted with the neutral methyl ester; and, isolation of protonated methyl benzoate ion m/z 137, with subsequent reaction with neutral ethanol. Both experiments resulted in the formation of protonated ethyl benzoate, m/z 151, but selective isolation of protonated methyl benzoate resulted in cleaner spectra.

The D_3O^+ ion m/z 22 was selected and reacted with ethanol- d_6 to form the deuterated ethanol- d_6 ion m/z 54, ($C_2D_6OD+D^+$). Deuterated ethyl- d_5 benzoate m/z 157 ($C_6H_5COOC_2D_5+D^+$) was formed in the ion trap through the reaction of isolated m/z 54 with benzoic acid. The esterification schemes for benzoic acid with ethanol- d_6 , the MS^4 scan function and mass spectra obtained following the different steps of scan function are shown in Figs. 1-3, respectively. The deuterated benzoic acid ion, m/z 125, was not observed in the esterification of benzoyl chloride with ethanol- d_6 . The hydrolyzed product of benzoyl chloride was therefore not a by-product in this reaction. The transesterification of methyl benzoate with ethanol- d_6 can be carried out either by reacting isolated deuterated ethanol- d_6 m/z 54 with neutral methyl benzoate, or by reacting isolated deuterated methyl benzoate m/z 138 with neutral ethanol- d_6 . Upon transesterification of ethyl benzoate with the deuterated ethanol- d_6 ion, the deuterated ethyl benzoate ion m/z 152 is not formed. This means the transesterification of the ethyl ester to form deuterated ethyl benzoate occurs directly from the reaction of ethyl benzoate with deuterated ethanol- d_6 . CAD of the parent ion m/z 157, ($C_6H_5COOC_2D_5+D^+$), resulted in loss of C_2D_5 (and not CO) to form the benzoic acid- d_4 ion m/z 125, ($C_6H_5COOD+D^+$). These results for deuterated compounds indicate that the loss of 28 as from CAD of protonated ethyl benzoate ion m/z 151 corresponds to C_2H_5 rather than CO . Increasing the C_2D_5OD pressure from 0.5 to 1.0 to 1.5×10^{-5} torr increases the intensity of the reactant ion m/z 54 and product ions m/z 157, as shown in Fig. 4. The ion current for m/z 157 increased more rapidly at higher ethanol- d_6 pressures.

The protonated s-butyl benzoate ion can be obtained by the reaction of s-butanol and either benzoic acid or benzoyl chloride, with water as reagent gas. The transesterification reactions were studied both with and without isolation of the protonated alkyl benzoate ions. The base peak m/z 151 ion can be found in the spectrum of transesterification of methyl benzoate with s-butanol, as shown in Fig. 5. The m/z 151 ion, the fragment ion of m/z 179 through a-cleavage by the elimination of C_2H_5 , is confirmed by CAD of m/z 179 ion.

IONIC DISSOCIATION OF 7-R-O-METHYLNAGAROL
AND ITS DEGRADATION PRODUCTS

T. Nishimura, R.H. Robins,* F.W. Crow* and A. Sonoda
Tsukuba Research Laboratories, Upjohn Pharmaceuticals LTD.
23-Wadai, Tsukuba-city Ibaraki 300-42 Japan

*The Upjohn Company
7000 Portage Rd. Kalamazoo MI 49001

7-R-O-methylnogarol is an antibiotic of the anthracycline family showing activity against gram-positive microorganisms and is an anticancer agent. The synthesized 7-R-O-methylnogarol contains process and degradation impurities. A variety of possible process and degradation impurities were identified by reverse phase ion-pair HPLC. Major degradation products under fluorescence and ultraviolet irradiation are nogarol, 7-deoxynogarol and nogarene. In this work dissociative ionization of these compounds synthesized were investigated using several mass spectrometric techniques (Electron ionization (EI) with low impact energies, isobutane chemical ionization (CI) mass spectrometry, collision induced dissociation (CID) mass spectrometry/mass spectrometry (MS/MS) (Fig. 1)).

Experimental conditions:

Instrument	Finnigan 4600 and TSQ-70
Mode	direct exposure: 20 C° to 600 C°
Manifold pressure	ca. 3×10^{-7} Torr
Mass resolution	ca. 1 mass unit
Scan range	m/z 35 - 1,000
Scan rate	1 scan / second
Electron multi.	- 1.2 kV
Conv. Dinode	- 5 kV for positive ion + 5 kV for negative ion
CI gas	Isobutane
source pressure	ca. 0.5 Torr
CID gas	Xe
pressure	ca. 0.5 Torr
collision energy	ca. 15 eV

7-R-O-methylnogarol The formations of m/z 523 and 509 ions result from losses of a water and methanol from the molecular ion (m/z 541). The m/z 491 ion is produced via simultaneous or successive eliminations of both water and methanol from the A-ring. This ion is common to the analogues, and was found to be the nogarene ion from MS/MS studies (Fig.1). This process is predominant in low energy EI mass spectra. The productions of m/z 454 and 116 ions are due to fragmentation at the dimethyl amino end. The m/z 454 ion is formed by elimination of $(CH_3)_2NCH=CHOH$ [87] from the molecular ion via a concerted mechanism while the formation of m/z 116 corresponding to $(CH_3)_2NCH(CHO)CH'-OH$ proceeds via a step-wise reaction requiring a hydrogen transfer before dissociation (Fig. 2 and 3). The m/z 422 and 404 ions are produced via eliminations of methanol from the m/z 454 ion and of $(CH_3)_2NCH=CHOH$ [87] from the m/z 491 (nogarene) ion. The positive CI mass spectrum consists mainly of three product ions: m/z 542, 510, and 492. Negative chemical ionization using isobutane leads to the formation of M^- due to resonance electron capture and its mass spectrum shows product ions of m/z 541, 523, 511, 509, and 491. These fragment ions produced in chemical ionization seem to be closely related to those in low energy EI mass spectra.

Nogarene The base peak is at m/z 116. The m/z 404 ion is formed via elimination of $(CH_3)_2NCH=CHOH$ [87] from the parent (m/z 491). The positive and negative CI mass spectra exhibit intensive peaks at m/z 491 and 492. The formations of m/z 404 and 116 ions are competitive in low energy EI mass spectra and result from fragmentation at the dimethyl amine end.

R-Nogarol The m/z 491 and 404 ions are produced via elimination of two water molecules from the A-ring and of $(CH_3)_2NCH=CHOH$ [87] from the m/z 491 ion. The formations of m/z 116, 491 and 404 ions are competitive in low EI energies.

7-Deoxynogarol The formation of m/z 493 ions is due to loss of a water from the parent. The m/z 424 ion is formed by elimination of $(CH_3)_2NCH=CHOH$ [87] from the

dimethyl amine end and the m/z 407 ion is produced via its successive loss of a water molecule.

Fig. 1. CID MS/MS spectra of m/z 491 ions produced from various precursors.

Fig. 3. A possible mechanism of the m/z 116 ion formation.

As a conclusion, major fragmentation pathways of the 7-R-O-Methylnogarol and its degraded analogues can be summarized as follows: (1) the formation of m/z 116 ions from the dimethyl amine end involving a hydrogen transfer before dissociation, and successive fragmentation of m/z 116 ions. (2) elimination of $(CH_3)_2NCH=CHOH$ [87] from the dimethyl amine end. (3) losses of neutral molecules (H_2O , CH_3OH) from the A-ring functionalities.

PHOTOCHEMICALLY-INDUCED REACTION OF CHLORPROTHIXENE WITH OXYGEN
UNDER METHANE NEGATIVE CHEMICAL IONIZATION CONDITIONS

Elaine K. Fukuda, Patrick S. Callery* and Preston P. Davis

Department of Drug Metabolism,
Hoffmann-La Roche Inc., Nutley, NJ 07110

*Department of Medicinal Chemistry,
University of Maryland, Baltimore, MD 21201

Chlorprothixene, 3-(2-chloro-9H-thioxanthen-9-ylidene)-N,N-dimethyl-1-propanamine, (I) has been observed to give rise to unusual ions in its methane negative chemical ionization (NCI) mass spectrum.

In particular, an unusual MH^- ion has been reported [P.S. Callery, W.A. Garland, and E.K. Fukuda, *Org. Mass Spectrom.*, in press]. This ion has been accounted for by electron capture followed by H $\cdot$ transfer from the reagent gas. In our studies with I, another unusual ion, m/z 246, has been observed and is presumably the molecular anion of 2-chloro-10-thioxanthone (II) formed by reaction of I with oxygen in the CI source. II is also observed to be a degradation product of I which forms only in the presence of air and light [A. Li Wan Po and W.J. Irwin, *J. Pharm. Pharmacol.*, **32**, 25, 1980]. This observation has been confirmed in our laboratories, as well as the observation that I undergoes rapid cis-trans isomerization in the presence of light.

To elucidate the mechanism of the reaction under methane NCI conditions, experiments with O_2 and $^{18}O_2$ were carried out. Under conditions where O_2 is minimized, the m/z 246 ion is not the base peak. When O_2 is admitted to the ion source, m/z 246 becomes the base peak. The methane NCI mass spectrum of 2-chloro-10-thioxanthone is very simple; only the molecular radical anion is observed at m/z 246 and m/z 248. When $^{18}O_2$ is admitted to the ion source, the m/z 248 ion increases relative to the m/z 246 ion confirming the thioxanthone structure. The chromatographic behavior of the m/z 246 ion shows considerable tailing which is consistent with a surface-mediated pathway.

A strict requirement of the exocyclic double bond was demonstrated by observing no m/z 246 in the methane NCI mass spectrum of reduced chlorprothixene (reduced at the exocyclic double bond).

N-desmethylchlorprothixene was derivatized with pentafluorobenzoylbromide in order to impart electron capturing ability to the side chain. The base peak in the methane NCI mass spectrum of this derivative was the $[M-HF]^-$ ion and no ions indicative of the possible aldehyde product were observed.

The proposed mechanism shown below involves the light-induced formation of a diradical from the exocyclic double bond, reaction with oxygen to form a four-centered intermediate and decomposition to II which captures an electron to form a radical anion.

This mechanism is consistent with the observation of the light-induced cis-trans isomerization of I observed in solution. The isomerization occurs via a diradical intermediate which has the proper symmetry to react with ground (triplet) state oxygen.

CHEMICAL IONISATION MASS SPECTRA OF URETHANES

R D Bowen, K R Jennings and A D Wright
University of Warwick, Department of Chemistry
COVENTRY CV4 7AL, U.K.

The methane chemical ionisation mass spectra of a range of 33 urethanes of general structure $\text{RNHCO}_2\text{C}_2\text{H}_5$ [$\text{R} = \text{C}_n\text{H}_{2n+1}$ ($n = 0 - 8$), $\text{CH}_2 = \text{CHCH}_2$, Ph , PhCH_2 , $\text{Ph}(\text{CH}_3)\text{CH}$ and PhCH_2CH_2] and $\text{R}_2\text{NCO}_2\text{C}_2\text{H}_5$ [$\text{R} = \text{C}_n\text{H}_{2n+1}$ ($n = 0 - 4$)] are reported and discussed. The spectra contain prominent $[\text{MH}]^+$ peaks (typical relative intensity 30 - 100%) accompanied by smaller adduct peaks, $[\text{M} + \text{C}_2\text{H}_5]^+$ (0 - 10%) and $[\text{M} + \text{C}_3\text{H}_5]^+$ (0 - 3%). Four main classes of fragment ions are also present in the spectra.

Two of these classes of fragment ions are associated with the O-ethyl group. Firstly, ions formed by the expulsion of ethene are of moderate abundance (10 - 60%). These ions are formed either from $[\text{MH}]^+$ ions initially protonated on the O-ethyl group or similar ions formed by proton transfer from the carbonyl group. Secondly, ions formed by ethanol loss from $[\text{MH}]^+$ are of significant abundance (5 - 25%) are present in the spectra. Although it is possible that these ions may be formed by H_2O loss from $[\text{MH} - \text{C}_2\text{H}_4]^+$ ions, this is unlikely on energetic grounds. Thirdly, ions formed by alkane loss from $[\text{MH}]^+$ are of analytical value. These ions are formed in a reaction involving elimination of the α -alkyl group together with a β -hydrogen atom from either the n-alkyl group or the NH hydrogen. Analysis of these $[\text{MH-alkane}]^+$ peaks (10 - 80%) can be used to identify most of the four butyl and eight pentyl isomers. Isomers differing beyond the α -carbon atom cannot be resolved. Finally, ions arising from elimination of an alkene from the N-alkyl group of $[\text{RNHCO}_2\text{C}_2\text{H}_5.\text{H}]^+$ have a mass-to-charge ratio of 90, and correspond to protonated O-ethyl carbamic acid $[\text{H}_2\text{NCO}_2\text{C}_2\text{H}_5.\text{H}]^+$. The abundance of this ion reflects the branching at the α -carbon atom of the N-alkyl group. When R is primary this ion is of low abundance (0 - 5%); it increases in importance when R is secondary (10 - 20%) and dominates the spectrum when R is tertiary (100%). This is clearly demonstrated in the spectra of the four butyl urethane isomers. The spectra differ greatly for the s-butyl and t-butyl isomers, but the n-butyl and i-butyl isomers give very similar spectra since they differ beyond the α -carbon atom of the N-alkyl group. This peak is also significant when the R-group can stabilise a positive charge i.e. aromatic groups such as $\text{Ph}(\text{CH}_3)\text{CH}$. This suggests that the mechanism for this reaction involves the formation of a putative

ion-molecule complex $[R^+ \cdots NH(HO)CO_2C_2H_5]$ which undergoes hydrogen transfer to give $(R - H)$ and $[H_2NCO_2C_2H_5 \cdots H]^+$. Such a mechanism would become increasingly favourable on progressing from primary to tertiary alkyl substituents.

Methane CIMS of the four isomeric butyl urethanes

REACTIONS OF BIDENTATE LIGAND ANIONS WITH LEWIS ACIDS AS PROBES OF
POTENTIAL ENERGY SURFACES

Babcock, Lucia M. and Taylor, William S.; Louisiana State University, Baton Rouge, LA, 70803.

Reactions of a wide variety of di-oxo and di-thio ligand anions with BF_3 and SiF_4 have been carried out in the gas phase using the flowing afterglow technique. These reactions can best be described by a generalized mechanism in which the anion first participates in a three-body addition step in which the coordination sphere of the Lewis acids is expanded; boron trifluoride goes from a trigonal planar neutral to a tetrahedral anionic species, while silicon tetrafluoride goes from a tetrahedral neutral to a trigonal bipyramidal anionic species. The presence of a second -OH or -SH chelating group on the bifunctional ligand anion presents the possibility of a second attack at the now saturated Lewis acid center, resulting in ring closure. This latter process can be viewed as a bimolecular substitution process in which a neutral HF molecule is ejected. Thirteen ligand anions of varying properties were selected in this study in order to assess the effects of certain ligand properties upon the reaction mechanism. These ligand anions included both substituted and unsubstituted aliphatic and aromatic 1,2-diols, 1,3-diols, and 1,4-diols as well as the unsubstituted, saturated 1,2-, 1,3-, and 1,4-dithiols and the aromatic 1,2-benzenedithiol. Rate coefficients and product branching ratios for this wide variety of reacting partners provide information on the influence of the following: (1) geometry about the central atom of the Lewis acid, (2) identity of the ligand anion donor atoms, (3) ligand flexibility, (4) ligand chain length, (5) substituent effects, (6) chelate ring size, (7) steric effects, (8) internal hydrogen-bonding in the Lewis acid-anion complex, and (9) internal hydrogen-bonding in the free ligand anion.

The reactions examined fall into three general classes: (1) those in which both monodentate and bidentate products are formed, (2) those in which only monodentate product is formed, and (3) those in which monodentate product and the oxide (BF_2O^- or SiF_3O^-) product are formed. The aromatic 1,2-diol anions and the saturated, unsubstituted 1,2- and 1,3-diol anions fall into the first category; these reactions result in formation of both monodentate addition product and bidentate chelation product. In marked contrast, none of the sulfur-donor ligand anions form bidentate product and, except in the case of the 1,2-ethanedithiol anion reaction, the sole primary products are the monodentate anion species, placing these reactions in the second category. Reactions of the aliphatic, substituted 1,2- and 1,3-diol anions as well as that of the anion of 1,4-butanediol belong to the third class in which the monodentate addition product and the oxide anion are formed. These reactions bear a striking similarity to reactions of the simple HO^- and CH_3^- reactions with BF_3 and SiF_4 .

For those reactions where both monodentate and bidentate anion products are formed, evidence indicates that the processes are occurring on a double-well potential energy surface in which the first well represents the monodentate anion and the second well represents the bidentate anion associated with the neutral HF molecule which subsequently is expelled. The height of the

barrier between the two potential minima is reflected in the branching ratios of the two product species. Results suggest that the geometry around the Lewis acid center as well as the size, flexibility, and degree of substitution of the ligand anion are factors which affect chelation and the extent to which it occurs. The ring closure mechanism appears to be facilitated by the presence of an intramolecular hydrogen-bond between the -OH proton and one of the fluorines of the Lewis acid in the adduct. Furthermore, inductive effects have a minimal effect on both the rate coefficients and the product branching ratios. Optimum geometries and single point energies for several of the Lewis acid/ligand anion pairs were obtained from *ab initio* calculations using extended basis sets. The results support this mechanistic picture and overlap population analyses point to hydrogen-bonded interactions as important.

Formation of the oxide anion product occurs where substituent effects or the length of the chain between donor groups in the ligand anion disfavor formation of an internal hydrogen-bond in the monodentate species; one such example is the reaction of the anion of 1,4-butanediol with both SiF_4 and BF_3 . The oxide anions BF_2O^- and SiF_3O^- produced in these reactions are the same products observed in the reactions of BF_3 and SiF_4 with both HO^- and CH_3^- , and indicate that, for this group of ligand anions, the effect of the second oxygen donor atom is negligible.

From our studies of this interesting group of reactions, the following summary points can be made: (1) hydrogen-bonding in Lewis acid-bifunctional anion complexes is important in subsequent formation of bidentate anion products, (2) where this hydrogen-bond is disfavored, either the monodentate species is the only product, or the oxide product is observed, (3) where both mono- and bidentate products form, the ratio of bidentate product to monodentate product is larger for the SiF_4 reactions relative to those for BF_3 indicating that the geometry about Si results in a less strained transition state, (4) steric hindrance and long chains may prevent hydrogen-bonding and thus orientation of the second attacking group, making anions with these properties behave like the simple hydroxide and methoxide anions, (5) rates of reaction do not vary with nucleophile, and these reactions occur at significant fractions (70 - 100%) of their corresponding collision rates, and (6) calculations show that the absence of bidentate anion formation in the reactions of the dithiolate anions may be due to energetic factors because reactions to form the bidentate anion plus HF are close to thermoneutral; however, the inability of sulfur to participate in strong hydrogen-bonding and its steric constraints as a result of its size may also be important factors.

PROTONATION ON PHENOXY OXYGEN IN METHANE CHEMICAL IONIZATION OF PROPOXYBENZENE

Richard W. Kondrat, Kyuseok Song, Dion A. Stams, and Thomas Hellman Morton

Department of Chemistry, University of California, Riverside, CA 92521

The predominant decomposition pathway for n-propyl phenyl ether under a variety of ionization conditions takes place via ion-molecule complexes. This is true from both electron-removal processes (Field Ionization Kinetics, Electron Impact, or Resonant Multiphoton Ionization, all of which generate $M^{+\bullet}$) and from chemical ionization. For the isotopically labelled compounds 1 and 2 the scrambling ratios (defined as the geometric mean of $PhOH^{+\bullet}/PhOD^{+\bullet}$ from 1 $^{+\bullet}$ and $PhOD^{+\bullet}/PhOH^{+\bullet}$ from 2 $^{+\bullet}$) are all greater than 2.0. Scrambling ratios for other

isotopically substituted variants are calculated from values in the literature, as summarized in the table. Scrambling ratios for CD_4 CI are also shown (the geometric mean of $C_6H_6DO^+/C_6H_5D_2O^+$ from 1 $+D^+$ and $C_6H_5D_2O^+/C_6H_6DO^+$ from 2 $+D^+$) as well as for other isotopic variants reported for other reagent gases.

Predicted for:	Scrambling Ratio	Observed for (this work):	Scrambling Ratio	k.i.e.

FIK (10^{-11} s) ¹	2.7			
" (10^{-8} s) ¹	3.0			
" (10^{-5} s) ¹	3.8			
EI (70 eV) ²	2.9	EI MIKES	4.3	1.15
CI (methane) ²	4.0	CI MIKES	3.6	1.38
" (isobutane) ²	4.9	(methane-d ₄ reagent gas)		

We find that CI MIKES and EI MIKES give nearly the same scrambling ratios, consistent with formation of an ion-molecule complex that contains isopropyl cation, which partially scrambles its hydrogens before transferring a proton to its neutral partner in the ion-molecule complex. The kinetic isotope effect for this proton transfer tells if it takes place to oxygen or to carbon. The data suggest it is to carbon; hence initial CI (as seen by MIKES) must be on oxygen.

1. F. Borchers, K. Levsen, and H.D. Beckey, *IJMSIP* (1976) **21**, 125-132.
2. F.M. Benoit and A.G. Harrison, *Org. Mass Spectrom.* (1976), **11**, 599-608.
3. D.J. McAdoo, F.W. McLafferty, and P.F. Bente III, *JACS* (1972) **94**, 2027-2033.

SCHEME I

The CI MIKES spectrum of 1 with CD_4 reagent gas shows evidence for exchange of the D^+ deposited by the CI with the propyl sidechain. This exchange is revealed by the formation of $\text{m/z } 95$ with an intensity about 10% that of the $\text{m/z } 96$ intensity. This can be rationalized in terms of the interconversion of ion-molecule complexes (the species drawn in brackets) depicted in Scheme I above. One prediction of this scheme is that if the alkyl cation maintains the isopropyl structure without scrambling its hydrogens, then this interconversion cannot lead to exchange of D for H in the CD_4 CI of compound 2. As portrayed by Scheme II below, the formation of $\text{CD}_3\dot{\text{C}}\text{HCD}_3$ prevents formation of $\text{m/z } 95$.

SCHEME II

As predicted by this mechanism, no $\text{m/z } 95$ is observed from the CD_4 CI of 2 in the MIKES. Scheme I works equally well if the neutral $\text{C}_6\text{H}_5\text{DO}$ in the first ion-molecule complex is PhOD or if it has a cyclohexadienone structure with the D attached to the sp^3 carbon. On thermodynamic grounds we believe that the $\text{m/z } 96$ and 97 product ions are ring-protonated phenols. If the neutral partner in the ion-molecule complexes has the cyclohexadienone structure, this results from H^+ or D^+ transfer to an oxygen lone pair. If the neutral partner is PhOD , then the transfer is to an sp^2 carbon. Since the latter reaction has a rehybridization barrier, a larger kinetic isotope is to be expected. For comparison, k.i.e.'s for M^{++} decompositions (where the transfer occurs to the oxygen lone pair of $\text{PhO}^{\cdot}$, which has nearly the same proton affinity as phenol) have been measured. The k.i.e. from 70 eV EI is 1.30,² while we measure values less than or equal to that for a variety of electron removal conditions. The scrambling ratio measures the internal energy of the ion-molecule complexes,³ so EI MIKES and CI MIKES have nearly the same energy. The former k.i.e. is much larger than the latter.

Observation of Diazonium Ion-Crown Ether Molecular Complexes in the Gas Phase by Field Desorption (FD) and Fast Atom Bombardment (FAB) Mass Spectrometry. Khosrow Laali*, Department of Chemistry, Kent State University, Kent, OH 44242 and Robert P. Lattimer, the BF Goodrich R&D Center, Brecksville, OH 44141.

Although host-guest complexation between diazonium salts and crown ethers is quite well documented in solution through kinetic, thermodynamic and spectroscopic studies [1-4], the extent and mode of this interaction in the gas phase has not been addressed. We have recently shown that fragile carbocation and carbodication salts as well as onium ions can be ejected and intact mono-cations observed by desorption-ionization techniques [5]. Intact dication ejection was also achieved with several dication salts [6]. In relation to these studies, we utilized FD-and FAB-MS to study diazonium/crown complexation and to provide the first comparison with the condensed phase studies. The results are summarized in Table I.

Solution stability of diazonium/crown complex is strongly dependent on both electronic and steric factors. Whereas electron withdrawing groups increase the diazonio character and favor complexation, electron donating groups enhance the diazo character of the bond, hence, weaken complexation. The accepted host-guest model for $\text{ArN}_2^+/\text{crown}$ in solution is an insertion complex (IC), for which one x-ray structure is already available, whereas a charge transfer model (CT) was proposed for the anilinium ion/crown complex [2,7]. Kinetic studies on dediazonation of crown-complexed diazonium ions [8] showed that the mechanism of dediazonation remains the same i.e. a tight aryl cation/nitrogen molecule pair is involved. This intermediate is, however, too large to fit inside the cavity of the crown in an IC model; a CT model satisfactorily explains the kinetics. IR and UV band shifts observed upon complexation of diazonium ions with crowns is the opposite to the order established based on equilibrium constants for binding i.e. maximum band shifts are seen with larger, more flexible, crowns. This is explained through crown puckering and pi acid/sigma base interactions in a molecular cluster [4].

We have investigated crown complexation with various diazonium salts. Apart from $\text{ArN}_2^+/\text{Crown}$ 1:1 complexes, higher order complexes i.e. $\text{ArN}_2^+/\text{Crown}$ 1:2 and 1:3 were also observed. Neither the ortho steric crowding on the diazonium ion nor peri interactions prevented cluster ion detection. The mode of complexation is suggested to be via CT interactions. Pi acid/sigma base interactions between the oxygen lone pairs and the aromatic pi system could be responsible for higher order cluster ion formation, generating "encapsulated" diazonium ions. We utilized FAB/MS-MS (Table II) to examine the nature of this interaction in a 1:1 cluster with 18-Crown-6. The ions corresponding to the 1:1 complexes were mass selected and subjected to CAD analysis. Apart from ArN_2^+ and Ar^+ (impact dediazonation), ions corresponding to $(\text{crown}+\text{H})^+$ and $(\text{crown}-\text{H})^+$ were observed. Crown protonation is explained via a benzyne mechanism, and $(\text{crown}-\text{H})^+$ ion detection via hydride abstraction by N_2 (see schemes).

DIFFERENCES IN THE MECHANISMS OF PARENT-MOLECULAR ION FORMATION IN CHEMICAL IONIZATION AND FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Qingmei Zha and Michel J. Bertrand

Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal Canada H3C 3J7

Fast atom bombardment (FAB) and chemical ionization (CI) are ideal techniques for the determination of the molecular masses of organic compounds because protonated molecular ions are usually generated under both conditions. Whether the protonation processes occurring in FAB and CI are the same has been a topic of interest since the development of FAB desorption-ionization. It was suggested initially¹ that FAB mass spectra are really produced by ion-molecule reactions in gas phase. FAB is a chemical ionization process with the matrix acting as the reagent gas. Alternatively, it was also postulated^{2,3} that ions observed in FAB mass spectra are the dissociation products of the precursors preformed in the matrix solution or of clusters ejected from the solution.

In our recent studies on the origin of predominant $[M-H]^+$ ions observed in both FAB and CI mass spectra of some derivatized sugars, it appears that simple hydride abstraction in gas phase can be used to describe the formation of $[M-H]^+$ ions in CI, but may not apply to FAB. Furthermore, the different mechanisms for the formation of parent-molecular ions occurring during FAB and CI conditions could be revealed from the exceptions, i.e. the major peaks observed in the molecular ion region are $[M-H]^+$ rather than $[M+H]^+$. We report in this paper on the different protonation processes observed in positively charged FAB and gas phase CI mass spectra for some acetal samples. The predominant peaks in the molecular ion region are $[M+H]^+$ in methane, isobutane and ammonia CI spectra while they are $[M-H]^+$ in the FAB spectra.

The FAB mass spectra of compound 1 and 2 are shown in Fig. 1. At first, these spectra caused confusion for the assignment of the molecular masses since the peaks in the molecular ion region were two mass units lower than expected from the protonated molecular ions. After confirming the structures of these compounds, it was realized that the observed parent-molecular ions were $[M-H]^+$. In order to determine the protonation properties of these compounds, their CI mass spectra were also recorded using methane, isobutane and ammonia as reagent gases. Interestingly, the CI mass spectra (Fig. 2) showed that the protonated molecular ions $[M+H]^+$ were observed to be the predominant peaks. The differences in parent-molecular ions observed in FAB and CI may imply that different mechanisms are involved in the generation of both types of mass spectra.

The major fragment ions observed in FAB and CI spectra of acetals are also different. An ion of m/z 107 is observed as the most abundant fragment ion in CI spectra of both samples. A plausible structure for this fragment ion is the benzyloxy ion $C_6H_5CH_2O^+$. This ion is, however, not observed as a major fragment ion in the FAB spectra. The most intense fragment ion under FAB conditions is m/z 105 whose structure is probably the benzoyl ion $C_6H_5CO^+$. Based on our observations, the major reaction pathways for sample 1 in FAB and CI are presented in Scheme 1. In CI, protonation occurs in gas phase by ion-molecule reactions and the protonated molecular ions in turns dissociate to form the benzyloxy ion (m/z 107). Protonation in FAB may differ from that in CI and may occur in solution through intermolecular hydrogen bonding. The protonated molecular ions, if formed in solution, are highly unstable in comparison with that in gas phase and readily form $[M-H]^+$ ions by elimination of hydrogens. This would explain why $[M+H]^+$ ions are essentially absent in the FAB spectra and that the predominant peaks correspond to $[M-H]^+$. The presence of benzoyl ions at m/z 105, produced by the dissociation of the $[M-H]^+$ ions, would also be consistent with the proposed reaction pathway.

It is not difficult to reach a conclusion that acetal samples may undergo different protonation processes under FAB and CI ionization conditions. In both cases, there seems to be a competition between the formation of $[M+H]^+$ and $[M-H]^+$ ions. Ion formation and fragmentation in the gas or liquid phases may be the origin of different mass spectral behaviors. Acetals are easily protonated in CI by ion-molecule reactions occurred in the gas phase, and the fragmentation behavior depends on their internal energies since the $[M-H]^+/[M+H]^+$ ratio varies with different reagent gas. It is unlikely that the generation of FAB mass spectra of acetals can simply be explained by gas phase processes since they differ from the CI data both in the type of parent-molecular and fragment ions and appear to show a different energy behavior.

MECHANISMS OF THERMALLY ANALOGOUS COLLISION-INDUCED CHARGE-REMOTE FRAGMENTATIONS

M. J. Contado and J. Adams: Department of Chemistry, Emory University, Atlanta, GA 30322.
N. J. Jensen and M. L. Gross: Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0362.

Charge-remote fragmentations of closed-shell ions are a new class of gas-phase ion decompositions that are of special interest analytically because they provide a useful mass spectrometric technique for determining structures of a variety of large biomolecules. Recently, Adams and Gross¹ showed that metastable ion and collision-induced decompositions (CIDs) of some β -hydroxy olefin fatty acid ions undergo charge-remote fragmentations by mechanisms that are directly analogous to thermolytic decompositions of neutrals. Here, we report other thermally analogous mechanisms for charge-remote CIDs of monounsaturated fatty acid ions.

The formation of fragment ions *b* and *c* (Fig.1), representing cleavages allylic to the double bond, were investigated using deuterium labelling, MS-MS, and B/E linked scan experiments. CID spectra of $(M+2Li-H)^+$, $(M+Li)^+$, and $(M-H)^+$ ions of *cis*-9-octadecenoic acid, *cis*-9-octadecenoic-9,10-*d*₂ acid, *cis*-7-dodecenoic acid, *cis*-7-dodecenoic-4,4-*d*₂ acid, and *cis*-7-dodecenoic-11,11-*d*₂ acid were acquired by performing both B/E linked scans and MS-MS experiments (VG 70-S at Emory University and MS-50 Triple Analyzer at University of Nebraska).

Fig.1 CID spectra of $(M-H)^+$ ions of *cis*-7-dodecenoic acid acquired by using B/E linked scans (VG 70-S, Emory).

A 1,4-elimination of H_2 and $C_4H_{2n}^2$ was previously invoked by others³ to account for the formation of fragment ions *b* and *c* (Fig.1). However, this mechanism requires transfer of vinylic hydrogens that would be energetically less favorable than the 1,4-eliminations that occur elsewhere along the alkyl chain, and would thus not account for the higher relative abundances. In contrast, CID spectra of $(M-H)^+$ ions of *cis*-9-octadecenoic-9,10-*d*₂ acid *cis*-7-dodecenoic-4,4-*d*₂ acid provide evidence that allylic cleavage on the carboxylic side of the double bond arises by a retro-ene mechanism (eqn.1). This reaction is analogous to the thermal

retro-ene, which has first-order kinetics, large negative entropies⁴, and describes reactions such as the thermal isomerization of methyl vinyl cyclopropane^{4c}.

The CID spectra of $(M-H)^+$ ions of *cis*-7-dodecenoic-11,11-*d*₂ acid provide evidence that the cleavage allylic

to the double bond on the alkyl terminus occurs by a different mechanism. A 1,4-conjugate elimination (eqn.2) is proposed that accounts for the formation of the fragment ion of m/z 153. 1,4-Conjugate eliminations are classic pyrolytic decompositions that involve losses of H-X from X-C-C=C-C-H systems, and are believed to occur via a concerted (large negative entropies of activation) as opposed to a diradical mechanism^{4a,5}.

CID spectra of (M-H)⁻ ions of monounsaturated ions also show an odd-electron fragment ion, b' (Fig.1), which was previously suggested to be a distonic species and also was reported to occur by metastable ion decompositions³. However, here we do not observe this radical anion in metastable ion decomposition spectra acquired either by using the VG 70-S or by using the MS-50 Triple Analyzer. Deuterium labelling indicates that this ion arises by a homolytic bond cleavage, remote from the site of charge, to give a distonic species that contains a stable, allyl radical site. Such a charge-remote homolytic cleavage is a direct analogy to the thermolytic homolytic cleavage of 1-butene to give an allyl radical⁶.

Mechanisms proposed here for CIDs of closed-shell fatty acid ions invoke charge-remote eliminations that are analogous to thermolytic decompositions of neutral molecules. These elimination mechanisms are in accord with the charge-remote thermal-like mechanisms presented previously for metastable ion decompositions of β -hydroxy olefinic closed-shell ions¹. We do not understand the preferential occurrence of each mechanism on either side of the double bond. It could be a result of product ion stability or of indirect electronic effects of the charge-site through the alkyl chain.

COLLISION-INDUCED DISSOCIATION OF MULTIPLY-CHARGED DIATOMIC CATIONS

Kevin L. Harbol and Robert W. Kiser

Department of Chemistry
University of Kentucky
Lexington, KY 40506-0055

The ion translational spectroscopy of S_2^{3+} , Se_2^{3+} , Te_2^{3+} , SeS^{3+} , Cl_2^{3+} , Br_2^{3+} , I_2^{3+} , $BrCl^{3+}$, IBr^{3+} and the corresponding doubly-charged ions was investigated. In previous studies, the appearance energies of these ions were found to be in the region of 50 to 62 eV. The experimental work of this investigation was completed on a VG ZAB-2F mass spectrometer. Doubly-charged and triply-charged diatomic ions were produced by electron impact ionization at 100 eV ionizing energy. The acceleration potential was normally set at 8 kilovolts. When the ion intensity permitted, lower accelerating energies were used in order that product ions of very high translational energy could be transmitted through the E-sector. Helium was employed as the collision gas, and yielded the best collision efficiency of all other collision gases. Variable potential on the collision cell in the second field-free region of the instrument permitted authentication of the collision reactions.

All the data reported here was obtained using the mass-analyzed ion kinetic energy (MIKE) spectrometry technique. For a simple, direct fragmentation process such as:

the kinetic energy release T can be calculated from the ΔE_2 , the width of the CID peak corresponding to the observation of the m_2^{y+} ion by the relationship:

$$T = \frac{y^2 m_1^2 V_a}{16 \times m_2 m_3} \left(\frac{\Delta E_2}{E_0} \right)$$

where V_a is the accelerating potential and E_0 is the E-sector voltage transmitting the main beam of ions, m_1^{x+} . From the kinetic energy release, a charge separation distance $r(\text{\AA})$ can be calculated from the coulombic energy of repulsion $\phi(r)$ relationship:

$$\phi(r) = - \frac{e^2}{4\pi\epsilon_0 r}$$

where e is the electronic charge, 1.602×10^{-19} C, ϵ_0 is the permittivity of a vacuum, 8.854×10^{-12} J⁻¹ C² m⁻¹, and r is the interchange separation in meters. One can then calculate r directly from the relationships:

$$r(\text{\AA}) = \frac{14.40}{T} : \text{ for the doubly-charged ions.}$$

$$r(\text{\AA}) = \frac{28.80}{T} : \text{ for the triply-charged ions.}$$

where T is the kinetic energy release in electron volts.

Kinetic energy release and charge separation values for the doubly-charged and triply-charged diatomic ions in this study are given below:

	KER(eV)	r(Å)		KER(eV)	r(Å)
S ₂ ³⁺	11.60	2.49	S ₂ ²⁺	6.71	2.15
SeS ³⁺	10.75	2.73	SeS ²⁺	5.87	2.45
Se ₂ ³⁺	10.47	2.75	Se ₂ ²⁺	4.72	3.05
Te ₂ ³⁺	9.27	3.11	Te ₂ ²⁺	4.62	3.12
Cl ₂ ³⁺	12.76	2.26	Cl ₂ ²⁺	6.86	2.10
BrCl ³⁺	13.10	2.20	BrCl ²⁺	6.13	2.35
Br ₂ ³⁺	9.30	3.09	Br ₂ ²⁺	7.70	1.87
IBr ³⁺	9.28	3.10	IBr ²⁺	5.31	2.71
I ₂ ³⁺	9.10	3.16	I ₂ ²⁺	5.04	2.86

One of the most significant results obtained in this study was the absence of any observable unimolecular fragmentation of the triply-charged ions. Other triply-charged ions were sought from combinations of atoms in the Group VI and Group VII elements i.e.: SCl, SeBr, TeI, etc. No triply-charged ions for these combinations were found. Atom superposition electron delocalization (ASED) calculations were completed for all the ions of study and for the Group VI - Group VII combinations. ASED predicts bond distances for the Group VI - Group VII combinations to be smaller than to the comparable Group VI or Group VII homonuclear diatomics. It is believed that the Group VI- Group VII diatomics encounter a dissociative level before undergoing triple ionization.

THE ROLES OF GAS-PHASE BASICITY AND SURFACE ACTIVITY IN THE FORMATION OF FAB MASS SPECTRA^{*}, T. Keough and M.P. Lacey, The Procter and Gamble Co., Miami Valley Laboratories, PO Box 398707, Cincinnati, OH 45239-8707.

It has been previously shown, for equimolar two-component mixtures, that the component with the higher gas-phase basicity (GB) generally dominates the static FAB mass spectrum¹. This observation has led to the development of a gas-collision model²⁻⁴ which states that initially desorbed ions and neutrals participate in gas-phase reactions, such as recombination and proton transfer, that ultimately determine which ions are detected in FABMS. On the other hand, it is well-known that FABMS response is strongly influenced by condensed-phase phenomena such as analyte surface activity (SA)^{5,6} and pre-forming ions in solution⁷⁻⁹. The purpose of this study is to gain some perspective on the relative importance of some of the factors effecting FABMS response.

Experimentally, we analysed equimolar mixtures of monoalkylammonium salts (A). The long alkyl chain largely determines the SA while the head group

largely determines the GB. Trimethylammonium chlorides (R's=CH₃, TMAC's) of varying chain length were used to study the effects of SA. GB differences are virtually eliminated because the TMAC's have identical head groups with no labile protons and no basic sites capable of accepting protons. Dodecylammonium chlorides were used to study the effects of GB. By varying the surfactant head group from -NH₃Cl to -N(CH₃)₃HCl, the GB of the corresponding free amines increase by about 12.5 kcal mol⁻¹. However, the SA's remain nearly identical since the long alkyl chain length is held constant. Variation in relative FABMS response as a function of analysis time, preference factors¹ and suppression factors¹ were experimentally determined for analytes of both low and high SA. Furthermore, some competitive experiments were conducted to directly assess the relative importance of SA and GB effects.

The TMAC's are very surface active as evidenced by their relatively large preference factors, Table 1. Analysis of an equimolar mixture (0.1 mol%) of C₈, C₁₂ and C₁₆TMAC showed that SA differences can lead to large variations in relative response as a function of analysis time. At first, the most SA component of the mixture (C₁₆TMAC) is preferentially detected. As it is depleted, the responses of the less SA components increase. This should be contrasted with the much more modest variation in relative response, as a function of analysis time, that is produced by a difference in GB of about 12.5 kcal mol⁻¹, Figure 1. The FAB spectra of an equimolar (0.1 mol%) mixture of dodecylammonium chloride and dodecyldimethylammonium chloride show only a minor time-dependent variation that may result because of slight differences in the SA's of the head groups. Similarly, the FABMS preference factors (Table 1) show a strong dependence on SA. The pfs increase by a factor of almost 70 from C₈ to C₁₆TMAC. However, in the absence of SA effects, a GB difference of 12.5 kcal mol⁻¹ changes the relative pfs by less than a factor of 2 (Table 1, hexyl and dodecylammonium chlorides). FABMS suppression factors also show a strong dependence on SA. The suppression factor between C₈ and C₁₆TMAC is 50-fold while that between dodecylammonium chloride and dodecyldimethylammonium chloride is only a factor of 3. These results suggest that, for very surface active compounds, SA effects can dominate GB effects on FABMS response. This conclusion is reinforced by the results obtained in some competition experiments summarized in Table 2. The first mixture establishes the suppression factor between two alkylammonium salts differing in alkyl chain length (SA) by six -CH₂- groups. Mixture 2 shows that the corresponding suppression factor, resulting from a difference in GB of 12.5 kcal mol⁻¹, is an

order of magnitude smaller. Mixtures 3 and 4 illustrate that the effects are cooperative. Note that in mixture 4, hexyldimethylammonium chloride is suppressed even though its GB is greater than that of dodecylammonium chloride.

The previously reported¹ suppression factor of ammonium chloride by aniline hydrochloride is $R=3.7$. We have attempted to estimate the contribution of SA effects to this overall suppression by analysis of a series of equimolar solutions of tetramethylammonium chloride and phenyltrimethylammonium chloride, Figure 2. From the solution containing 10 mol% of each analyte, we calculate a suppression factor of 2. We conclude that even for analytes of low surface activity, SA effects may still be as important as GB effects. In general, it will be difficult to accurately assess the effect of any single factor on FABMS response. All factors, including GB, SA, relative solubilities, sampling efficiencies, etc. will have to be evaluated.

*This work is dedicated to the memory of David E. Chapman.

Table 1 Summary of FAB/MS preference factors

Compound	X	Preference Factor
NX_4Cl	H	20 ¹
	CH_3	42 ^a
PhNX_3Cl	H	37 ¹
	CH_3	88 ^a

UNIMOLECULAR DISSOCIATION OF METASTABLE $\text{Mn}_2(\text{CO})_{10}^+$ IONS
WEN YU, XIANGQIU LIANG, AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON HOUSTON, TX 77204-5641

INTRODUCTION: Metastable $\text{Mn}_2(\text{CO})_{10}^+$ ions have been studied using tandem mass spectrometry. The unimolecular dissociation rate constants of $\text{Mn}_2(\text{CO})_{10}^+$ produced under different ionization/excitation conditions are reported. The RF-only quadrupole ion guide of a tandem mass spectrometer is shown to be suitable for studying the kinetics of unimolecular dissociation of metastable ions. It provides a variable and relatively long ion residence time (10^{-5} - 10^{-3} sec). It is possible to correlate the unimolecular dissociation rate constants with the internal energy distribution of metastable ions by theoretical calculation using the threshold energy obtained from collision-induced dissociation (CID).

EXPERIMENTAL: The $\text{Mn}_2(\text{CO})_{10}^+$ ions were generated by electron ionization of $\text{Mn}_2(\text{CO})_{10}$ vapor. Mass-selected ions were injected into an RF-only quadrupole ion guide via a series of retardation lenses. The ion kinetic energy on entering the RF-only quadrupole can be adjusted such that the ion resident time is varied. The translational energy distribution of the ion beam was calculated from the first derivative of the curve of total ion current vs E_c , where $E_c = V_s - V_c$, where V_s and V_c are the potentials of the ion source and collision quadrupole. The peak of distribution curve was chosen as the zero-point of ion kinetic energy. The RF level of the quadrupole ion guide was carefully controlled to minimize its effect on primary ion transmission efficiency. The RF level is proportional to $E_T^{1/2}$ ($E_T = V_c - V_{c0}$) under optimized tuning. Argon gas was used as the collision gas in the CID experiment. The number density of the gas inside collision cell was calculated from the gas pressure outside the quadrupole chamber and the gas conductance through the collision cell apertures. The effective length of quadrupole ion guide was taken as 12.5 cm. No compensation for E_T was made.

RESULTS AND DISCUSSION: An ion beam has a translational energy distribution function $i(V_c)$. When such an ion beam passes through the ion guide, the first-order kinetics become

$$i(V_c) = i_0 \exp \{ (V_c - V_{c0})^2 / 2\gamma^2 \} \quad (1)$$

$$I_p / (I_p + \Sigma I_{Fi}) = \{ \int_{V_{c0}}^{\infty} i(V_c) \exp(-k_T t) dV_c \} / \{ \int_{V_{c0}}^{\infty} i(V_c) dV_c \} \quad (2)$$

where i_0 and γ are empirical constants and I_p and I_{Fi} are the ion intensities.

Within the time window from 10^{-5} to 10^{-4} sec, the translational energy spread of the ion beam has little effect. The rate constants can be calculated from a plot of $\ln(I_0/I_p)$ versus t and I_{Fi}/I_0 versus $\{1 - \exp(-k_T t)\}/k_T$.

TABLE 1. Unimolecular Dissociation Rate Constants of $\text{Mn}_2(\text{CO})_{10}^+$							
Rate constants (s^{-1})	423K			473K			523K
	30 eV	50 eV	70 eV	30 eV	50 eV	70 eV	30 eV
Total	2300	2200	2400	2600	3300	3500	3400
→ $[\text{Mn}(\text{CO})_5]^+$	2100	2000	2300	2400	3000	3300	3100
→ $[\text{Mn}_2(\text{CO})_9]^+$	160	89	190	170	160	200	200
→ $[\text{Mn}(\text{CO})_6]^+$	78	83	72	100	210	160	130

The value of unimolecular dissociation rate constant increases as the temperature increases. This indicates that the internal energy of the ions reflects the temperature of the neutral parent compound. The ionizing electron energy also has an effect on the dissociation rate constants. Within the electron energy range shown above this is smaller than temperature effect.

COLLISION-INDUCED DISSOCIATION: With argon gas in the quadrupole ion guide, the collision-induced dissociation (CID) of $\text{Mn}_2(\text{CO})_{10}^+$ can be studied. Under ideal conditions, the CID cross section $\sigma(E)$ should have the energy dependence described by

$$\sigma(E) = \sigma_0 (E + E_{\text{int}} - E_0)^n / E \quad (3)$$

where E_0 is the threshold energy for CID and E_{int} is the internal energy of the ions.

Figures 1 and 2 show the energy dependence of the CID cross section for $\text{Mn}_2(\text{CO})_{10}^+$. The value $(E_{\text{int}} - E_0)$ for the fragments was obtained by fitting the experimental data to a theoretical model. The ions were produced using 12 eV ionizing electrons and $T = 473\text{K}$.

Fig. 1: Energy Dependence of the CID cross section for $\text{Mn}_2(\text{CO})_{10}^+$

Fig. 2: Energy Dependence of the CID cross section for $\text{Mn}_2(\text{CO})_{10}^+$

INTERNAL ENERGY: An RRKM calculation was performed in order to correlate the unimolecular dissociation rate constant with the internal energy of the ions at the point at which they enter the quadrupole ion guide. The basic expression of $k(E)$ given in RRKM theory is

$$k(E) = \alpha G(E^+)/hN(E^*) \quad (4)$$

The sum of states $G(E^*)$ in the transition state is evaluated by direct computer counting since an analytical approximation has a large error when E^* is small. The density of states $N(E^*)$ of excited ions were calculated using a Whitten-Rabinovitch approximation. The vibrational states of $\text{Mn}_2(\text{CO})_{10}^+$ were assigned to be the same as its neutral analog. The vibrational frequencies of the transition states were chosen as the mean of initial reactants and final products. We assumed that the internal energy distribution of ions is narrow enough that only a discrete value of E_0 contributes to the unimolecular dissociation and CID significantly so that

$$k_{\text{uni}} = \langle k(E) \rangle = k(E_{\text{int}}) \quad (5)$$

When the unimolecular dissociation rate constant and energy dependence of the CID cross section were measured under the same ion beam conditions, the apparent CID threshold value E_0' can be used in an RRKM calculation. Hence, the internal energy of the ions can be obtained. Once the internal energy of the ions was known, the CID threshold energy E_0 of the ions can be obtained.

TABLE 2. Results of RRKM Calculations

	$\text{Mn}(\text{CO})_5^+$	$\text{Mn}(\text{CO})_6^+$	$\text{Mn}_2(\text{CO})_9^+$
$k_i (\text{s}^{-1})$	221.7	7.06	-

TABLE 3. Dissociation Thresholds

Fragment	$E_0' (\text{eV})$	$E_0 (\text{eV})$
$\text{Mn}(\text{CO})_4^+$	0.32	1.12
$\text{Mn}(\text{CO})_5^+$	-0.20	0.60
$\text{Mn}(\text{CO})_6^+$	-0.05	0.75
$\text{Mn}_2(\text{CO})_5^+$	0.53	1.33
$\text{Mn}_2(\text{CO})_6^+$	0.39	1.19
$\text{Mn}_2(\text{CO})_7^+$	0.19	0.99
$\text{Mn}_2(\text{CO})_9^+$	-0.15	0.65

CONCLUSIONS: The unimolecular dissociation of metastable $\text{Mn}_2(\text{CO})_{10}^+$ was observed in the RF-quadrupole ion guide of tandem mass spectrometer. Unimolecular dissociation rate constants were reported for the ions produced using various ionization/excitation conditions. Dissociation kinetics (ion resident time = 10^{-5} to 10^{-3} sec) have been examined. The translational energy spread of the ion beam was shown to be responsible for a nonlinear deviation when $t > 10^{-4}$ sec. Collision-induced dissociation of $\text{Mn}_2(\text{CO})_{10}^+$ was investigated using tandem mass spectrometry. The energy dependence of the CID cross section was used to obtain the threshold energy ($E_0 - E_{\text{int}}$) which then was used in a RRKM calculation. RRKM theory was used to relate the unimolecular dissociation rate constant to the internal energy of metastable ions. The CID threshold energies corrected for ion internal energy were reported.

MASS SPECTROMETRY OF RHODIUM CHELATES: HYDROGEN TRANSFER DURING ION DECOMPOSITION.

John B. Westmore and Gary A. Stern, Department of Chemistry,
University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2

Introduction. Bidentate β -ketoenolate and monothio- β -ketolate ligands (L) react with rhodium(III) to form stable, neutral complexes (RhL_3) that are soluble in organic solvents and can be sublimed. These d^6 complexes are diamagnetic, kinetically inert, and have structures based on a metal-centred octahedron. Our ^{19}NMR studies show that the β -ketoenolates are formed as a nearly statistical mixture of *fac* and *mer* isomers and confirm a *facial* octahedral structure for the thio complexes. Positive ion electron ionization (EI) mass spectra of the listed complexes, which have both perfluoroalkyl and phenyl substituents attached to the chelate rings, exhibit several decompositions involving hydrogen transfer. The origin of the hydrogen transferred in these reactions was determined by deuterium-labelling at the chelate ring carbon.

Experimental. Positive ion EI mass spectra of complexes, introduced on the solids probe, were recorded with a VG-7070E-HF double-focussing mass spectrometer of EB geometry, at an electron beam energy of 70 eV, a source temperature of 200°C, and an ion acceleration voltage of 6 keV. Ionic decompositions (collisionally assisted, if necessary) in the first field-free region were identified by linked scanning at constant E/B (daughter ion spectra). Exact masses of ions were measured at a spectrometer resolution of $M/\Delta M = 5000$, or higher if necessary to resolve isobaric ions. PFK was used as the mass calibrant.

Results and Discussion. The EI mass spectra are strongly influenced by the presence of S in the chelate ring, with different ion decomposition pathways being followed for $X = O$ and $X = S$. Here we focus on those reactions that involve H transfer, the most prominent of which are summarized by:

The origins of the hydrogens involved in the transfer reactions, for $n = 2$, were calculated by assuming that isotope effects in the transfer reactions are negligible. The results are summarized in the Table. Note that, in addition to the different ion species formed, there is also a dichotomy with respect to the hydrogen transfer behavior. When sulfur is present the hydrogen *lost* originates mainly from the phenyl group and the hydrogen *retained* comes mainly from the chelate ring. When sulfur is absent these preferences are reversed.

TABLE. Source (%) of hydrogen transferred in the formation of the indicated ions for complexes with $n = 2$.

Ion species	Lost from ion		Retained in ion	
	phenyl	chelate ring	phenyl	chelate ring
$X = S$				
$[Rh(L-H)]^+$	~93	~7		
$[SRh(L-H)]^+$	~82	~18		
$[SRhL+H]^+$			20±10	80±10
$X = O$				
$[Rh(L-HCO)]^+$	~42	~58		
$HRhL^+$			~65	~35
$[HRhC_6H_5]^+$			~82	~18
$[HRh(CO)(C_6H_5)]^+$			~79	~21

In the mechanisms proposed below for some of these reactions, we observe a greater tendency for H migration to Rh when X = O (schemes D - F) than when X = S (schemes A - C).

INTRODUCTION

With β -ketoenolate ligands (L) iridium forms stable, neutral complexes (IrL_3) that are soluble in organic solvents and can be sublimed. The IrL_3 (d^6) complexes are diamagnetic, kinetically inert and have a structure based on a metal-centered octahedron. The three titled complexes are hereinafter referred to as $\text{Ir}(\text{acac})_3$, $\text{Ir}(\text{tfa})_3$ and $\text{Ir}(\text{hfa})_3$. We have shown by ^{19}F NMR spectrometry that $\text{Ir}(\text{tfa})_3$, which has unsymmetrical ligands, is formed as a nearly statistical mixture of *mer* and *fac* isomers. There is only one possible geometrical isomer for $\text{Ir}(\text{acac})_3$ and $\text{Ir}(\text{hfa})_3$ since each has symmetrical ligands.

	R_1	R_2
$\text{Ir}(\text{acac})_3$	CH_3	CH_3
$\text{Ir}(\text{tfa})_3$	CH_3	CF_3
$\text{Ir}(\text{hfa})_3$	CF_3	CF_3

EXPERIMENTAL

Synthesis. All three iridium chelates were prepared by a modified procedure of Davignon *et al*.^{1,2} On purification by fractional sublimation, yellow $[\text{Ir}(\text{acac})_3]$ and $[\text{Ir}(\text{tfa})_3]$ and orange $[\text{Ir}(\text{hfa})_3]$ crystalline products were obtained. These were characterized by mass, ^1H and ^{19}F NMR spectrometries. Deuteration of Hacac at the bridging carbon atom was achieved by mixing it with CH_3OD containing DCl . From this the iridium complex was then prepared as above except that all necessary reagents were replaced by their deuterated analogues.

Mass spectrometry. Positive ion electron ionization mass spectra of complexes, introduced by the direct insertion probe, were obtained with a VG-7070E-HF double-focussing mass spectrometer of EB geometry at an electron beam energy of 70eV, a source temperature of 200°C and an ion acceleration voltage of 6 KeV. Ionic decompositions (collisionally assisted, if necessary) in the first field free region were identified by linked scanning at constant E/B (daughter ion spectra). Exact masses of ions were measured at a spectrometer resolution of $M/\Delta M=5000$ or higher if necessary to resolve isobaric ions. PFK was used as the mass calibrant.

RESULTS AND DISCUSSION

The major metal-containing ions are IrL_3^+ and IrL_2^+ ; the former corresponds to the base peak for $\text{Ir}(\text{acac})_3$ and $\text{Ir}(\text{tfa})_3$, the latter for $\text{Ir}(\text{hfa})_3$. Ions of all three complexes show an overwhelming tendency to decompose by losses of even-electron neutral species, i.e. CO, CF_2 , HF, and CF_2CO for $\text{Ir}(\text{hfa})_3$; CO, CH_4 , C_2H_4 and CH_2CO for $\text{Ir}(\text{acac})_3$, and a combination of these for $\text{Ir}(\text{tfa})_3$. These preferred decompositions are attributed to iridium's preference for the +III and +IV oxidation states and of its ability to form single and multiple bonds with carbon. These consecutive losses can only be explained by initial scission of an Ir-O bond and formation of an Ir-C bond (schemes 1 and 2). Migration of a $\cdot\text{CF}_3$ or $\cdot\text{CH}_3$ group to iridium, evident by formation of ions such as LiIrCF_3^+ , $[\text{IrL}+(\text{CO})(\text{CF}_3)]^+$, LiIrCH_3^+ and $[\text{Ir}+(\text{CO})(\text{CH}_3)]^+$ would also facilitate loss of a carbonyl group. Losses of odd-electron fragments, such as $\cdot\text{CF}_3$, $\text{CF}_3\dot{\text{C}}\text{O}$, $\cdot\text{CH}_3$ and $\text{CH}_3\dot{\text{C}}\text{O}$ do occur, but almost exclusively after oxidation of Ir(III) to Ir(IV) .

To illustrate, decomposition pathways from $[\text{Ir}(\text{hfa})_2]^+$, 1, are shown in scheme 1. Formation of Ir- CF_3 and Ir-CO bonds, and loss of the even-electron fragment $\text{CF}_3\dot{\text{C}}=\text{CHO}$

yields $[\text{IrL}+(\text{CO})(\text{CF}_3)]^+$, 2. Although unconfirmed by metastable evidence, loss of F $\cdot$ from 2 would yield the fluorocarbene ion $[\text{IrL}+(\text{CO})(\text{CF}_2)]^+$, 3, containing iridium (IV). From 3, consecutive losses of CO and CF_3CO (loss of this odd-electron species indicates reduction to iridium(III)) yield LiIrCF_2^+ , 4, and $[\text{IrL}-\text{F}-\text{CO}]^+$, 5, respectively. Alternatively, when loss of CF_3CO precedes loss of CO the ions $[\text{IrL}-\text{F}]^+$, 6, and once again 5, result. This ion and its daughters undergo numerous decompositions that involve losses of even-electron species exclusively, i.e. CO, CF_2 and HF.

Scheme 2 shows decomposition pathways from $[\text{Ir}(\text{acac})_2]^+$, 1. Initial loss of CH_2CO yields 7a, which then undergoes sequential losses of C_2H_4 , CO, CO and CH_4 . The formation of the resulting ions, 8-11, is rationalized by several rearrangements, supported by the mass spectrum of the deuterated analogue of $\text{Ir}(\text{acac})_3$, that include migration of H and CO to Ir.

STRUCTURAL IMPLICATIONS REGARDING FRAGMENTATION OF 12-CROWN-4 FROM PHOTOIONIZATION MASS SPECTROMETRY.

Mehdi Molai

Department of Pharmacology, George Washington University Medical Center,
Washington, DC 20037

John Allison and George E. Leroi

Department of Chemistry, Michigan State University, East Lansing, MI 48824.

We have investigated the photoionization of the crown ether, 12-crown-4 ($C_8H_{16}O_4$). Structural information regarding fragment ions is inferred from appearance energies when combined with known thermochemical data. The fragmentation of 12-crown-4 molecular ion will be discussed in light of these results.

The photoionization mass spectrometer has been described previously (1). The hydrogen many-line spectrum, generated from a dc discharge using low pressure hydrogen, serves as the light source for these experiments. The relative photoionization efficiency (PIE = ion count/transmitted photon count) is calculated at a variety of wavelengths and plotted as a function of photon energy to produce the PIE curve.

PIE curves for twelve fragment ions were obtained and are shown in Figures 1 and 2.

Figure 1. Photoionization efficiency curves for daughter ions of 12-crown-4.

Figure 2. Photoionization efficiency curves for daughter ions of 12-crown-4.

Their appearance energies (AE) and suggested chemical compositions for ionic products are given in Table 1. The molecular ion at m/z 176 was never observed in these experiments. Heats of formation for the ions formed were obtained by combining their AEs with heats of formation of likely neutral products, when available. The results are summarized in Table 2.

Table 1. Ionization and appearance energies (298 K) of 12-crown-4 and its fragment cations.

m/z	Ion	IE or AE, eV
176	$C_8H_{16}O_4^+$	8.60 ^a

A comparison of reported mass spectra (2-4) of similar compounds including catechol polymethylene diether derivatives, aromatic crown ethers and saturated crown ethers suggests that the dissociation constraints, and therefore that fragmentation need not necessarily produce the most thermodynamically stable daughter ions. The thermodynamic implications of the AEs reported here support kinetic control of the

photolionization/fragmentation of 12-crown-4. The dissociation mechanism of the 12-crown-4 molecular ion can be easily explained on the simple mechanistic basis shown in Figure 3. Presumably removal of a nonbonding electron from an oxygen atom in 12-crown-4 leads to prompt fragmentation of the molecular ion. It appears that some fragments, of the type $[C_2H_4O]_n^+$ ($n=1,2$) are formed by immediate dissociation of this structure. For other molecular ions an intramolecular H-shift appears to occur, which catalyzes ring-opening. This leads to ions of the type $[C_2H_4O]_nH^+$ ($n=1-3$).

Trends in appearance energies of the investigated photofragments, plus structural implications derived from thermochemical analysis and results from EI mass spectra of crown ethers (3) suggest that the fragmentations observed follow simple mechanisms, but that the fragment ions do not necessarily exist in their most stable isomeric forms.

A COMPETITION BETWEEN TWO ISOMERIZATION PROCESSES IN UNIMOLECULAR DISSOCIATION

One of the advantages of the photoelectron photoion coincidence (TPEPICO) time-of-flight mass spectrometry is to determine the decay rate constants for unimolecular dissociations. The rates observed in the TPEPICO experiments are indicated by the TOF distributions. A symmetric peak shape implies that the decomposition is relatively fast with the rate constant greater than 10^7 s^{-1} . On the other hand, metastable decomposition ($< 10^7 \text{ s}^{-1}$) is reflected by asymmetric TOF distributions. For the later case, the rate constants can be numerically calculated by analyzing the TOF distributions.

It is well established that the analysis of asymmetric TOF distributions for the first generation fragment ions gives only the total decay rate of the parent ion. Therefore, in a unimolecular dissociation involving two simple cleavages the rate constants calculated from TOF distributions should be identical for the two competitive processes. The decay rate constant for each fragment process is then obtained from the total rate constant and relative abundance of ions in the breakdown graph at a given internal energy. This is described by Equation 1 where k_T is the total rate constant, $B(m_i, E)$ is the branching ratio of mass m_i at the internal energy E .

$$k(m_i, E) = k_T B(m_i, E) / \sum B(m_i, E) \quad [1]$$

Recently, the formation of m/z 28 (C_2H_4^+) and m/z 56 ($\text{C}_2\text{H}_4\text{CO}^+$) in the unimolecular dissociation of ethyl formate ions at low internal energies were found to have different rate constants with a single-component feature (Figure 1). The rate constants calculated from the TOF distributions for the formation of m/z 28 are higher than those for m/z 56 by an order of magnitude. This observation, however, cannot be simply explained by a competition between two direct fragmentation or a competition between a direct fragmentation and a prior isomerization¹. A plausible explanation may be that the fragmentations occur from intermediate isomers specific to each fragment ion (Figure 2). It is likely that m/z 28 is formed via a stepwise McLafferty rearrangement² which is characterized by the formation of a stable isomeric structure, the distonic radical. It is also postulated that the m/z 56 is formed from its specific isomer, the enol ion of propionic acid. The potential energy surface for the formation of m/z 56 is summarized in Figure 3.

To determine the rate for the system shown in Fig. 2, one needs to determine the solutions of the determinant of a 5×5 matrix.

$$\begin{vmatrix} (k_1 + k_3) - k_i & k_2 & k_4 & 0 & 0 \\ k_1 & -(k_2 + k_5) - k_i & 0 & 0 & 0 \\ k_3 & 0 & -(k_4 + k_6) - k_i & 0 & 0 \\ 0 & k_5 & 0 & -k_i & 0 \\ 0 & 0 & k_6 & 0 & -k_i \end{vmatrix}$$

It will yield five solutions for k_i : one real, two imaginary and two zero solutions. The general solutions for I_1 and I_2 are given by linear combination of three non-zero solutions simplified by Euler equation. Thus, the rates for P_1 and P_2 will exhibit multi-component behavior.

Since the rate constants observed for the formation of both m/z 28 and m/z 56 in the unimolecular dissociation of ethyl formate ions are characterized by single-component behavior, it seems that a steady-state approximation could be applied to this specific case. Thus, the total rate constants can be given by Equation 2:

$$k_T = (k_1 + k_3) - k_1 k_2 / (k_2 + k_5) - k_3 k_4 / (k_4 + k_6) \quad [2]$$

which is generally satisfied under conditions of Equation 3:

$$k_2(k_4 + k_6) \frac{dI_1}{dt} + k_4(k_2 + k_5) \frac{dI_2}{dt} \ll [k_1 k_4 k_5 + k_1 k_5 k_6 + k_2 k_3 k_6 + k_3 k_5 k_6] \exp(-k_T t) \quad [3]$$

The rates for the two final products formed from their corresponding precursors are determined by Equations 4 and 5.

$$dP_1/dt = k_1 k_5 / (k_2 + k_5) \exp(-k_T t) \quad [4]$$

**HIGH MASS CARBON CLUSTERS FORMED FROM POLYCYCLIC AROMATIC HYDROCARBONS
OBSERVED BY LASER MASS SPECTROMETRY; LINEMAN, D.N., VISWANADHAM, S.K.,
SHARKEY, A.G., HERCULES, D.M.; UNIVERSITY OF PITTSBURGH, PITTSBURGH, PA.
15260**

EXPERIMENTAL: All samples were analyzed with the Leybold-Heraeus LAMMA-1000 laser TOF MS, using a Nd:YAG laser (266nm). All samples were deposited on zinc foil for analysis, using a variety of organic solvents.

DISCUSSION: Laser irradiation of Polycyclic Aromatic Hydrocarbons (PAH) has been found to generate carbon clusters from C₁⁺ through C₆₀₀⁺. Unlike earlier research by Kaldor(1), Smalley(2), and others concerning laser vaporization of graphite, in which two cluster types were observed (low mass and high mass), laser vaporization of PAH's yields four different cluster types. The appearance of each type is strongly influenced by laser energy and focus conditions. Figure 1 shows the LMS spectrum of each cluster type and the cluster's corresponding formula. Carbon clusters observed at the laser focal point are Type IA. Type IA clusters are of the form C_nH_m⁺, where: n = 1-30 (approx.) and H = 0-3. By defocusing 100 microns, cluster Types IA, IB, II and III can be observed. Type IB clusters are of the form C_nH_m⁺, where: n = 3-50 and m = 2-10. Type II clusters are of the form [xM - yH]⁺ where: M = Mol. Wt. of the PAH, x = 1 to 5, and yH is a compound dependent loss of H. Type III clusters are the so called "high mass" carbon clusters. These clusters are composed only of carbon, and are observed for even numbered carbons only. Type III clusters are of the form C_{2n} where n = 20 to 300. Type III clusters have been generated from a variety of organic compounds, very diverse in structure. Compounds such as pyrene, tetraphenylbenzene, phenazine, polyimide, and even coal all produce Type III clusters which are identical. Upon examination of the structures of these compounds, one finds that the commonly occurring moiety in each is the benzene ring. Of all the compounds we have analyzed to date, only those containing aromatic rings formed Type III "high mass" carbon clusters. The ease with which Type III clusters are formed is directly proportional to the compounds aromaticity. Those compounds which contained a high number of conjugated rings (coronene) formed Type III clusters most easily, while those which contained aromatic rings connected through single bonds (tetraphenylbenzene) or aromatic rings separated by heteroaromatic rings (phenazine) were most difficult to form Type III clusters. Tripyridyltriazine, a compound composed entirely of heteroaromatic rings formed no Type III clusters. The combustion process plays an interesting role in Type III cluster formation. Soot generated by PAH's will also yield Type III clusters upon laser irradiation. While Type III clusters are easier to generate from conjugated PAH's than compounds with nonconjugated aromatic rings, the combustion products of both types of compounds yield Type III clusters with approximately equal efficiencies. However, only those compounds which contain some degree of aromaticity will form combustion products capable of generating Type III clusters; an example of this can be seen in figure 2. Soot formed from esterone (aromatic) will generate Type III clusters, while soot formed from testosterone (non-aromatic), will not. Type III clusters have been seen in both positive (through C₅₈₄⁺) and negative (through C₂₀₀⁻) ion mode, as shown in figure 3.

CONCLUSION: The structures and mechanisms of formation of the four carbon cluster types detected are not yet clearly understood. There is however evidence which seems to indicate possible relationships between the cluster types, which will give insight into the processes involved in the formation of "high mass carbon clusters". Work is currently being done in this area.

THE KINETIC ENERGIES OF IONS FORMED BY RESONANT AND
NON-RESONANT MULTIPHOTON IONIZATION

Jeffrey A. Zimmerman and Rebecca M. O'Malley
Department of Chemistry, University of South Florida
Tampa, Florida 33620

Measurement of the translational energy of product fragment ions is a method which has been used to obtain information on ionic fragmentation mechanisms (1). In this study the translational energies of fragment ions produced by both resonant and non-resonant MPI have been measured to provide answers to the following questions: are the fragmentation mechanisms different in the case of resonant and non-resonant MPI when the spectra are superficially similar? And, are the fragmentation mechanisms the same for two different non-resonant MPI cases? The system chosen for study was fluorobenzene. 70 eV, 266 nm, 532 nm and 355 nm MPI spectra are shown (Fig. 1).

All experimental data were obtained using a laser/time-of-flight mass spectrometer in which it was possible to alter the time between the laser light crossing the source and the application of the draw-out pulse (time-lag) on the microsecond time-scale. Experimental time-of-flight profiles were obtained at different time-lag values. Agreement with computer generated profiles, which allowed input of different ion energies and time-lag values, was very good (see Fig. 2). At long time-lag values ion-loss effects, which are dependent on ion energy, become important. Comparison of experimentally obtained and computer generated ion-loss curves allowed the determination of ion energies (Fig. 3). Table 1 summarizes the experimentally determined kinetic energies of the fluorobenzene ions for the three wavelengths and Table 2 summarizes ion energies, calculated using equations from (1) for different fragmentation mechanisms.

Table 1 Experimental K.E.'s of Fluorobenzene Ions in eV.

m/z	ion	266 nm	355 nm	532 nm
96	$C_6H_5F^+$	0.04	not obs	0.07
70	$C_4H_3F^+$	0.12	"	not obs
57	$C_3H_2F^+$	0.18	"	"
31	CF^+	0.15	2.8	0.40
24	C_2^+	not ms'd	2.2	0.35

Table 2 Calculated K.E.'s of Fluorobenzene Ions in eV.

Reaction	Threshold(eV)	Number of Photons*	KE(eV)	*For 266 nm MPI, double this number for 532 nm.
$C_6H_5F \rightarrow C_4H_3F^+ + C_2H_2$	14.1	4	0.10	
$C_6H_5F \rightarrow C_3H_2F^+ + C_3H_3$	13.6	3	0.05	
		4	0.22	
$C_6H_5F \rightarrow CF^+ + C_5H_5$	16.8	4	0.11	
		5	0.23	
		6	0.35	
$C_4H_3F^+ \rightarrow CF^+ + C_3H_3$		1	0.24	
$C_3H_2F^+ \rightarrow CF^+ + C_2H_2$		1	0.39	

The data indicate that at 266 nm $C_4H_3F^+$, $C_3H_2F^+$ and CF^+ are formed via a direct ionic fragmentation route after the absorption of four photons by the neutral molecule. At 532 nm the best fit for CF^+ production is for further photon absorption by $C_3H_2F^+$ indicating an ionic ladder switching mechanism. The high energies observed for CF^+ and C_2^+ at 335 nm fit neither of these schemes but might result from coulombic repulsions in the formation of more than one ion from a single neutral molecule.

FRAGMENTATION OF $M^{+\bullet}$ IN METHYL KETONES IN THE ION TRAP:
VARIATION OF MECHANISM WITH CHAIN LENGTH

R.T. Mason and H.M. Fales, Laboratory of Chemistry, NHLBI, NIH,
Bethesda, MD 20892; L.K. Pannell and Pu Quan-long, Laboratory of
Bioorganic Chemistry, NIDDK, NIH, Bethesda, MD 20892.

The collisionally activated dissociation of the molecular ion in a series of methyl ketones ranging from 2-butanone to 2-octanone has been studied using a Finnigan Ion Trap Mass Spectrometer. Helium was used as the buffer gas and the tickle voltage was 400mv in each case, resulting in about 10 e.v. excitation energy. Under these conditions only a few fragment ions were produced, mainly $M^{+\bullet}$ -alkyl and McLafferty-type ions at m/z 58, 72 and 86, depending on chain length.

Loss of methyl from 2-pentanone (Fig. 1) then methyl and ethyl from 2-hexanone and 2-heptanone suggests displacement of the alkyl group first from the beta, then gamma positions. In higher ketones, loss still occurs from the gamma position (m/z 85) but further cleavage is also observed (m/z 99).

McLafferty-type ions are observed where they are feasible (m/z 58 in 2-pentanone) but a similar ion is seen one methylene unit more at m/z 72 in higher members of the series. Eventually this ion represents the most important cleavage pathway as seen in 2-octanone (Fig. 2).

An attempt was made to determine the source of the migrating proton in these peaks using 2-hexanone labelled in positions both alpha and gamma to the carbonyl. The gamma position was the source of the proton for the m/z 58 (Fig 3.), but scrambling had also occurred as evidenced by the ion at m/z 86. Interestingly, self-CI (m/z 103) involved none of the deuterium atoms.

Further experiments with specifically labelled compounds will be carried out in an effort to delineate these processes more completely.

Mass Spectrometric Techniques Applied to Assignment of Structures
in Three or Four Step β -Lactam Syntheses

R. A. Day and B. D. Bennett; Department of Chemistry
University of Cincinnati; Cincinnati, Ohio 45221
and

K. Jayasimhulu; Department of Environmental Health
College of Medicine; University of Cincinnati
Cincinnati, Ohio 45267

The pharmaceutically useful β -lactams are currently made from fermentation derived penicillins. Typically a penicillin G salt is produced by fermentation and then deacylated enzymatically to give 6-aminopenicillanic acid (APA). This synthon, APA, is then chemically modified to give the currently used semi-synthetic penicillins and cephalosporins. Direct chemical synthesis of β -lactams has been achieved several times by means of multiple step syntheses--typically 10-25 steps from a simple precursor. We have found a four step procedure from glycine to APA--the first direct synthesis of this synthon--by means of Leuchs anhydride intermediates as depicted in Figure 1 (1). Mass spectrometry played an important role in confirming the structures of intermediates in part because of the inherent lability of Leuchs anhydrides; the anionic intermediates Na⁺ FLAG and LATZ are somewhat stabilized as anion derivatives.

The first crucial intermediate was GLA reported in Houben-Weyl (2) to have a m.p. of 100°; instead, we find that it decomposes over a wide temperature range, but gives a clean DI mass spectrum with the molecular ion m/z

RAPID IDENTIFICATION OF URINARY METABOLITES OF ADINAZOLAM (U41123)
IN HUMANS USING TANDEM MASS SPECTROMETRY

JJ Vrbanac, GW Peng and IA O'Leary

The Upjohn Company, Drug Metabolism Research, Kalamazoo, Michigan 49001

One of the objectives of our laboratory is to critically evaluate the utility of tandem mass spectrometry, interfaced with various sample introduction/ionization techniques, in elucidating drug metabolite structures without the use of radioisotopes. Adinazolam (U-41,123F, 8-chloro-1-[(dimethylamino)methyl]-6-phenyl-4H-s-triazolo[4,3-a][1,4]benzodiazepine) is a psychoactive drug demonstrating pharmacological activities in animals characteristic of both benzodiazepine anxiolytics and tricyclic antidepressants. The major metabolic products of adinazolam present in human urine have previously been determined using radio-isotope labeled drug and various physico-chemical techniques. This particular compound represents a challenging test case in that most of the drug is excreted in urine as one metabolite and the other metabolites present represent less than 10% of the total. The present study has examined the utility of FAB MS-MS analysis of crude urinary fractions and GC-MS-MS analysis of an organic solvent extract in elucidating the structures of metabolites of adinazolam.

Sample preparation: ODS FRACTIONS: Urine (50 ml) was extracted using a C-18 ODS solid phase extraction cartridge and crude separations of this complex mixture were obtained by elution with 5 ml washes of increasing amounts of methanol in water (0, 5, 10, 15, 20, 25, 30, 35, 40, 50, 75, and 100% methanol). The crude extracts were then concentrated and analyzed by FAB-MS. SOLVENT EXTRACTION: Urine (50 ml) was combined with 10 ml 2 M K₂HPO₄ and extracted with 10 ml of butyl chloride. Following centrifugation the organic phase was washed with 10 ml 1 M NaOH, dried under a stream of nitrogen and redissolved in 250 µl CH₂Cl₂. Instrumentation: Finnigan MAT TSQ-70 triple quadrupole mass spectrometer, Hewlett-Packard 5890 gas chromatograph and Ion Tech FAB source. Analysis Conditions: GC-MS: GC column, 20 m DB-1, J&W Scientific, 0.25 mm I.D., 0.1 µm film thickness; methane reagent gas at 1 Torr. FAB: 2-Hydroxyethyl disulfide matrix; xenon at 8 kV. MS-MS: Argon collision gas, 1 mTorr.

All metabolites of adinazolam previously observed resulted from metabolic changes occurring in the 1-[(dimethylamino)methyl] moiety. The structures of these metabolites and % of total dose excreted as extractable metabolites in urine were observed as follows: Unmetabolized drug, 0.7%; 8-chloro-6-phenyl-4H-s-triazolo[4,3-a][1,4]benzodiazepine (estazolam), 0.8%; 1-[(methylamino)methyl]-estazolam, 53.4%; 1-hydroxymethyl-estazolam and formamide, N-[(8-chloro-6-phenyl-4H-[1,2,4]triazolo[4,3-a][1,4]benzodiazepine-1-yl)methyl]-N-methyl-, 4.0%; acetamide, N-[(8-chloro 6-phenyl-4H-[1,2,4]triazolo[4,3-a][1,4]benzodiazepinyl)methyl]-, 3.7% and 1-aminomethyl estazolam, 1.2%. At collision energies less than 50 eV the daughter ion mass spectrum is dominated by cleavage products originating from the (dimethylamino)methyl side chain and triazolo ring system. Performing parent scans of these ions would be an obvious choice to detect metabolic transformations occurring at this side chain (knowing nothing about the metabolism of this compound). When the solvent extracted sample was analyzed by GC-MS-MS using parent ion scans for m/z 295 (the 8-chloro-6-phenyl-4H-s-triazolo[4,3-a][1,4]benzodiazepine ring system, estazolam) the chromatogram was observed to be dominated by m/z 338, the N-demethyladinazolam metabolite. Daughter ion mass spectra of m/z 295, 338 and 352 confirmed the presence of adinazolam, N-demethyladinazolam and estazolam. The metabolite structures could have

been easily deduced without the availability of reference compounds. Detection and confirmation of other metabolites was complicated by lower concentrations and lack of chromatographic resolution from the N-demethyl metabolite when enough sample was injected to obtain daughter ion mass spectra.

An intense signal at m/z 338 was also observed for FAB-MS-MS analysis (again, parents of m/z 295). The daughter ion mass spectrum of m/z 338 confirmed the presence of the N-demethyl metabolite (again, this structure could easily have been deduced without the availability of reference compound). Identification of parent drug and other metabolites was complicated by the presence of large amounts of the major metabolite (for example, m/z 295 is observed in the FAB mass spectrum of the N-demethyl metabolite) and by sample suppression of ionization. This latter observation was demonstrated by spiking the ODS eluate samples with 0.5 μ g of adinazolam and observing the response compared to adinazolam alone. Greater than a 100-fold reduction in signal was observed. Summary: 1. Using information obtained from the positive ion CAD mass spectrum obtained for MH^+ of adinazolam, FAB-MS-MS and GC-MS-MS analysis easily identified the major early formed metabolite of this drug in human urine. 2. GC-MS-MS analysis identified parent drug and two other minor metabolites. This particular example represents a special case in that drug metabolites, especially urinary, are usually not amenable to GC analysis without chemical derivatization. 3. The failure of FAB-MS-MS analysis of crude fractions eluted from an ODS extraction cartridge to identify parent drug and minor metabolites was related to both the presence of other compounds in the sample and the absence of any chromatographic separation from the major metabolite.

EFFECT OF PHTHALATE IMPURITIES ON PEAK AREAS DURING NEGATIVE ION METHANE GC/MS ANALYSES OF NABILONE AND DEUTERATED NABILONE IN HUMAN PLASMA SAMPLES. P. H. Dhahir, R. Barton, R. L. Wolen, and A. P. Breau, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285

INTRODUCTION: Cesamet® (nabilone hydrochloride, Lilly) is a synthetic cannabinoid used in the treatment of nausea and vomiting secondary to oncologic chemotherapy. To facilitate the development and evaluation of oral formulations, we have utilized the technique of coadministration of a suspension of deuterated nabilone (D6) together with individual formulations of the unlabeled drug. The time related concentrations of both the labeled and unlabeled drug in human plasma are quantitated by negative ion GC/MS to permit the direct comparison of various formulations while minimizing individual subject variability.

In the course of the analyses an abrupt loss of signal was observed in some samples. Full scan GC/MS analyses indicated that a co-eluting contaminant, dioctyl phthalate, was present in these samples which quenched the ionization of nabilone. This work demonstrates the ability of certain plasticizers to influence negative ion CI which can result in quantitation errors.

MATERIALS AND METHODS: Plasma Extraction--A fixed amount of internal standard was added to a 500 μ l plasma sample and the protein precipitated with acetonitrile. The supernatant liquid was recovered following centrifugation of the sample and the acetonitrile removed with nitrogen gas. The aqueous residue was made alkaline with sodium hydroxide solution extracted into butyl chloride which was washed with dilute hydrochloric acid. The organic extract containing nabilone and internal standard was dried under nitrogen, reconstituted in hexane and derivatized by the addition of trifluoroacetic anhydride (TFAA) (Figure 1). The derivatized extract was dried under nitrogen and reconstituted in hexane for analysis.

INSTRUMENTATION: The samples were analyzed in the spitless mode on a Finnigan 4500 gas chromatograph/mass spectrometer in the negative ion CI mode. Helium carrier gas head pressure was maintained at 10 psi. A 15 meter DB-1 capillary column (0.25 μ film thickness) was utilized with initial temperature at 150°C. The oven temperature was programmed at 100/min at 250°C. The derivatized internal standard eluted at 5.83 minutes and derivatized nabilone at 6.5 minutes (Figure 2). The methane reagent gas was maintained at 0.6 torr in a 150°C ion source. The filament was held at 70 eV with an emission current of 0.25 mA. The electron multiplier voltage was held at 1450 V. The nabilone and deuterated nabilone negative ions were monitored at m/z values of 371 and 377, respectively. The internal standard, an analog of nabilone, was monitored at $m/z=357$ (Figure 3). Monitoring rate was 0.3 seconds/scan.

RESULTS: The reconstructed ion chromatograms for most samples displayed normal gaussian shaped peaks (Figure 3) which were quantitated by AutoQuant. An occasional sample produced peaks of non-gaussian shape that abruptly terminated (Figure 4). Reanalysis of the aberrant samples by EI GC/MS revealed a co-eluting contaminant (Figures 5 & 6), not present in the unaffected samples (Figure 7). The co-eluting material was the common plasticizer dioctyl phthalate (Figure 8). The source of the contamination was traced to tubing that came in contact with the trifluoroacetic anhydride reagent.

DISCUSSION: The ability of the phthalate material to quench negative ion chemical ionization emphasizes the need for care in avoiding contact with plastics. Although the mechanism of this interesting observation has not been defined it is speculated that the phthalate structure may either charge exchange with the analyte or compete more favorably for the slow thermal electrons needed to produce a stable negative ion. The work demonstrated the need to complement single ion monitoring procedures with full scan spectra to insure the purity of observed peaks. The need for visual review of data is also emphasized by this finding in order that problems of this type can be identified and corrected without undue delay.

HYBRID MS/MS of AROMATIC DIAMIDINO ANALOGS

G. Dean Marbury, M. J. Charles, Dept. of Environmental Science and Engineering and J.E. Hall, I. Donkor, B.E. Berger, and R. Tidwell, Dept. of Pathology, University of North Carolina, Chapel Hill, N.C. 27599.

Introduction: Aromatic diamidino compounds such as pentamidine have been shown to be effective chemotherapeutic agents in the control of *Pneumocystis carinii* pneumonia, complications of which are a leading cause of death in AIDS patients. A systematic investigation of structure/activity relationships of pentamidines included mass spectrometric characterization of reference materials, new synthetic mixtures, and mixtures of biological origins such as human urine and blood extracts. These studies required the development of MS/MS techniques to enhance specificity and provide structural information on novel compounds.

Experimental: Compounds were synthesized using proprietary techniques and verified by FT-NMR, FTIR, UV, and mass spectrometry. All mass spectra were acquired using a VG 70-250SEQ tandem hybrid MS/MS of EBQ geometry, operated either in the EI or liquid secondary ionization (LSIMS) mode, with the following conditions: EI: 200 °C source, 70eV I.P., $V_{acc} = 8$ kV, 200mA standard source configuration; resolution = 1000 (10% valley) or >25,000 (accurate mass confirmations); LSIMS: Cs ion gun at 30 kV, $V_{acc} = 8$ kV, 1000 resolution, glycerol matrix. Collision experiments were conducted using 2×10^{-4} mbar Ar (guage) in the rf-only collision cell (q). Parents were focused using MSI, with 50% main beam attenuation at CE = 30eV (lab reference). All source tuning conditions were held constant during MS/MS experiments, minimizing collision energy variation between experiments.

Results and Discussion: Ring-closed compounds proved to be amenable to EI MS/MS analysis and were characterized by hydride loss followed by ring cleavage to stable nitriles (fragmentations shown in Fig. 1.) Subsequent losses included fragments of amidine-phenols, sequential alkyl-chain cleavages, and numerous hydrogen rearrangements. For one lot of suspected low purity, the MS/MS spectra of sequentially selected parents allowed determination of a free amidino impurity in the presence of ring-closed propamidine, since no daughter scans produced a signal for the putative M^+ of the impurity and the impurity gave a MS/MS spectrum unlike that of the principal analyte. Ring-open diamidino compounds were thermally labile and highly dependent upon initial conditions, thus requiring LSIMS for production of molecular species with few structurally informative fragments, necessitating MS/MS (Fig. 2). The effect of collision energy on the appearance of amidino CAD spectra was investigated by selecting the $[MH]^+$ ion with MSI (EB) and scanning MSII (Q) at either a pre-determined CE or by collecting CAD spectra sequentially in 5 eV increments over the CE range 20-80 eV. The ion abundance recorded showed higher mass species favored at lower energies, with greater collection of lower mass collision products at higher CE (Fig. 3). This observation may reflect both the actual production of lower mass daughters in the collision experiment and the ion-energy acceptance range of the quadrupole analyzer, although optimization of MSII (Q) ion energy acceptance at any given CE did not significantly change the observed abundances. The use of LSIMS, MS/MS, and selection of optimum CE allowed the determination of small amounts of compound spiked into urine (Fig 4), by selection of a low S/N signal (m/z 313, MH^+) using MSI followed by CAD to yield an MS/MS spectrum highly correlated to that of an authentic reference standard. Application of the MS/MS techniques to qualitative and quantitative analysis of amidino compounds and metabolites is presently under investigation.

A SELECTED CAD-DAUGHTER ION RECORDING ASSAY FOR FLUPHENAZINE
AND A DEUTERIUM LABELLED ANALOG IN PLASMA

R.W. Edom, G. McKay, E.M. Hawes and K.K. Midha
College of Pharmacy, University of Saskatchewan, Canada S7N 0W0

Fluphenazine (FLU) is a piperazine-type phenothiazine drug widely used in the therapy of schizophrenia. In order to evaluate the single dose pharmacokinetics of this drug in patients undergoing chronic therapy, it was necessary to develop an assay with sufficient sensitivity and specificity to allow simultaneous quantitation of FLU and a stable isotopomer (d_4 -FLU) in plasma.

Fluphenazine

d_4 -Fluphenazine

The d_4 -FLU was synthesized in our laboratories (Sardesai et al, J. Labelled Compd. Radiopharm. 23: 317, 1986). The deuterium labels were strategically placed in the propyl portion of the side chain where it is currently believed little metabolism occurs. To investigate the isotopic effect of the deuterium substitution in d_4 -FLU, it was co-administered with equimolar doses of FLU via oral and IV routes to three purebred Beagle dogs. Plasma and urine samples were collected serially over 56 hours. The new assay procedure was developed and applied to this study.

Quantitation of FLU is challenging because of the low plasma concentrations observed with therapeutic oral doses. In addition, GC-MS analysis is difficult due to its tendency to adhere to non-silanzed surfaces, and LC-MS cannot provide the required sensitivity. Therefore the assay was developed using quantitative EI-MS/MS on a tandem hybrid mass spectrometer (VG-70SQ). Selected ion recording was used to monitor daughter ions arising from specific parent ions in FLU and d_4 -FLU via collisionally activated dissociation (CAD). Samples were introduced on the direct probe with the selectivity of MS/MS obviating the need for chromatography. A solvent extraction using 5% isopropanol in n-pentane, and derivatization with MTBSTFA (producing the tert-butyl dimethyl silyl ether) was necessary to improve the sensitivity of the assay.

The parent ions for FLU and d₄-FLU (m/z 406 and 410 respectively) were chosen for their intensity and for their tendency to yield primarily one intense daughter ion with CAD. Shown below in the MS/MS spectrum for each parent ion are the daughter ions monitored for quantitation.

Using 2 mL plasma samples the assay can be applied through the range of 100 to 0.1 ng/mL. The recovery from plasma averages 50.7% for FLU and 50.4% for d₄-FLU. Replicate analysis of samples showed an average coefficient of variation $\leq 8\%$, and quality control samples showed an average accuracy of $\geq 94\%$.

Above is the plasma concentration vs. time profile for a dog given a single oral dose containing equimolar amounts of FLU and d₄-FLU (≈ 5 mg each). Also typical of the IV doses, the profiles for each isotopomer are virtually coincident. In this example, the half-life is 1.44 hours for FLU and 1.54 hours for d₄-FLU. AUC values are also very similar: 7.644 for FLU and 7.654 for d₄-FLU. Each isotopomer had identical values for T_{max} (1.53 hours) and C_{max} (2.70 ng/mL). We conclude this evidence demonstrates the lack of measurable isotopic effect caused by the deuterium substitution in d₄-FLU.

In all cells maintenance of sodium and potassium concentrations within the cell involves $\text{Na}^+\text{-K}^+$ ATPases (Stahl, 1986). Since these ions are so vital to the processes within the cell, many endogenous modulators have been proposed to regulate $\text{Na}^+\text{-K}^+$ ATPase function. A convenient means of detecting this modulation involves monitoring ouabain binding.

The previous use of high mass mass spectrometric techniques has focussed on confirmation of the sequence of various bulk isolated proteins. To date fewer examples of the use of these techniques to identify various minor neuropeptides are extant. In one example the authors confirmed the existence of Substance P in a sample isolated from the cat spinal cord (Lisek et al., 1989). In a second example, this technique was used to identify various proopiomelanocortin peptides in the bovine intermediate-posterior pituitary (Feistner et al., 1988). Finally, a previously unknown endogenous neuropeptide modulating calcium channels was further characterized by mass spectrometry (Callewaert et al., 1989).

We employed the high pressure liquid chromatograph to isolate various compounds from the bovine posterior pituitary, characterized them using ouabain binding and further identified them using mass spectrometry. The mass spectrometer thus confirmed the presence of a distinct material, clarified the purity of the isolated material, aided in structural identification and identified any inorganic ions which may also be present.

Experimental

Freeze dried bovine posterior pituitaries were extracted with acetone; defatted using petroleum ether and the peptides were dissolved using 0.2 M acetic acid. This extract was chromatographed on a Sephadex G-25 column and that fraction corresponding to material of from 1,000 to 5,000 atomic mass units (a.m.u.) was further chromatographed on a Bio Rad AG-50 W column to remove sodium and potassium. The peaks of material from both columns were determined using the Lowry protein assay. Following removal of the salts, the material was assayed for ouabain binding inhibitory activity. Those fractions with activity were pooled and further purified using a Waters high pressure liquid chromatography system. Fifty-seven milligrams of extract were chromatographed on a μ Bondapak reversed phase column using a linear gradient of acetonitrile (from 0 to 100% over 60 minutes). The initial peak had the greatest activity and also the greatest amount of material (32.8 mg). Using a shallower acetonitrile gradient (0 to 100% acetonitrile over 120 minutes) the initial sample was resolved into 5 regions of ouabain inhibiting activity, with the initial peak weighing 18 mg compared to 0.4 mg for peak 2, 4.9 mg for peak 3, 4.0 mg for peak 4 and 4.2 mg for peak 5. The initial peak reduced ouabain binding to 65% of control. This material also had potency in an in vitro potency test. The tension on a canine heart muscle preparation was reduced by 200 nanograms of this material. Using nitrocellulose, this initial peak was examined using both plasma desorption (courtesy of Dr. P. Roepstorff) and cesium ion desorption. In both cases a major peak at 1085 a.m.u. was observed. This peak was identified as arginine vasopressin (Feistner et al., 1988). Arginine vasopressin failed to have activity in the ouabain binding assay. A second smaller peak of mass 401 a.m.u. was also observed.

The mixture was resolved further using an analytical μ Bondapak column and a very shallow solvent gradient (0 - 20% acetonitrile). The arginine vasopressin was separated from several other peaks. A late peak had activity over several fractions while a very sharp division between

activity and lack of it was observed in fractions 77 and 78. Fraction 77 had only 40% of the control activity in the ouabain binding assay. Upon examination in the time-of-flight mass spectrometer (Tang et al., 1988) fraction 77 had a strong mass at 391 a.m.u. and a smaller one at 550 a.m.u. (Figure 1). Fraction 74 also was examined; this fraction did not have those masses observed in Fraction 77. This pattern was very similar to that observed for leucine enkephalin (Gaskell et al., 1989). Another sample appearing in fraction 70 (i.e. 70 minutes into the HPLC run) appeared to have two larger masses associated with activity i.e. 1473.5 a.m.u. and 999.5 a.m.u. These masses were not observed in those fractions not having activity.

Conclusions

- 1) Mass spectrometry identified a neuropeptide as having activity
- 2) Confirmed that activity was not due to ion contamination
- 3) Provided some structure and identity information
- 4) Confirmed purity
- 5) These results suggest that within the posterior pituitary there exists a family of related peptides with modulatory properties toward Na^+ , K^+ ATPase and sodium-potassium homeostasis.

THE STRUCTURE ELUCIDATION AND MASS SPECTROMETRY OF PENICILLINIC ACID THIOLACTONES

Edward K. Chess, Kirk A. Ashline, David E. Pereira, and Walter J. Smith, III
Baxter Healthcare Corporation, Round Lake, IL 60073

The degradation pathways and products of penicillins in various aqueous media are studied by the pharmaceutical industry to determine product potency, shelf-life, and safety. Recent investigations of the degradation of nafcillin (**1a**) and oxacillin (**1b**) in aqueous solutions revealed one minor component of unknown identity for each drug. The unknown components were isolated in small quantities, and their structures elucidated by means of infra-red (IR), nuclear magnetic resonance (NMR), and mass (MS) spectrometries.

Initial IR, ^1H -NMR, and MS results on the oxacillin and nafcillin degradants revealed that the spectra did not match the spectra of any previously known aqueous degradants. However, these techniques gave structural information which was used to postulate possible structures for the degradants. For example, the C=O stretch of the β -lactone, normally found in the IR spectrum at 1763 cm^{-1} for the sodium salt of nafcillin or at 1789 cm^{-1} for the free acid, was missing in the IR spectrum of the nafcillin degradant. Also missing were the characteristic absorbances for the free or cationated carboxylic acid of nafcillin. However, absorbances consistent with the structure of a penicillenic acid derivative (e. g., δ -lactone C=O stretch at 1732 cm^{-1}) were present.

The ^1H -NMR spectra indicated that the R-groups from both the nafcillin and oxacillin (the ethoxy-substituted naphthalene and the phenyl-substituted isoxazole, respectively) were present in the corresponding degradants. The proton spectra for both degradants were similar when the specific resonances for the naphthalene and isoxazole groups were removed. These data suggested that identification of one degradant would provide the structure of the other degradant.

Electron ionization (70 eV) mass spectrometric analyses of the unknown components confirmed the similarity between the two structures and provided further structural information. Potential molecular ions were found at m/z 383 and 396 for the degradants of oxacillin and nafcillin respectively, corresponding to 18 amu less than the molecular weights of the parent penicillin free acids. Apparent losses from the molecular ion of 28, 55, 60, and 88 daltons were also observed in the spectra of both degradants. Accurate mass fast-atom bombardment mass spectrometry provided an elemental composition of $\text{C}_{19}\text{H}_{18}\text{N}_3\text{O}_4\text{S}$ for the protonated molecular ion of the oxacillin degradant at m/z 384. This experiment was followed by further electron impact studies which provided the elemental compositions of the molecular ion of the nafcillin degradant ($\text{C}_{21}\text{H}_{20}\text{N}_2\text{O}_4\text{S}$) and all major fragment ions in the spectra of both degradants. Thus, the elemental compositions of the unknowns were determined to be the same as those of dehydrated (one water molecule) forms of the corresponding parent penicillins. The losses of 28 and 60 were found to be losses of CO and COS, respectively, indicating the presence of a thioester.

Although substantial structural information was available regarding specific moieties, subgroup connectivity remained unknown. ^{13}C NMR experiments provided the final information needed to postulate structures for the two unknowns. Unambiguous determination of proton

To further confirm the proposed structures, the thiolactones (IIb,c) of the penicillenic acids of oxacillin (Ib) and Penicillin-G (Ic) were synthesized and characterized by mass, NMR, and IR spectrometries. The synthesis consisted of converting the parent penicillin to the penicillenic acid,¹ followed by dehydration of the penicillenic acid with DCC (1,3-dicyclohexylcarbodiimide). The nafcillin penicillenic acid was not synthesized, but enough was isolated from degradation experiments to allow small crystals to be grown. X-ray crystallographic analysis of a selected crystal provided the definitive structure proof of the penicillenic acid thiolactone structure. Although a literature search at the time of structure elucidation did not yield any references to penicillenic acid thiolactones as known penicillin degradants, Fujii et al. have since reported the corresponding penicillenic acid thiolactone (IIa) as a degradant of methicillin (Id).²

intermediate structure is especially interesting, and is under further investigation.

MASS SPECTROMETRY OF MITOMYCIN C AND SELECTED ANALOGS

W.M. Hammargren, B.S. Iyengar, W.A. Remers and K.H. Schram
Department of Pharmaceutical Sciences, College of Pharmacy
University of Arizona, Tucson, AZ 85721

Mitomycin C (MMC) is of clinical interest as a potent anti-cancer alkylating agent (1). The mass spectral behavior of MMC and several of its analogs were studied. Using MMC as a model (2,3) analogs substituted at the 7-amino and/or 1a- positions were examined to determine the role of these side chain substituents on fragmentation. Another set of analogs with potential clinical utility as anti-tumor agents are the nucleoside and nucleotide adducts of MMC (4). These were examined using FAB-MS with the objective of applying this fragmentation information to the study of other MMC analogs as well as MMC-DNA adducts.

Work done with MMC using various ionization methods such as EI, CI, DCI, and FAB have confirmed the earlier EI results of Van Lear and Hodges(2,3): the major fragmentation pathways involve the mitosene moiety with the most abundant ions arising from loss of the carbamate and/or 9a-methoxy side chain. Metastable studies using EI and CI have shown new fragmentation pathways previously not reported. For example, ions from the decomposition of m/z 334 include m/z 291, 261, and 242, in addition to the m/z 302 and 273 peaks reported by Van Lear (2). Although there was some variation in the EI fragmentation exhibited by the 7-amino and 1a- substituted analogs of MMC, the basic pathways shown by MMC are observed. All the analogs showed a molecular ion in EI. A difference generally noted with substitution at the 7- position is the significant increase in the relative intensity of M^+ (with the exception of the propargyl derivative 4) with respect to MMC and 2 (see Table). Other differences observed in the spectra of the 7-amino analogs include an increase in the relative intensity of the M^+-HCNO ion (except for 4) and a decrease in the relative intensity of ions a and b. The base peaks with EI generally involve loss of the 7-amino side chain. In fact, the 7-aminofurfuryl side chain is the base peak (m/z 81) for 5. The FAB-MS (+) spectra of MMC and 8 gave good results using 3-nitrobenzyl alcohol (NBA) as the matrix (less sample-related peaks were observed using glycerol). Intense molecular ion-related peaks are observed, as well as some structurally significant fragmentation. This is of particular use in identifying metabolites of MMC in addition to the more polar, less volatile analogs.

Preliminary work has been done on MMC-nucleoside and nucleotide adducts. This includes FAB-MS (+) of the adduct of MMC and 6-mercaptapurine riboside, an important anti-tumor agent. Ions are observed which represent both the intact adduct (MH^+ and MH -carbamate) as well as fragmentation arising from both components. For example, $B+2H$ at m/z 153 from the nucleoside portion and ions at m/z 302 and 242 from the mitosene portion are seen. Also, the positive and negative ion (Fig. 1) FAB-MS has been done on MMC-uridine-5'-monophosphate (MMC-UMP). The negative ion spectra provides useful molecular weight information ($M-H^-$), while the positive ion spectra yields much more structurally significant information, such as mitosene+H, mitosene - carbamate, and UMP+H. Examples of MMC adducts in which the anti-cancer nucleotides 5-fluorouridine-2'-deoxy-5'-monophosphate (FdUMP) and arabinosyl cytosine-5'-monophosphate (araCMP) are complexed with MMC have also been done. Work is in progress on elucidating the MS behavior of the MMC-tide and side adducts, including metastable and high resolution studies.

Analyses were performed using NERMAG Sidar mass spectrometer. We used GC/MS EI+ and we obtained 40 peaks in the spectra of chloroform extract of the plant "yareta". Our work is a demonstration of computer assisted structure determination from 10 µg of sample. We identified 7 long chain aliphatic acids, 6 hydrocarbon, 2 aromatic substances, 6 terpenes and 2 terpenes like products.

TRACHYLOBANE

ANALYSIS OF BLOODROOT EXTRACT USING TLC/SIMS,
HIGH RESOLUTION MS, AND MS/MS

Steven J. Doherty and Kenneth L. Busch
Indiana University Department of Chemistry Bloomington, IN 47405

The benzophenanthradine alkaloids (see structure 1) are a pharmacologically important class of natural products, with nematocidal, antitumor, and cytotoxic activity. The extract of the bloodroot plant contains several of these alkaloids, and this extract has been used in various medications for over 100 years. The extract is a crude mixture of alkaloids, as seen in the glycerol FAB spectrum (Figure 1). The diversity of the benzophenanthradine alkaloids is indicated in Table 1, which tabulates the number of candidate structures corresponding to each of the prominent ions in the FAB mass spectrum. The purpose of the present work was to employ a combination of mass spectrometric techniques, including TLC/SIMS, high resolution mass spectrometry, and tandem mass spectrometry, to identify some of the components of a crude plant extract, and resolve uncertainties about the composition of the extract. By utilizing the complementary information provided by the different mass spectrometric techniques, the amount of sample manipulation could be kept to a minimum.

Twenty eight grams of bloodroot rhizomes were dried, pulverized, and extracted with chloroform. The extract, (dry weight 0.46 grams), was diluted into 5 ml of chloroform, and 5 μ l aliquots were used in the ensuing analyses, without further purification. TLC/SIMS analysis was performed on a custom-built instrument using cesium ions at 6 kV and a quadrupole mass analyzer. High resolution work was done on a ZAB-HF instrument, operating with a resolution of 12,000 at 8 kV. Tandem mass analysis was performed on a Finnigan TSQ-70, using argon as the collision gas and a collision energy of 30 eV.

A discrepancy was noted in a literature survey of previous work on bloodroot extract. A crystal structure study (2) found the primary component in the extract to be oxysanguinarine, (molecular weight of 348), whereas an HPLC analysis (3), determined sanguinarine to be the most abundant. The latter study identified six components in the extract, only one of which, chelerythrine, had a molecular weight on 348.

Using the above-mentioned techniques, we determined the material at m/z 332 to be sanguinarine, based on R_f in TLC, mass spectrum from TLC, tandem mass spectrometry (Figure 2), and exact mass measurement. Two components were found to be present at nominal mass 348, in a 10:1 ratio. Based on exact mass measurements (Figure 3), these components were tentatively identified as oxysanguinarine and chelerythrine. Certified, purified standards for these materials were not available for comparison of response factors in TLC. Identification of the higher mass components in the extract was similarly hindered by the absence of standards. However, exact mass measurement and MS/MS reduce the possibilities to positional isomers. This information can rapidly be collected on the components of a complex mixture, without any sample purification, owing to the molecular specificity of mass spectrometry and the complementary nature of the various techniques.

DERIVATIZATION OF PUTATIVE BRADYKININ
METABOLITES FOR GC-MS ANALYSIS

JJ Vrbancac¹, IA O'Leary¹, KD Ballard² and DR Knapp²

¹The Upjohn Company, Drug Metabolism Research
Kalamazoo, MI 49001 and ²Department of Pharmacology
Medical University of South Carolina, Charleston, SC 29425

The long-term objective of this research project is to identify and quantify metabolites of bradykinin (BK; RPPGFSPFR) in human urine and/or plasma. Metabolic peptide fragments that have been reported to be present in plasma following I.V. administration of BK include RPP, RPPG and RPPGF. We have attempted to develop GC-MS procedures to quantitate these three peptides. One problem with this approach (GC-MS) is the poor yields observed for many of the derivatization reactions used to form products amenable to GC analysis. This is especially true for amounts totaling approximately 10 nmol or less. For this reason we chose to 1) examine derivatives amenable to negative ion chemical ionization (NCI) and 2) synthesize stable isotope labeled internal standards. Peptides were converted to dimethylpyrimidylornithine pentafluorobenzyl (DMPO-PFB) derivatives by first condensing with 2,4-pentanedione followed by reaction with pentafluorobenzyl bromide (PFBB).

Samples were dried under nitrogen at R.T., 5 μ l H₂O, 10 μ l ethanol, 5 μ l triethylamine and 10 μ l 2,4-pentanedione added and heated at 100 °C for one hour. Following drying under N₂, 25 μ l of 1 M acetic acid was added and the samples were heated at 100 °C for 10 min. Samples were extracted 2 times with approximately 1 ml. of ether and dried as above. Pentafluorobenzyl derivatives were formed by reaction with PFBB for 30 min. at R.T. (30 μ l CH₃CN, 20 μ l 20% PFBB in CH₃CN and 10 μ l diisopropylethylamine in CH₃CN). Reagents were removed as above and samples were dissolved in toluene.

The RPP-, RPPG- and RPPGF-DMPO-PFB derivatives were observed to be amenable to GC (methyl silicone bonded phase capillary, 5 m) although RPPGF-DMPO-PFB eluted at relatively high temperatures (> 310 deg C) and the approximate relative responses (GC-NCI-MS) of RPPGF:RPPG:RPP were 1:10:100. NCI mass spectra all exhibited M⁻ - 181 (M⁻ - PFB) as the base peak (m/z 611, 668 and 815 respectively, Figures 1-3). The decreased response for RPPG and RPPGF could be related to thermal decomposition in the injection liner. For this reason direct probe -NCI (DP-NCI) was also evaluated and proved satisfactory since equal amounts of each peptide derivative gave a similar response. Using selected ion monitoring (SIM) GC-NCI analysis of the RPP derivative gave a S:N of 10,000:1 for 40 pmole (2.7 nmoles derivatized) and DP-NCI analysis gave a S:N of 20,000:1 for 8 pmole (2.7 nmoles derivatized, Figure 4). We also synthesized ¹⁸O₂-internal standards by exchange in acidic H₂¹⁸O (100 °C, 18 hr.). Preliminary data obtained using this derivative and an ¹⁸O-labeled internal standard suggested the presence of RPP in human urine, however, we now believe this observation to be at least in part an artifact of the purification procedure.

APPLICATION OF AUTOMATED GC/MS/MS FOR THE QUANTITATIVE DETERMINATION OF NE-11740 IN PLASMA

The Procter & Gamble Company
Miami Valley Laboratories
P.O. Box 398707
Cincinnati, OH 45239-8707

INTRODUCTION

The primary objectives of this work were: 1) to develop a sensitive and selective assay for NE-11740 in plasma; and 2) to evaluate the utility of GC/MS/MS for the routine trace-level assay of drugs in biological matrices. The work described here goes beyond initial method development and validation studies by demonstrating the high efficiency and reliability of quantitative GC/MS/MS methodology over 22 months of routine application.

NE-11740, 1-[3,5-Bis(1,1-dimethylethyl)-4-hydroxyphenyl]-5-hexyn-1-one, is being evaluated for anti-inflammatory/anti-rheumatic indications. In support of investigatory pharmacokinetic studies, an automated GC/MS/MS method for the determination of ppb-level NE-11740 in plasma was developed. The need for rapid turnaround for thousands of samples placed stringent requirements on this methodology. In addition to high sensitivity and selectivity, short analysis time and high reliability were also vital.

EXPERIMENTAL

Plasma Sample Preparation. Plasma samples (0.1 to 2 g) were spiked with 50 ng $^{13}\text{C}_{18}$ -labeled NE-11740. Proteins were precipitated by addition of acetonitrile and the supernatant extracted with ethyl ether. The organic layer was taken to dryness under nitrogen and reconstituted in 100 μl of 4-decanone. Typically, 2 μl splitless injections were employed.

Automated GC/MS/MS Approach. Analyses were conducted on a Finnigan TSO-45 using automated GC/(EI)MS/MS with collisionally activated dissociation (CAD) and selected reaction monitoring (SRM). Below are shown EI mass spectra for NE-11740 (MW= 300) and the $^{13}\text{C}_{18}$ -NE-11740 internal standard (MW= 303), along with corresponding ion reactions that were used in the MS/MS SRM detection scheme. Daughter ions were formed using CAD with an 11.7 eV ion collision energy and a collision gas pressure of 2.2 mtorr Ar.

The GC/MS/MS analysis was automated via Macro programs that allowed computer control of all assay steps, from sample injection via the Varian 8080 autosampler, to final report printout. Cycle time was only 6-7 min. By running the GC/MS/MS assay in an unattended manner, 70 real samples were typically assayed in a single day.

The selectivity of the MS/MS detection scheme employed here was such that the only GC eluents detected from plasma extracts were NE-11740 and $^{13}\text{C}_{18}$ -NE-11740. This "ultimate" selectivity redefined the role of the GC as simply a reproducible means of sample introduction. Thus, a combination of short column (< 15 m), high initial temperature (180°C), and rapid temperature ramp (25°C/min), minimized GC retention time (1.5 min).

By eliminating interferences, this MS/MS methodology provided excellent low-level detectability for NE-11740, with minimal sample preparation and short analysis time. The quantitation limit ($S/N > 10:1$) was typically 1 ng/sample (20 pg on column). The SRM (m/z 300-to-248) chromatogram for an extract of a 2 ml plasma sample containing 1.4 ng NE-11740 (right) shows a strong signal over a background consisting only of electronic noise.

RESULTS

Initial Validation. High sensitivity of the GC/MS/MS detection scheme, combined with the use of an M+3 stable-isotope-labeled internal standard resulted in a 1-to-3000 ng/sample (20 pg to 60 ng on column) linear dynamic range. A typical standard analytical curve (right) shows the linearity of this method, with correlation coefficients of > 0.999 for both the entire range and a 1-to-50 ng/sample subset, which also have nearly equal slopes.

Accuracy and precision of the overall method was determined through assay of NE-11740-spiked 1 ml plasma aliquots. Results are summarized below.

N	ng SPIKED	ng DETERMINED	% RECOVERY
4	2.00	2.08 $\pm$ 0.20	104 $\pm$ 9.6

19	100.	98.7 $\pm$ 6.4	99 $\pm$ 6.5
11	200.	205. $\pm$ 14	103 $\pm$ 6.9
5	2000	1980 $\pm$ 130	99 $\pm$ 6.7

Long-Term Performance. Method accuracy was continually assessed by analyzing NE-11740-spiked plasma samples. Data accumulated over 22 months for 20 to 270 ng NE-11740-spiked plasmas ($N = 215$) showed a 100.05 ± 5.24 % analytical recovery, indicating no bias in the method.

A measure of method precision was based on duplicate (parallel) assays of real plasma samples (right). Duplicates were analyzed on the same day, but with 2-6 hr between GC/MS/MS runs. From these data, an overall 6.2 % ($N = 350$) method relative standard deviation was calculated.

SCOPE OF APPLICATIONS/CONCLUSIONS

A 1-to-3000 ng/sample working range for 0.1 to 2 g samples allowed access to an effective 0.5-to-30,000 ppb NE-11740 range in plasma. This, along with method automation, facilitated its application to > 3000 real plasma samples (5000 GC/MS/MS runs). The method was equally applicable to mouse, rat, dog, monkey, and human (clinical) plasma. With minor variations in sample work-up, it was also applied to the assay of NE-11740 in urine.

We have found this GC/MS/MS assay to be very forgiving of instrumentation wear (column degradation, dirty ion volumes, etc.). This is due largely to its high selectivity and use of a stable-isotope-labeled internal standard.

TYPICAL STANDARD ANALYTICAL CURVE

**CHARACTERIZATION OF DERIVATIVES OF CHIRAL ANTIARRHYTHMIC DRUGS
AND THEIR METABOLITES USING FAB-MS**

Brian J. Sweetman, Chandra Prakash & Ian A. Blair

Department of Pharmacology, Vanderbilt University, Nashville, TN 37232-6600

Optimal drug therapy for conditions associated with disturbances of cardiac rhythm is often complex and requires detailed knowledge of the pharmacology of the drugs used. Many antiarrhythmic drugs are chiral molecules, normally given as racemic mixtures, where each enantiomer may show its own spectrum of pharmacological activities. Therefore, rational drug therapy would be assisted greatly by preparation and pharmacological testing of individual enantiomers. There is also a need for methodology to easily detect enantioselective drug metabolism by resolving enantiomers of drugs and their metabolites which have been isolated from biological fluids or tissues. In this regard we have prepared the (-) menthyl chloroformate derivatives of propranolol, propafenone, encainide, flecainide and several of their pharmacologically-active metabolites and resolved the resultant diastereomers using HPLC (C_{18} reversed phase column methanol containing 15-20% water as solvent system.) The products were characterized using positive ion FAB-MS with 3-nitrobenzyl alcohol (3-NBA) as matrix since electron impact ionization could not be used to verify molecular weight because of the lability of these molecules. By contrast, the FAB spectra each showed intense peaks due to MH^+ and $(MH^+ - \text{menthyloxycarbonyl})$ together with several structurally-significant fragment ions. We have also examined the spectra of other diastereomeric derivatives of propafenone such as propafenone glucuronide, a major circulating metabolite of propafenone, which was synthesized via its triacetyl methyl ester derivative. HPLC was carried out one of two separate systems. System A used an ultrasphere ($5\mu m$, 4.6mm X 250mm, Altex) silica column at ambient temperature and a mobile phase of ethyl acetate/hexane/triethylamine (15:85:1, v/v) at a flow rate of 1 ml/min. System B and a C_{18} reversed phase column with methanol containing 15-20% water as elution solvent.

Conversion of chiral drugs to their menthyl carbamate derivatives was effected as follows: The sample containing drug (10ng to $5\mu g$) was dissolved in acetonitrile containing N,N'-diisopropylethylamine ($50\mu l$, 90:10v/v) and to this mixture was added (-) menthyl chloroformate in acetonitrile ($50\mu l$, 10:90v/v). The solution was heated for 2 hr. at 60° and the acetonitrile was evaporated. The residue was dissolved in the initial mobile phase prior to analysis by HPLC.

FAB-MS spectra were obtained using a VG 70-250 HF instrument equipped with a standard unheated VG FAB ion source and a standard saddle field gun (Ion-Tech Model B11N) producing a beam of xenon atoms at 8 keV and 1mA. The mass spectrometer was adjusted to a resolving power of 2500 and spectra were obtained at 6 kV and at a scan speed of 10 sec/decade. 3-NBA or glycerol was applied to the stainless steel stage via a glass rod and was spread to a thin continuous layer. Compound dissolved in an appropriate solvent at a concentration of $1-5\mu g/\mu l$ and $1.5\mu l$ was applied to the center of the stage.

The FAB⁺ spectra of the menthylcarbamate derivatives of chiral, antiarrhythmic drugs using 3-NBA as matrix are typified by the spectrum of (+) flecainide (-) menthyl carbamate shown below which shows an intense peak for MH^+ together with several structurally significant fragment ions.

In summary, conversion of chiral, antiarrhythmic drugs and their metabolites containing a phenolic or secondary amine function to their menthyl carbamate derivatives using (-) menthyl chloroformate and analysis of the resultant mixture of diastereomeric derivatives using reversed phase HPLC with methanol containing 15-20% water was solvent system provides an effective means for evaluating the possibility of enantioselective drug metabolism. These derivatives have been prepared for the chiral drugs encainide, propranolol, propafenone and flecainide. This methodology has been used to demonstrate the enantioselective metabolism for each of these drugs. Derivatization of encainide is interesting in that it was observed that (-) menthyl chloroformate reacts with the tertiary (piperidine) nitrogen to give two menthyl carbamate diastereomers which could be resolved easily on normal phase HPLC on a silica column. Positive ion FAB-MS using 3-nitrobenzyl alcohol as matrix provides an excellent means for the characterization of the menthyl carbamate derivatives formed. For each derivative an intense peak corresponding to MH^+ is observed together with a peak arising by loss of the carboxy-menthyl group and other fragment ion information. Negative ion FAB-MS provides a useful means for the characterization of glucuronide conjugates of drugs. This was illustrated using the glucuronide of propafenone. Choice of FAB matrix is quite critical. Despite the fact that the free glucuronide is freely-soluble in either glycerol or 3-nitrobenzyl alcohol, vastly superior spectra of this and other free glucuronides are obtained using glycerol as matrix. However, when the glucuronide is converted to the less polar per-acetyl methyl ester derivative, superior results are obtained using 3-nitrobenzyl alcohol as matrix. These observations extend to other poly-hydroxylic compounds such as oligosaccharides and phosphatidyl inositols. The utility of this methodology has been demonstrated by studying the metabolism of (+) encainide using rat liver microsomes where it was observed that (-) encainide underwent O-demethylation at a greater rate than (+) encainide. No such enantioselectivity was observed for N-demethylation. The methodology was further applied for the simultaneous determination of propranolol enantiomers in human urine after administration of (+) propranolol where it was shown that (+) propranolol was metabolized at a greater rate than (-) propranolol. This methodology should have wide applicability in investigations involving the pharmacology of chiral drugs. Supported by NIH grants GM31304 and RR01688.

FAST ATOM BOMBARDMENT MASS SPECTROMETRY OF PLATINATED OLIGONUCLEOTIDES

L. B. Martin, A. F. Schreiner, and R. B. van Breemen
Department of Chemistry, North Carolina State University

Raleigh, N. C. 27695-8204

The reaction of *cis*-diamminedichloroplatinum (II) (cisplatin), an important anticancer agent, and ribonucleic acids are well known, on the molecular level. Numerous studies have shown that the anticancer activity of cisplatin is due to platination of DNA resulting in adducts that interfere with cell functions. Cisplatin hydrolyzes to the very active diaquo and to the slightly less reactive monoquo forms. The water ligands are good leaving groups and allow the platinum to form two coordinate bonds to DNA. The primary site of this coordination is the N7 of guanine and to a lesser extent O9, although similar reactive sites on other nucleotides, such as adenine, are known. 1. Cisplatin can bind to one base on a single strand of DNA, bind to two bases on a single strand, or bind to two bases on different (duplexed) strands.

The modes of binding have been observed by numerous analytical methods, primarily ^{195}Pt and ^1H NMR (2), X-ray crystallography(3), all coupled with standard biochemical digestion and separation techniques. The negative ion fast atom bombardment (FAB) mass spectrometry of natural oligonucleotides has been described by Grotjahn and others (4). The present study attempts to establish a methodology to purify and analyze by mass spectrometry small quantities of platinated oligonucleotides. Fast atom bombardment mass spectrometry will be used to complement other analytical methods in the characterization of cisplatin complexes with the DNA tetramer, d(GpCpGpC).

Procedures and Results

Platination of 100 μg aliquots of nucleotide was carried out using 10 equivalents of cisplatin in water at 37°C for 3 to 6 days. The platination reaction resulted in two DNA products that were separated by open bed gel filtration monitored at 254 nm; these corresponded to a single diammineplatinum adduct and a bis-diammineplatinum adducts. FAB mass spectra were obtained using a JEOL HX-110HF mass spectrometer at 10 kV accelerating potential. Approximately 4 μg of each sample were analyzed in 2 μl of triethanolamine matrix. Negative ion FAB mass spectra contained deprotonated molecular ions, $[\text{M-H}]^-$, and fragment ions corresponding to the elimination of all associated ammonia ligands. No doubly stranded adducts were detected.

B/E linked scanning with collisional activation was carried out on the $[\text{M-H}]^-$ ions of the single stranded nonplatinated tetramer (m/z 1173), the single diammineplatinum adduct (m/z 1401), and on the bis-platinum adduct $\text{d(GpCpGpC)}\cdot(\text{Pt})_2$ (m/z 1561). The most abundant fragment ions of the unplatinated molecule corresponded to $[\text{d(GpC)}]^-$ (m/z 635), loss of guanine (249) and the resulting deguanylated fragment (m/z 1023) (Figure 1). Similar fragmentation was observed in the daughter ion scan of the mono-platinated oligonucleotide except that ions corresponding to phosphodiester cleavages were absent (Figure 2). Fragmentation of the bis-platinated oligonucleotide molecular ion show loss of one and two platinum atoms, as well as loss of cytidine (289) and the resultant ion $[\text{M-Cp}]^-$ (m/z 1271), although at very low relative abundance (Figure 3).

Conclusions

Negative ion FAB mass spectrometry confirms that reaction of high levels of cisplatin with self complementary, double-stranded small oligonucleotides results in denaturation and release of single strand DNA significant structural changes that have measureable effects on the mass spectrometry of DNA. Cisplatin then binds to active sites on the unduplexed d(GpCpGpC) strand. The presence of both mono- and bis-platinated species indicates than cisplatin is doubly coordinated to the N7 and O9 of guanine, since addition to cytosine would be highly unfavorable. Cisplatin stabilized the phosphate backbone in the immediate vicinity of binding. In the mono-platinated species, binding most likely occurred at the 3' guanine, and fragmentation at the 5' guanine. In the bis-platinated species, the two platinum atoms were probably bound to guanine bases. This study indicates that FAB mass spectrometry is a useful method for the characterization of metal-oligonucleotide complexes.

GAS CHROMATOGRAPHY-ION TRAP MASS SPECTROMETRY DETERMINATION OF ARECOLINE IN HUMAN PLASMA. H.U. Shetty, N.H. Greig, T.T. Soncrant and S.I. Rapoport. Laboratory of Neurosciences, Bldg. 10, Rm. 6C 103, National Institute on Aging, NIH, Bethesda, MD 20892., and Athena Neurosciences Inc., 800F-Gateway Blvd., S. San Francisco, CA 94080.

Alzheimer's disease is accompanied by an impairment of the forebrain cholinergic system. Despite selective regional reductions of presynaptic terminals, the postsynaptic muscarinic receptors remain unaffected¹. Stimulation of these receptors with cholinergic agonists may compensate for the neurotransmitter deficit and, thereby, improve the cognitive functions of these patients. The muscarinic cholinergic agonist, arecoline, has been reported to enhance memory in normal healthy subjects². However, its value in treating patients with Alzheimer's disease remains inconclusive³ due, potentially, to a failure to achieve and maintain a pharmacologically adequate concentration. We describe, for the first time, a sensitive and specific assay for arecoline in human plasma that we are presently using to define the therapeutic window and evaluate the clinical potential of this agent in the treatment of Alzheimer's disease.

A Finnigan Mat 700 Ion Trap Detector (ITD) was interfaced with a Perkin-Elmer Sigma 2000 Gas Chromatograph (GC), *via* a transfer line. The GC setup featured a splitless inlet system with a narrow bore glass insert and a J&W DB-5 fused-silica capillary column of 30 m x 0.25 mm dimension and 0.25 μ m film thickness. Helium was used as the carrier gas. Typically, a column flow rate of 1.6 ml/min, a split vent flow of 33 ml/min and a septum purge flow of 3 ml/min were maintained. Samples were analysed by "cold trapping" and, for this, the injector temperature was set to 170°C and the initial oven temperature to 50°C; then, 30 sec after injection, the oven temperature was ramped at 20°C/min up to 130°C and, thereafter, by 5°C/min to a final temperature of 150°C. The split vent valve was opened 60 sec after injection. The transfer line temperature was maintained at its default value of 200°C. The ITD was tuned manually for high sensitivity detection and its data acquisition was set in the multiple ion detection mode. Prior to analysis, 1,3-diphenyl-1,1,3,3-tetramethyldisilazane was injected (0.5 μ l, twice) into the GC at 200°C. An internal standard, homoarecoline, was prepared by esterifying arecaidine with ethanol. It was purified by distillation, converted to HBr salt, and NMR and MS data were obtained. Buffer solutions, ranging between pH 2.0 and 12.0, were spiked with arecoline, equilibrated with ether and the quantity partitioned to this layer was determined by GC with Nitrogen Phosphorus Detection. Homoarecoline (free base) was used as an external standard in this experiment to determine the optimum pH for arecoline extraction. For the standard curve, human plasma (1 ml) was spiked with arecoline HBr (100-0.78 ng free base) followed by the internal standard (100 ng free base). The pH was adjusted (100 μ l, 0.5M borate buffer, pH 9.0) and the plasma sample then was extracted with a mixture of pentane and ether (80:20, v/v). The solvent layer was transferred to silanized tapered tubes, subjected to centrifugal evaporation (40 mm Hg pressure at room temperature), the residue then was reconstituted in n-hexane containing 1% triethylamine (25 μ l), and 1-1.5 μ l volumes of this, finally, were injected into the GC. In additional studies, male Fischer-344 rats were administered arecoline (5 mg/kg, i.v.), blood samples were withdrawn at different time intervals and plasma separated. The plasma profile of arecoline then was determined, using 250 μ l of plasma.

The mass spectra for arecoline and homoarecoline, acquired by ITD, are shown in Figure 1. The prominent fragment ion m/z 140, common to both, was chosen for selected ion monitoring. A plot of percentage recovery of arecoline versus pH of the aqueous phase, from three independent determinations, indicated a pH range of 8.0 to 10.0 is optimal for recovery, and a higher pH promoted hydrolysis. Consequently, pH 9.0 was chosen for the extraction. A representative ion chromatogram, obtained by spiking 12.5 ng of arecoline and 100 ng of

homoarecoline, the internal standard, into 1 ml human plasma, is shown in Figure 2. Retention times of 8 min 12 sec and 9 min 25 sec were noted for arecoline and homoarecoline, respectively. The standard curve exhibited linearity between 100 ng and 0.78 ng of arecoline per ml of plasma ($r = 0.9988$). The applicability of the assay procedure was demonstrated in animal studies: Figure 3 shows the plasma concentration-time profile of arecoline in rats. Arecoline rapidly disappeared with a half-life of 3.5 min. In summary, this selected ion monitoring assay takes into account the inherent volatility, adsorptive nature and sensitive functionality of the molecule and, thereby, provides adequate sensitivity and specificity. The methodology is presently being used to monitor the plasma profile of arecoline in treated Alzheimer's patients.

ECNI - SELECTED REACTION MONITORING FOR QUANTITATION OF DEXAMETHASONE IN PLASMA Kathleen A. Kayganich*, Timothy G. Heath*, and J. T. Watson*+; Departments of Chemistry* and Biochemistry+, Michigan State University, East Lansing, MI 48824

The dexamethasone suppression test (DST), used for years to diagnose Cushing's Syndrome, has been proposed for diagnosing endogenous depression in psychiatric patients.¹ After administration of 1 mg of dexamethasone the plasma levels of cortisol are normally suppressed for a 24-hour period. In patients with endogenous depression, cortisol levels return to normal within 3 to 4 hours. In order to make a proper diagnosis it is necessary to determine the dexamethasone plasma levels at 8, 16, and 24 hours following drug administration. Plasma levels of dexamethasone will normally diminish from 4 to 0.1 ng/ml during this 24-hour period. Such analyses require sensitive and selective methodology.

Previous results² from an assay based on oxidation of dexamethasone to a highly electrophilic species with detection by electron-capture negative ionization (ECNI) GC-MS indicated that the limit of detection (LOD) was ca. 1 ng/ml of dexamethasone in human plasma and the limit of detection of a pure standard of oxidized dexamethasone was ca. 30 pg injected on-column using an HP5985 GC-MS modified for negative ion detection. Recently, with the acquisition of a Finnigan triple stage quadrupole, TSQ70, we have evaluated the extent to which selected reaction monitoring (SRM) might increase the selectivity and sensitivity of the oxidation-based ECNI-SIM (selected ion monitoring) assay.

Dexamethasone is a synthetic corticosteroid drug which contains one fluorine atom. Shown in figure 1 is the oxidation reaction of dexamethasone as well as the ECNI mass spectrum of the oxidized product. Upon collisionally activated dissociation (CAD), the molecular anion of the oxidation product of dexamethasone undergoes the loss of HF. Interfering substances from the plasma matrix are unlikely to contain any fluorine atoms and therefore will not undergo a neutral loss of 20 u.

Figure 1. a) oxidation of dexamethasone b) ECNI spectrum of oxidized dexamethasone

Monitoring the reaction of m/z 330 (M^-) to m/z 310 ($M-HF^-$) using low energy CAD eliminates interference from the plasma matrix. The improved selectivity of SRM over SIM is illustrated in Figure 2 which compares SRM and SIM for the detection of oxidized dexamethasone after extraction from a plasma sample. Ca. 30 pg of oxidized dexamethasone and 400 pg of the oxidized isotopically labelled ($M+9$) internal standard was injected onto the column.

Figure 2. reconstructed ion current profiles obtained by a) SIM and b) SRM

Experimental

Sample processing consisted of extraction using a 200 mg C18 PrepSep column conditioned with 5ml of 8M urea, 5 ml methanol, and 10 ml distilled water. After loading 1.5 ml of plasma that had been spiked with 50 ng of $^{13}C_6$ - $2H_3$ -dexamethasone internal standard, the column was rinsed with 4 ml H_2O and 4 ml of 15% MeOH- H_2O . The dexamethasone was eluted with 4 ml of 70% MeOH-hexane. After solvent removal, the extract was

oxidized in 1 ml CH_2Cl_2 with pyridinium chlorochromate. Anhydrous sodium acetate was added to buffer acid liberated from the oxidant. After 6 hours the reaction mixture was passed through a 500 mg silica solid phase extraction column that had been conditioned with CH_2Cl_2 . The column was then rinsed with 1.5 ml CH_2Cl_2 and the oxidized dexamethasone was eluted with 4 ml of 5% acetone in CH_2Cl_2 . The eluate was reconstituted in 100 μl of ethylacetate; 2 μl was taken for analysis by both SIM and SRM.

Conditions for mass spectral analysis were as follows: 300 μA , 100eV, pressure of NH_3 ca. 1 torr (9300 mtorr on convection gauge situated on the gas inlet line), EM = 1200V for SIM and 1400V for SRM, source temperature 120° and 100°C for SIM and SRM, respectively. GC conditions: 30m x 0.25mm DB-5, 11 psi, 60°-260°C @ 40/min then 260°-280°C @ 4/min, splitless injection. A study of the effects of collision gas pressure and collision energy, E_{lab} , indicated that the optimum argon pressure and E_{lab} value for the production and transmission of m/z 310 from m/z 330 are 2.5 mtorr and 3 eV, respectively.

Results

The LOD for a pure standard of oxidized dexamethasone under CAD conditions by SRM is about the same as that obtained by SIM ($S/N = 4$ for ca. 160 fg of pure standard). At this low collision energy, autodehydration of the electron apparently does not occur to any appreciable extent. Therefore, the absolute sensitivity of the SRM and SIM assays are expected to be the same. The limits of detection for dexamethasone in plasma, however, may differ due to lower background in SRM. A criterion for the limit of detection is the concentration of analyte that produces a signal greater than the signal from the blank (containing internal standard) by at least three times the standard deviation of a blank value.³ Based on this criterion, the LODs for the SIM and SRM assays are 0.31 and 0.26 ng/ml, respectively.

A number of plasma samples taken at various times following drug administration to patients undergoing the DST were analyzed using both SIM and SRM. The quantitative results are shown in table 1. Given the high selectivity of negative ion detection in combination with MS/MS, as well as the selectivity imparted by the chemical oxidation, simplification of the procedure through the use of the direct probe (DIP) rather than the GC for sample introduction was also investigated. The results obtained by DIP-ECNI-SRM are also shown in table 1.

Triplicate analysis of duplicate spiked plasma samples gave relative standard deviations of 3.6% by SRM and 9.1% by SIM for the procedure. In spite of this variation, most of the concentrations of dexamethasone found in the real plasma samples by SIM and SRM are quite similar. The concentrations obtained by DIP-SRM vary more from those obtained by GC-SRM and GC-SIM. This may be due to the presence of interfering ion current at either m/z 310 or m/z 319.

Table 1. Concentrations of dexamethasone in ng/ml of plasma

Sample	SIM	SRM	DIP-SRM	RIA (n=10)
P2	0.64	0.61	0.81	0.66
P5	0.64	0.87	0.50	0.42
P11	2.97	2.75	2.35	0.91
P18	27.4	33.8	49	20.5
P3	0.18	0.14		0.26
P4	0.088	<LOD		0.24
P14	0.045	0.093		0.12
P15	0.097	0.018		0.08
P16	0.175	<LOD		0.10
P17 (blank)	<LOD	<LOD		0.07
7A*	2.09(s=.11)	1.88(s=.10)		
7B*	1.83(s=.13)	1.82(s=.04)		

*duplicate spiked plasma sample (2 ng/ml), measured in triplicate

Conclusions

The limit of detection of the SIM assay is comparable to the LOD of the SRM assay, however, the precision for the SRM assay appears to be better. The limits of detection of the SIM and SRM assays both appear to be limited by the high blank values, rather than the chemical or instrumental procedures. The presence of unlabelled dexamethasone in the isotopically labelled internal standard is probably responsible for these high values. Adding a structurally similar compound to act as the carrier during the sample preparation would allow the addition of a smaller quantity of internal standard, resulting in lower blank values and probably a lower LOD. The fact that no appreciable increase in selectivity or sensitivity is gained by using MS/MS suggests that substantial discrimination against the biochemical background and in favor of the analyte is provided by the chemical oxidation and by negative ionization of the oxidized product.

Negative Chemical Ionization Versus Electron Impact Ionization Detection of Scopolamine by Gas-Chromatography/Mass Spectrometry in Human and Rat Plasma. J. Deutsch, T.T. Soncrant, N.H. Greig and S.I. Rapoport. Laboratory of Neurosciences, National Institute on Aging, N.I.H., Bethesda, MD 20892.

INTRODUCTION

Scopolamine, a natural alkaloid, has a broad spectrum of biological activities. Being an antagonist of the muscarinic receptor, it has been found to significantly impair memory and, in some cases, to mimic the memory impairment of normal aging^{1,2}. Due to the time consuming nature and poor sensitivity of existing assays, previous pharmacodynamic studies of scopolamine were carried out without extensive understanding of its in vivo pharmacokinetics. We report here an improved GCMS assay, using negative ion chemical ionization together with electron impact detection, that is suitable for quantitation of scopolamine in various biological tissues.

EXPERIMENTAL

The GCMS measurements were carried out on either a Finnigan 4500 GCMS, equipped with an electron impact and a chemical ionization ion source, or a HP 5970 bench top electron impact GCMS. The reactive gas for the chemical ionization was CH₄ and the ions were monitored on either positive or negative ionization mode. The samples were separated on the GCMS with a DB5 capillary column, 30m x 0.25mm. Samples were run in a temperature programming mode at 145 °C for 3 minutes followed by a 10°C/min increase for 5 minutes, with the injector at 200 °C and the detector line at 280 °C. The retention time of the heptafluorobutyl scopolamine derivative (Fig. 1b) was 4.7 minutes at 5 psi He pressure at the top of the column. The multiple ion monitor was set to detect ions m/z 331 and m/z 334 for the negative ion chemical ionization, and at m/z 138 and m/z 141 for the electron impact ionization.

Extraction procedure: Plasma (0.5 ml) or homogenized tissue (1.0 g) was spiked with trideuterated scopolamine.HBr (50-200 ug), treated with 1M Na₂CO₃ solution (0.5 ml), and extracted twice with n-butyl chloride (2.0 ml). Following centrifugation, the organic layer was separated and the solvent was removed by speedvac. To the remaining material, 5M NaOH solution (0.5 ml) was added and heated at 50 °C for 20 minutes. The alkali solution then was diluted with water (1.0 ml) and extracted with methylene chloride (2.5 ml). The organic phase was washed twice with water (1.0 ml) and dried on anhydrous CaCl₂. After removal of the solvent, the extracted material again was dissolved in methylene chloride (100 ul), treated with heptafluorobutyric anhydride (10ul) and heated at 40 °C for 20 minutes. Following removal of the solvent, the remaining material was dissolved in acetone (20 ul). 1-5 ul of the acetone solution then was injected into the GCMS for quantitation.

RESULTS AND DISCUSSION

It is well established, that for GCMS determination³, scopolamine, an ester of scopine (Fig. 1a) with mandelic acid, is first hydrolyzed by alkali to scopine which is further derivatized with the heptafluorobutyric anhydride to the highly electrophilic heptafluorobutyl scopine, MW 351 (Fig.1b). This derivative elutes well on a commercial DB5 capillary GC column and can be detected by mass spectrometry, using positive chemical ionization or electron capture negative chemical ionization or electron impact ionization. The positive ion ionization leads to a protonated molecular ion at m/z 352; the electron capture negative ion leads to a M-HF fragment at m/z 331; electron impact ionization leads to a fragment at m/z 138, (Fig.1c) due to thermal decomposition. The ion yield of the first is low; thus, only the last two ionization methods are suitable for scopolamine quantitation.

In the electron impact ionization assay, the fragment at m/z 138 was monitored, using d₃-derivative (m/z 141) as an internal standard. In negative chemical ionization mode, the M-HF

ion at m/z 331 was measured, again using d_3 -deuterated scopolamine (m/z 334) as an internal standard.

The EI-SIMS profiles obtained from plasma and brain extracts obtained from rats 5 minutes after a dose of 2.5mg/kg scopolamine.HBr was injected i.p. is shown in Fig. 2. The internal standard concentration was about 50ng per GC injection. For lower doses, measurements at the high mass region by the negative chemical ionization mode which have a higher signal/background ratio, are likely to yield sensitivity greater than that of electron impact mode.

STRUCTURE ELUCIDATION OF ISOMERIC HYDROXYALOINS AND
OXANTHRONE GLUCOSYLS BY HIGH RESOLUTION AND TANDEM MS

E. Schroeder, Finnigan MAT GmbH, Barkhausenstr. 2, D-2800 Bremen, FRG
H.W. Rauwald, Institute of Pharmaceutical Biology, University of Frankfurt, FRG

Purpose. A method for the fast and reliable differentiation of isomeric anthrone and oxanthrone glucosyls is described.

Introduction

Samples: plant extracts of *Aloe capensis* and *Aloe barbadensis* (*Aloe vera*).

Activity: purgatives of the large intestine (1). Quantitative and qualitative analyses of active components are significant for the pharmaceutical industry (2,3).
Prior work: negative CI-MS/MS has been used to determine aloin and its derivatives in plant extract of *Aloe* species (4).

This work: NCI-MS/MS is used to differentiate between isomeric hydroxyaloins and oxanthrone glucosyls.

Experimental

Plant extracts: commercially available. Fractionated by HPLC: dissolved in CH_3OH , 1:1000; 20 μl injected on a RP-10 column, eluted with a $\text{CH}_3\text{OH}:\text{H}_2\text{O}$ ratio of 9:5, 1 ml min^{-1} .

Mass Spectrometry: Finnigan MAT HSQ 30 and MAT 900Q. MS1 resolution: 1,000 (for MS/MS) and 10,000 (10 % valley) (for exact mass measurements). Internal standard: perfluorokerosin. MS2 (QQ) resolution: adjusted to unit (50 % valley). Collision gas: argon. Collision gas pressure: 0.5 Pa (for excitation of M^+); 7 Pa (for excitation of m/z 283). Collision energy: 45 eV.
Ionization: DCI, negative ions. Reagent gases: isobutane or ammonia. Electron energy: 70 eV. Emission current: 0.2 mA. Ion source pressure: 5 Pa.

Results

$\text{M}^+/(M-H)^+$: this ratio depends on reagent gas pressure. At a source pressure of 5-10 Pa: M^+ predominates. Above 10 Pa: $(M-H)^+$ predominates. See Figure 1.

MS/MS of M^+ and $(M-H)^+$: differences in spectra are seen with excitation by low-energy collisions, but not by high-energy collisions. See Figures 2.

Fragmentation: the glucosyl group, 163 u, is lost; see Figure 5. Formation of m/z 283: by loss of H_2O (18 u) and $\text{C}_5\text{H}_{11}\text{O}_6$ (151 u) from the anions of oxanthrone glucosyls; see Figure 6. Loss of m/z 151: aided by HO^- at position 10 of the aglycone? See Figure 7. Fragmentation of m/z 283: requires a 10X higher collision pressure than for fragmentation of M^+ .

Discussions

These fragmentations were used for the fast differentiation of isomeric hydroxyaloins. Structures were verified by NMR and LC, using known compounds (5).

MS/MS is useful for analysis of single compounds in these complex biological matrices. NCI is a highly sensitive ionization technique for these compounds.

SELECTIVE DETECTION OF SULFUR-CONTAINING COMPOUNDS BY REACTION INTERFACE/MASS SPECTROMETRY AND ITS APPLICATIONS IN METABOLISM STUDIES

Mehdi Moini, Donald H. Chace and Fred P. Abramson

Department of Pharmacology, The George Washington University Medical Center,
Washington, D.C. 20037

INTRODUCTION

Addition of a reactant gas to a low pressure microwave-induced plasma (MIP) creates a reaction interface in which complex molecules are converted into small stable neutrals. For a given reactant gas the molecules formed represent the elemental composition of original analyte. In this study HCl has been found most effective as a reactant gas for selective detection of sulfur-containing compounds using capillary gas chromatograph-reaction interface/mass spectrometry (GC-RIMS).

EXPERIMENTAL

The GC-RIMS has been described previously (1). The end of the a 30 meter DB-5, 0.25 μ m film thickness capillary column of an HP gas chromatograph was connected to a 4" long, 1/4" o.d. 1/32" i.d. ceramic tube by conventional vacuum components. The reactant gas was also added to this end of the ceramic tube. The other end of this tube was connected to an Extrel quadrupole mass spectrometer using deactivated, uncoated wide-bore fused silica tubing. The mass spectrometer was controlled by a Teknivent data acquisition interface, software, and an IBM AT computer. The microwave cavity was powered by 100 W, 2450 MHz power supply. In this study helium was used both as a carrier gas for the GC and the MIP.

RESULTS and DISCUSSION

Selection of the Reactant Gas: When oxygen was used as a reactant gas carbon forms CO and CO₂, nitrogen forms NO and NO₂, and hydrogen forms water. Results for sulfur were inconsistent, probably due to further reactions of newly-formed sulfur compounds with H₂O in the plasma and formation of adsorptive complexes. In order to solve this problem, a reaction gas with completely different chemistry was used, i.e. HCl. When HCl was used as a reactant gas, carbon in the presence of nitrogen predominantly produced HCN at m/z 27 along with other minor components of hydrocarbons, e.g., CH₄, C₂H₂, and chlorocarbons of the type C_nH_nCl_n. Nitrogen in the presence of carbon also predominantly produced HCN. Sulfur produced SCI at m/z 67, with other minor components including S₂Cl₂.

Selectivity: Detection at m/z 67 was completely selective for sulfur. The selectivity of this detection channel was demonstrated using thiopental and phenobarbital as examples of sulfur and nonsulfur-containing compounds. The GC-RIMS chromatograms are shown in Figure 1. m/z 27 represents a nonselective carbon channel while m/z 67 represents the selective sulfur channel.

Sensitivity: The GC-RIMS detection limit for thiopental was 20 picograms on-column at a S/N = 3 in the single ion detection mode with 600 ms integration time. The linear dynamic range of the calibration curve using phenobarbital as an internal standard is shown in Figure 2.

Figure 1. GC-RIMS selective detection of sulfur using HCl as a reactant gas. HCN at m/z 27 is a nonselective carbon channel. SCI at m/z 67 is a selective sulfur channel.

Figure 2. The linear dynamic range of the calibration curve for thiopental using phenobarbital as an internal standard.
